HARMSWORTH SELF-EDUCATOR

1907

Vol. VIII. Pages 6097—7008

A KEY TO THE HARMSWORTH SELF-EDUCATOR

At the heading of each article in the Self-Educator is the number of the group to which the article belongs, and a reference to this key indicates precisely the place of the article in the scheme of the book. This key, therefore, enables the student at any time to understand what has preceded and what is to follow any part of the work to which he may happen to turn.

Group 1.
Agriculture. Beekeeping. Gardening.
Farming. In all its Branches. Dairying. Poultry.
Beekeeping. A Practical and Commercial Course.
Gardening. How to Get the Most out of a Minimum of Land. Gardening for Pleasure and Profit. Market Gardening.

Group 2.
Art. Architecture. Glass. Earthenware. Carving.
Art. Theory and Training. Painting. Sculpture. Architecture (Theory. Styles. Practical Training). History and Ideals of Art.
Glass and Earthenware. Including Pottery.
Carving. Wood. Bone. Ivory. Horn. Tortoiseshell.

Group 3.
Biology. Psychology. Sociology. Logic. Philosophy. Religion.
Biology. Including Evolution, Palæontology, Heredity, Anthropology, Ethnology.
Psychology. Including Psychical Research.
Sociology. Including Political Economy.
Logic. The Science of Reasoning.
Philosophy. Systems of Thought.
Religion. History and Systems. Christianity.

Group 4.
Building. Cabinet Making. Upholstering. Fire.
Building. Excavating. Drainage. Manufacture of Bricks, Limes, and Cements. Bricklaying. Clay Wares. Reinforced Concrete. Masonry. Carpentry. Slates and Tiles. Plumbing. Joinery. Foundry and Smiths' Work. Painting. Paperhanging and Glazing, Heating, Lighting, and Ventilation. Building Regulations. Quantity Surveying. Building Abroad. In Business as a Builder.
Cabinet Making and Upholstering. A Practical Course.
Fire. Fireproof Materials. Fire Prevention. Fire Extinction.

Group 5.
Chemistry and Applied Chemistry.
Chemistry. Inorganic and Organic. Chemistry of the Stars.
Applied Chemistry. Acids and Alkalies. Oils (Fixed Oils and Fats; Waxes; Essential Oils and Perfumes; Paints and Polishes) Candles Soaps. Glycerin. Glues and Adhesives Starches. Inks Tar and Wood Distillation. Matches. Celluloid. Manure. Waste Products. Petroleum. Paper Making (including Paper Staining and Uses of Paper). Photography.

Group 6.
Civil Service. Army and Navy.
Civil Service. Municipal. National. Imperial.
Army and Navy. How to Enter Them.

Group 7.
Clerkship and the Professions.
Clerkship and Accountancy. Complete Training. Bookkeeping.
Banking. The Whole Practice of Banking.
Insurance. Life, Fire, Accident, Marine.
Auctioneering and Valuing. Practical Training.
Estate Agency. Departments and Officials of a Great Estate. Training a Land Agent.
Medicine. Training of a Doctor. Specialists. Veterinary Surgeons. Dentistry: The Dental Mechanic Home and Professional Nursing.
Church. How to Enter the Ministry of all Denominations.
Scholastic. Teachers. Professorships. Governesses. Coaches. Tutors.
Secretaries, etc. Institutions, Political Organisations. Lecturers.
Law. Solicitors and Barristers. Personal and Commercial Law. Copyright.

Group 8.
Drawing and Design.
Drawing. Freehand. Object. Geometrical. Brush. Memory. Light and Shade.
Technical Drawing. For Engineers; Coppersmiths, Tinmen, Boilermakers; Architects; Stonemasons; Carpenters and Joiners; Plumbers.
Design. Book Decoration. Illumination. Textiles. Wall Papers and Stencilling.

Group 9.
Dress.
Dress. Dressmaking. Underclothing. Children's Clothing. Tailoring. Millinery. Men's Hats. Furs and Furriers. Feathers. Shirts and Collars.

Group 10.
Electricity.
Electricity. Electrical Engineering. Telegraphs and Telephones (including operation of). Cables and Insulated Wire. In Business as an Electrical Engineer.

Group 11.
Civil Engineering.
Civil Engineering. Surveying. Varieties of Construction. Machines Employed. Roads. Bridges Railways and Tramways. Water Supply. Sewerage. Refuse. Hydraulics. Pumps. Harbours. Docks. Lighthouses. Foreign Work. In Business as a Civil Engineer.

Group 12.
Mechanical Engineering. Military Engineering. Arms & Ammunition.
Mechanical Engineering. Applied Mechanics. Workshop Practice. Tools (Hand and Miscellaneous. Machine Tools. Portable Machine Tools). Machines and Appliances (A General Guide to Construction). Clocks and Watches. Scientific Instruments.
Military Engineering. Pontoons. Bridges. Fortifications. Rafts. Trenches. Passing Rivers. Conditions in Peace and War.
Arms and Ammunition. Manufacture of Arms and Explosives.

Group 13.
Geography. Astronomy.
Geography. Physical. Political. Human. Commercial.
Astronomy. A Survey of the Solar System.

Group 14.
Geology. Mining. Metals and Minerals. Gas.
Geology. The Making of the Earth.
Mining. The Practice of Mining: Coal, Gold, Diamonds, Tin, etc.
Metals. Metallurgy. Iron and Steel. Iron and Steel Manufacture. Metal Work. Cutlery.
Minerals. Mineralogy. Properties of Minerals.
Gas. Manufacture of Gas.

Group 15.
History.
A Short History of the World from the Beginning.

Group 16.
Housekeeping and Food Supply.
Servants. Qualifications and Duties of Every Kind of Servant.
Cookery. A Practical Course, with Recipes.
Laundry Work. Washing. The Laundry as a Business.
Foods and Beverages. Milling. Bread-making Biscuits and Confectionery. Sugar Condiments. Fruit. Fisheries. Food Preservation Catering Brewing. Wines and Ciders. Mineral Waters. Tea. Coffee. Chocolate. Cocoa.

Group 17.
Ideas. Patents. Applied Education.
Ideas. The Power of Ideas in Life. Brains in Business.
Patents and Inventions. How to Protect an Idea.
Applied Education. Application of Education in Daily Life. Finance.

Group 18.
Languages.
How to Study a Language. Courses in Latin, English, French, German, Spanish, Italian, Esperanto, Greek. A Table of Root Words.

Group 19.
Literature. Journalism. Printing. Publishing Libraries.
Literature. A Survey of the World's Great Books and their Writers. Poetry Classics. Fiction. Miscellaneous How to Read and Write.
Journalism. A Guide to Newspaper Work, with Practical Training.
Printing. Composing by Hand and Machine. Type Cutting and Founding. Engraving and Blocks.
Books. Bookbinding and Publishing.
Libraries. Officials and Management of Libraries.

Group 20.
Materials and Structures. Leather. Wood Working.
Materials. The Characteristics and Strength of Materials.
Structures. The Stability of Structures.
Leather. Leather Industry. Leather Belts. Boots and Shoes. Saddlery and Harness Gloves. Sundry Leather Goods.
Wood Working. Design and Operation of Wood Working Machines. Wood Turning. Miscellaneous Woodwork.

Group 21.
Mathematics.
Mathematics. Arithmetic. Algebra. Geometry. Plane Trigonometry. Conic Sections.

Group 22.
Music. Singing. Amusement.
Music. Musical Theory Tonic Solfa Tuition in all Instruments. Orchestration. Conducting. Bell Ringing. Manufacture of Musical Instruments.
Singing. The Voice and Its Treatment.
Amusement. Drama and Stage, including Elocution. Business side of Amusement. Sports Officials.

Group 23.
Natural History. Applied Botany. Bacteriology. Natural Products.
Natural History. Botany. Kingdom of Nature—its Marvels, Mechanism, and Romance; Flowers, Plants Seeds, Trees, Ferns, Mosses, etc. Zoology; Animals, Birds, Fishes, Reptiles, Insects.
Applied Botany. Tobacco & Tobacco Pipes. Forestry. Rubber and Gutta Percha. Basket Making. Cork, Wattle. Cane Work. Barks. Brush Making.
Bacteriology. Pathological and Economic.
Natural Products. Sources. Values. Cultivation.

Group 24.
Physics. Power. Prime Movers.
Physics. A Complete Course in the Science of Matter and Motion.
Power. A General Survey of Power. Natural Sources. Liquid and Compressed Air.
Prime Movers. Engines. Steam. Gas. Heat. Turbines. Windmills.

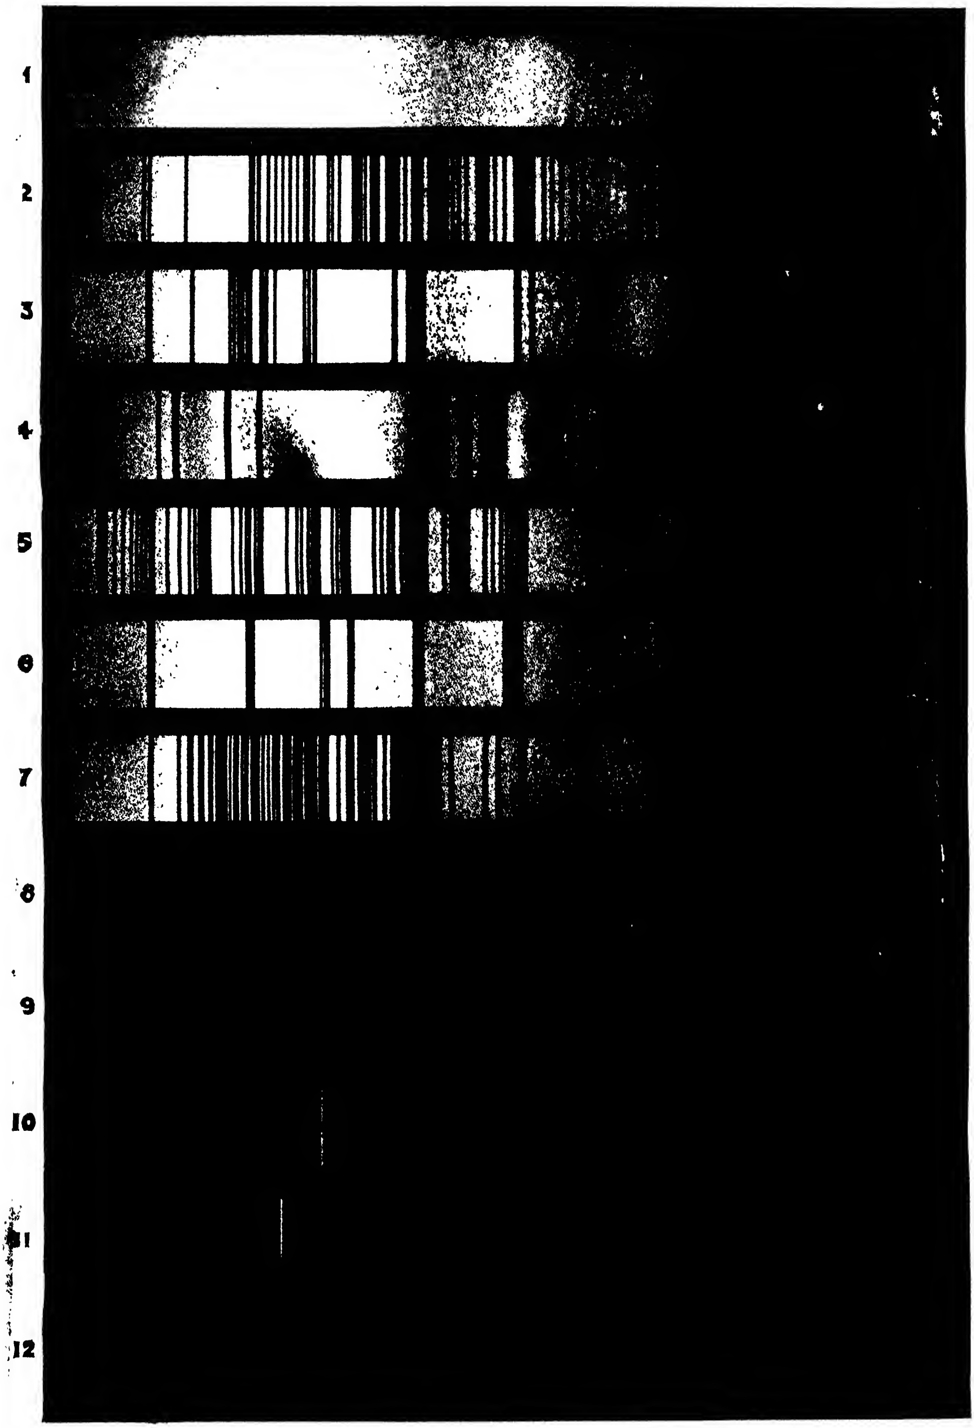
Group 25.
Physiology. Health. Ill-health.
Physiology. Plan of the Body. Digestive. Circulatory. Respiratory. Locomotor and Nervous Systems. The Senses.
Health. The Five Laws of Health Personal Hygiene. Environment. State Medicine and the Public Health.
Ill-health. General Ill-health. Its Special Forms. Common Ailments and Domestic Remedies.

Group 26.
Shopkeeping. Business Management. Publicity.
Shopkeeping. A Practical Guide to the Keeping of all Kinds of Shops.
Business Management. The Application of System in Business.
Publicity. Advertising from all Points of View As a Business.

Group 27.
Shorthand and Typewriting.
Shorthand. Taught by Pitmans.
Typewriting. Working and Management of all Machines.

Group 28.
Textiles and Dyeing.
Textiles. The Textile Trades from Beginning to End.
Dyeing. Dyes and Their Application.

Group 29.
Travel and Transit.
Travel. How to See the World. The Business Side of Travel.
Transit. A General Survey of Means of Communication.
Vehicles. Construction of Air, Land and Sea Vehicles. Business of Liveryman, Carrier, etc. Driving.
Railways. The Management and Control of Railways.
Ships. Shipbuilding. Shipping. Management of Ships.



THE STUDY OF THE STARS BY THEIR SPECTRA

1. Continuous spectrum 2. Solar spectrum 3. Spectrum of a red star 4. A temporary star 5. Alpha star in constellation Hercules 6. The star Sirius 7. The star Aldebaran 8. A nebula. 9. Calcium 10. Magnesium 11. Sodium 12. Hydrogen

THINKING SCIENTIFICALLY

How to Argue. A Man and His Conscience. Rationalism and Scepticism. Fallacies. Theory and Practice. The Laws of Thought. Herbert Spencer's Test of Truth

By Dr. C. W. SALEEBY

ONE reason why the synthetic philosophy of Herbert Spencer has created an epoch in the history of human thought is that it is the first system of philosophy in which the due balance between induction and deduction and the necessity for the correction of each by the other are fully recognised.

How Spencer "Squared" his System with Facts. In order to frame secure inductions, the author spared no pains. He spent three thousand hard-earned pounds and many years of labour in order to collect facts as to the social life of various peoples, ancient and modern, so that he might have a wide enough base upon which to build any sociological generalisations that might be forthcoming. When, on the other hand, he had reached an induction by this process, his next proceeding was to use it as the starting-point for a process of deduction, and then to see whether the inferences from it "squared" with facts. Thus, for instance, he has the inductions of ethics leading up to the principles of ethics, and the principles of ethics leading to practical maxims, which may or may not be already realised in human life.

And here is where faith comes in. You begin with a number of facts, and infer or induce from them an induction or generalisation; then you make a fresh start with this, saying to yourself: "Well, if this be so, what follows?" Deducing from this proposition according to the accepted laws of reasoning, you may well reach certain amazing conclusions.

A Man's Fight Against his Convictions. This was not so in the case we have quoted, but it has often been so. These conclusions are totally at variance with accepted belief. They seem incredible. They may involve the destruction of half one's convictions. Such cases are constantly encountered by the man who lives the intellectual life. What are the possibilities for him in such a fight?

One begins by re-examining the whole process. First of all, were the facts facts? Secondly, were there enough of them? Were they properly chosen? Or were they selected with a view to proving (not to proving *or disproving*) a certain proposition?—which is the commonest form of intellectual dishonesty, and a sin of which none can cry "Not guilty." But supposing that all these questions can be satisfactorily answered, then the induction must stand. It will be well at this point to ask ourselves whether we have not unconsciously made our generalisation rather too wide. The only conclusion from an adequate study of facts in this country and at this time may be that vaccination confers immunity from smallpox. But we may have neglected the qualifying clauses and may have declared that vaccination will protect every species of man or of animal from smallpox. This may or may not be true, but it is at any rate a fallacious or illogical induction from the facts at our disposal.

But suppose that our induction is free from all these flaws, then we must turn to our deductive reasoning, or ratiocination, and seek for fallacies in it. We shall do this the better if we have ever had occasion to make a systematic study of sources of fallacy. But suppose all fallacies have been excluded, there remain but two choices.

Faith and Doubt. Either we must have faith and accept the processes of our reasoning as valid, and Nature as a trustworthy and incorruptible witness, letting all our preconceptions go without a murmur, or we may be sceptical. In all ages there have been philosophers of both these classes. Those of the one class believe in the reason and the rational processes; they have faith. The proper philosophic name for their belief is *rationalism.* It is one of the unfortunate facts of language that words are constantly diverted from their proper meaning, and the word rationalism has suffered this fate. But, nevertheless, that is its proper meaning.

On the other hand, there are the philosophers who are sceptical. They declare that when the processes of logic are allowed rope enough, they always hang themselves. Therefore, whenever a conclusion is reached which seems absurd, such philosophers have no hesitation in saying that it *is* absurd, and that its absurdity demonstrates the worthlessness of the process by which it was reached. This attitude of mind is properly to be called *scepticism.* In the language of philosophic literature it is very commonly known as Pyrrhonism, from the Greek Pyrrho, the founder of the school of Sceptics.

"How Came it that Neptune was There?" The reader will not expect from us anything so impertinent as a dogmatic assertion that rationalism is the whole truth or that scepticism is the whole truth. On the contrary, we believe that it is the truth partially discovered by each that has kept it alive during thousands of years. Merely we note this—before leaving a fascinating subject—that the faith of the rationalist in the absolute validity of logic leads him into strange difficulties whenever his logic is pushed to the ultimate limits; whilst, as for the sceptic, who denies the validity of reasoning at all, he may be asked one question, typical of the question always put by science to sceptics, "How comes it that when Adams and Leverrier, each independently, placed his telescope upon a certain spot in the heavens, *Neptune was there?*"

We may also note that, just as absolute rationalism can always be made to look foolish, so absolutely consistent scepticism is impossible as a practical guide of life. The absurd stories invented about the sceptical philosophers, such as Pyrrho, are a testimony to the popular recognition of this truth. Let us note, also, that the reader should try to make up his mind about scepticism, provisionally, at any rate. For if his conclusion be that the rational or logical processes are untrustworthy—even proximately—plainly he must read, let us say, the course on Philosophy, just as one reads Mark Twain, by way of *divertissement*, and his only comment on concluding will run, "What fools these mortals be."

Therefore. Reading this course so far as it has gone, any student of logic prior to 1843, and many students since, might wonder when, if ever, the writer would proceed to discuss logic at all. It is now certainly time for us to consider, in outline, that rational process with which alone logic used to be supposed to be concerned—the process of "*pure reasoning*," "ratiocination," "deduction," "*a priori* argument," or "inference from the general to the particular." We may say that a study of deduction is a study of the conditions under which one may rightly employ the wonderful word "therefore." We call this a wonderful word because it is the mark of the rational process, which has been extolled as wonderful in all ages.

So-and-so is so-and-so; therefore, a new conclusion follows—really the new conclusion is implicit or bound in the old one. If the premise be granted, the conclusion is inevitable. One does not need to look, so to speak; one knows that it must be so, without looking, without experiment or observation, and one can thus reach sure conclusions which are in their very nature incapable of verification by experiment or observation.

Theory and Practice are Never Opposed. Thus, the power of this process is immeasurable; but, just in proportion to its power, it is dangerous—dangerous because, as Bacon shows, its facility and potency tempt the mind, leaving us to employ deduction which is insecure. Hence the repeated criticism that a thing is all very well in theory but does not work in practice. Long ago Mill showed that there is confused thought in such criticism. If a thing is really sound in theory, it will work in practice. There is no opposition between theory and practice, and the reason why practice repeatedly fails to confirm theory is that theory is unsound. Either the premisses of the logician are false or his reasoning from them contains a fallacy. Men say of a perpetual motion machine that it works admirably on paper, but that somehow the results are not obtained in practice. But such a machine does *not* work admirably on paper; it is only thought to do so. If it really did so it would work neither better nor worse in practice.

Deduction has one great instrument. Every deductive argument without exception can be cast into a form which illustrates the employment of this instrument. It was first recognised by Aristotle, and so searching and thorough was the founder of logic in his investigation of this great rational instrument that more than 2,000 subsequent years have added very little to his study of it. This instrument is known as the syllogism; and time was when the study of logic was the study of the syllogism. Nowadays we may employ such a term as the syllogistic logic synonymously with the deductive logic. Right deduction is the right use of the syllogism. It is not our hopeless purpose here to discuss in a column or two a subject about which books innumerable have been written. We can merely present the barest outlines of it to the reader.

The Syllogism, the Great Instrument of the Mind. What, then, is this marvellous *organon* or instrument by means of which the mind is enabled, by its own power alone, and without reference to the external world at all, to discover new facts? Let us begin with a concrete instance, such as has already been quoted. "All men are mortal: I am a man; therefore I am mortal." This argument, with its three propositions and three terms, is a syllogism. Every syllogism has three and only three terms—the major term, the minor term, and the middle term. Every syllogism contains three and only three propositions, which are called the major premise, the minor premise, and the conclusion, and the middle term must be "distributed" once at least in the propositions. In the instance which has been quoted, the three terms and the three propositions are evidenced. The middle term, the distribution of which is essential, may be recognised by the fact that it does not occur in the conclusion—the invariable rule. Obviously, it is the term "men." Furthermore, as in all syllogisms, the minor term is the subject of the conclusion, "I"; and the major term is the predicate of the conclusion, "Am mortal."

Furthermore, every syllogism, such as this, compares the major and the middle terms in a major premise—"All men are mortal"—and similarly compares the minor and middle terms in a minor premise—"I am a man"—whilst the third proposition or conclusion contains the minor and major terms alone—"I am mortal." Properly speaking, one should always place the major premise first, and then the minor premise. But whatever the order, the premise containing the major—that is to say, the bigger or wider term—is the major premise.

The Middle Term. The all-important term of the syllogism is its middle term, and it is absolutely essential, as we have already said, that the middle term be distributed, and properly distributed. Error in this respect is perhaps the most common cause of what is called fallacy. The commonest source of fallacy is what logicians call "the undistributed middle." In such cases the major and minor premise may both be absolutely true, but the conclusion ludicrously false. To quote an instance from the distinguished logician Jevons, "by the middle term being distributed once at least, we mean that the whole

of it must be referred to universally in one premise, if not both. The two propositions :

All Frenchmen are Europeans,
All Russians are Europeans,

do not distribute the middle term at all, because they are both affirmative propositions," the predicates of which are undistributed. If, following the method of Euler, we draw a circle and call everything within it Europeans and then within that two little circles, one labelled French and the other Russian, we see that there is no real middle term. So far as the propositions are concerned Russians might or might not be Frenchmen. "Again, the two propositions

All Frenchmen are Europeans,
All Parisians are Europeans,

do not enable us to infer that all Parisians are Frenchmen." So far as the premisses are concerned, the circle Parisians need not be placed within the circle Frenchmen, but may be placed anywhere within the big circle, Europeans. This argument gives us an instance, since, as a fact, all Parisians are included amongst Frenchmen, of a case where premisses and conclusions of a syllogism are all true and yet the syllogism is fallacious.

Fallacies. The word fallacy, so important to the logician and containing an idea of the utmost importance for every serious thinker, is constantly misused in common speech, and common writing too. By an unfortunate confusion of thought the word is applied to any statement or belief that is asserted to be untrue. "It was a fallacy to think that the sun went round the earth," people will say. But this is an utter misuse of the term. A fallacy is not an error of fact or an error of statement. The belief that the sun went round the earth was not a fallacy ; it was arrived at by a fallacy or a fallacious argument, which is a very different thing. Similarly, as has often happened, truths may be reached by fallacies. A fallacy is an error of logic, or an error of reasoning. It is an impropriety of method, not an impropriety of belief. Correct premisses correctly reasoned from must always lead to correct conclusions. Correct premisses incorrectly reasoned from will usually lead to incorrect conclusions. By sheer chance correct conclusions may be thus reached, but they are not correct because the argument says so. Incorrect premisses correctly reasoned from must necessarily lead to incorrect conclusions ; incorrect premisses incorrectly or fallaciously reasoned from may lead to either correct or incorrect conclusions—but the latter more commonly, of course.

Truth may Lie Behind a Fallacy. The history of thought is full of instances of all these possibilities. Let us, then, in future use the word error to mean one thing and fallacy to mean another, realising all the possibilities ; not, for instance, hastily condemning a conclusion because it has been fallaciously arrived at, and realising that many true conclusions have thus been stated and that a non-fallacious argument for their truth may yet be forthcoming. Someone declares, for instance, that he has proved that the earth goes round the sun. When his arguments are studied they are found to be fallacious. But one would be a fool, therefore, to scoff at his conclusions. Truth and error are opposites but not truth and fallacy. Fallacy is a matter of interpretation or logic alone.

We have already noted that the first thinker to study the syllogism practically exhausted the subject, and it is a noteworthy fact that the intelligent student can usually recognise for himself without previous study the sound and the unsound, the logical and the fallacious argument.

The Logical Sense. Here, again, is a parallelism between logic and grammar, which is the logic of language. Everyone knows how at school there are inherent differences between children in respect of parsing, analysis, and the like. One boy never learns any of these things. They are absolutely self-evident to him from the first. To another, who is without the language sense, the operations and conclusions of parsing are mysterious and arbitrary from the first, and always remain so. He cannot be taught any more than one can teach the blind to see. The case is the same with logic, and one is almost inclined to hazard the proposition that the same boys belong to corresponding classes in both cases. Some men think coherently and consecutively though they may have scarcely heard the name of logic. One may meet an intelligent blacksmith, and begin to talk about the Education Bill, let us say, and in a moment he will declare "that is a bad argument," and be right. On the other hand, there are people who may be of great use in the world, capable, energetic, and trustworthy, to whom apparently one sequence of propositions is as consequent or inconsequent as another, who will support the truest beliefs by the most fallacious arguments, and who are practically as incapable of acquiring the logical sense as other people of acquiring the language sense.

This is not, of course, to say that training can do nothing, nor is it to say that the systematic study of fallacies is not worth pursuit, but it is to assert that the great majority of readers to whom the subject presents any attraction at all will find, if they pursue the subject further, that the greater part, if not the whole of it, has a peculiar character of being self-evident. The natural comments will be "of course," "obviously," "certainly."

Symbolic Logic. In comparatively recent times much has been made of a new method of studying or stating logic. If we are to state the syllogism in its simplest and most abstract terms, its simplest form will run thus : A is B, C is A, therefore C is B. Here, instead of propositions, we use symbols. All the other forms of the syllogism can similarly be represented by the use of such symbols, as also can those fallacies which are classified as "logical" as distinguished from "material fallacies.". For instance :

All Y's are X's.
No Z's are Y's,
therefore No Z's are X's.

This is a fallacious syllogism, the major term X being improperly distributed. The common-

sense comment on it will run "No one said that *nothing but* Y's are X's, and therefore the mere statement that no Z's are Y's does not exclude the possibility that some or all Z's may be X's." For instance, all birds are vertebrates, no mammals are birds, but it does not therefore follow that no mammals are vertebrates. It does not matter what particular terms be employed; the letters which have been used as symbols will serve the purpose of the systematic logician. The parallelism is, of course, obviously that between algebra and arithmetic. What is then called the *symbolic logic*, which discusses the subject in symbolic or algebraic form, has been proved to be of great value, and has been carried to a very great degree of complexity. The mere recognition of its existence is of the utmost value even to the elementary student, just as the smallest acquaintance with algebra is of value to the student of arithmetic. It teaches the inevitable and necessary character of the logical processes, no matter what particular terms be employed, just as algebra teaches the necessary and inevitable nature of mathematical truths, no matter what particular numbers be under discussion.

Kinds of Fallacies. Having endeavoured to clear up the real meaning of the word fallacy, so that the reader will never be guilty of fallaciously accepting the erroneous opinion that fallacies and errors are identical, or that the detection of a fallacy in an argument implies a condemnation of its conclusion, we do not propose to discuss the kinds of fallacy in detail. We have neither space nor necessity. But a few kinds of fallacy may be noted, because they are so extremely common, and because the terms describing them are so frequently met with. There are, for instance, the kinds of fallacy included by Aristotle under the term Irrelevant Conclusion. This has various varieties, but they are all much easier to understand than the strictly logical fallacies, to which we will not here refer, such as the fallacy of an undistributed middle, instances of which have already been quoted.

It is an instance of the fallacy of irrelevant conclusions to prove one thing when you think you are proving another. There is thus the celebrated advice given to the barrister for the defendant in a law suit, whose brief was marked "No case: abuse the plaintiff's attorney." It might be proved up to the hilt that the plaintiff's attorney was a blackguard. But that is an irrelevant conclusion. It is not what one set out to prove The Latin phrase for this is the *argumentum ad hominem;* another Latin phrase, *argumentum ad populum,* indicates another form of irrelevant conclusion, the instrument of dishonest orators of all ages, who appeal to the prejudices and private passions of the people.

Begging the Question. This familiar fallacy also has a Latin name, *petitio principii.* It is also often called arguing in a circle. To beg the question is to assume what you are seeking to prove. You use the conclusion as one of your premisses. Instances of this are too familiar to need quotation. Often, as the great Bentham pointed out, one may beg the question by a mere word; such words he called "question-begging epithets." Thus Jevons says, "In like manner we beg the question when we oppose any change by saying it is un-English." Then, again, there is the extremely common fallacy, also recognised by Aristotle, which is most commonly known by the Latin phrase *non sequitur*—it does not follow. This is most commonly applied to arguments wherein the conclusion has no real connection with the premisses. Lastly, there is the fallacy, recognised by Aristotle and constantly employed by barristers, which consists of assuming the answers to certain questions whilst putting a still further question? For instance, "When did you leave off beating your wife?" or, better still, "Have you left off beating your wife?" Obviously, the unfortunate husband condemns himself equally whether he answers yes or no. This is called the *fallacy of many questions*, and, as Aristotle pointed out, "Only a single question admits of a single answer; only one predicate of one subject ought to be affirmed or denied in a single answer. Therefore, several questions put as one, should immediately be separated into their several parts."

The First Law of Thought. Lastly, we may consider what have been called the three primary laws of thought. They are of interest not only in themselves, but also because so soon as we examine any deductive argument to its utmost, we find that the truth of these laws of thought is assumed. If two men are not agreed as to their truth, they cannot argue with one another. There is no common ground whatever from which they may start. Similarly, we saw when discussing inductive logic that all its arguments depend upon the acceptance of the tremendous proposition that Nature is uniform and causation universal. The discussion of these laws of thought is also of deep interest, because it shows us the relations between logic and psychology, or, so to speak, the dependence of the rational processes upon the structure of the reason. Logic is thus, at bottom, a province of psychology, and the validity of all logical or rational conclusions must stand or fall in the last resort with the validity of mental processes. "What is truth?" said jesting Pilate. But that is too great a question to be considered here.

These are the names of the laws of thought: *The law of identity, the law of contradiction,* and *the law of excluded middle.* The first is simply "*whatever is, is.*" That may not seem worth saying, but we must not be too hasty.

The Second Law of Thought. The second law, which has been named the law of contradiction, is this: *Nothing can at one and the same time both be and not be.* Sir William Hamilton, the great Scottish philosopher, suggested that this should really be called the law of non-contradiction, and perhaps that phrase expresses it better. The law of identity we may here ignore and take for granted, but the law of contradiction or non-contradiction is absolutely fundamental and essential. It implies that in so far as anything is black, it cannot at the same time be white. Define shut and open, and a door cannot be at one and the same time both open

and shut. This, says Jevons, "seems to be the most simple and general truth which we can assert of all things." It is the very nature of existence that a thing cannot be otherwise than it is; and it may be safely said that all fallacy and error arise from unwittingly reasoning in a way inconsistent with this law. All statements or inferences which imply a combination of contradictory qualities must be taken as impossible and false, and the breaking of this law is the mark of their being false.

The Third Law of Thought. The third law of thought, or the law of excluded middle, is as familiar in practice as the others, *Everything must either be or not be.* If a line exists at all, it is either a straight line or not a straight line. That, indeed, is evident. But there are cases which look as if the law were untrue—cases of quantity, as, for instance, in the use of such relative terms as hard and soft. Logic does not assert that there may not be degrees of softness or hardness. It simply asserts that if a given meaning be allotted to the word hard, a given thing is either hard or not hard. It is upon these three laws of thought that the syllogism and all its possibilities, together with the whole of inductive reasoning, are based.

A Great Test of Truth. These three laws, and pre-eminently the second, help us in some measure towards realising our great need, the establishment of some criterion of truth. The denial of these laws is inconceivable. *They must be so*—or, at any rate, if we are to be cautious, *we are so made that they must be so to us.* If there are any truths of which we can be certain, these are such truths. There is a great argument of Herbert Spencer's upon this subject. Like many before him he asked whether there is any test of truth. As students of psychology we will be prepared to agree that at best our perception of truth is at the mercy of our perceiving minds. The nearest approach to a test of truth, says Spencer, therefore, must be found by way of the ultimate laws of thought. He says: "In the last resort we must accept as true a proposition of which the negation is inconceivable." Our highest certainty may or may not be an absolute certainty, but, at any rate, it is a certainty based upon the inconceivableness of its denial. Whether or not absolute or infallible, our ultimate criterion of a certainty is the inconceivableness of its negation.

What the Reason Must Reject. Thus stringently judged, it will at once be seen that our highest certainties are very few. The most positive generalisation of science, for instance, the so-called laws of Nature, such as the law of gravitation, are not even in the neighbourhood of the highest certainties. One is defying no mental necessity in denying or questioning the law of gravitation. Yet, though this principle will not enable us to regard, as having the highest certainty, any but the three primary laws of thought and the necessary deductions from them, it is nevertheless of the utmost negative value. Any proposition, for instance, that defies a law of thought—any proposition, that is to say, which is inconceivable or only the negation of which is conceivable—must be rejected by the reason. It may very well be accepted by something other than the reason. But that is no concern of ours here. Here we are discussing merely the laws of reasoning, and, so far as these are concerned, such propositions must be rejected. There is, for instance, a highly paradoxical German system of philosophy, invented by Hegel. It is based upon the proposition that being and not-being are the same—a proposition which, as one may readily imagine, enables him to prove to his own satisfaction anything that he cares to prove. If this proposition of his is to be accepted in the sense which it bears, one does not need to have read any of Hegel in order to reject him. One is entitled to feel that there is no time for the consideration of conclusions which are founded upon an absurdity. Observe here the utter distinction between laws of Nature, so-called, and laws of thought. It would be a grave abuse of language to call the denial of the law of gravitation an absurdity, but that is just the word which occurs to us to describe a denial of a law of thought.

The Duty of the Reason. If we must be true to our reason in all matters, then the importance of recognising the law of contradiction, as we practically do, cannot be overestimated. It was said of a famous man of science, Faraday, that his science and religion did not quarrel, because he kept them in different pockets. This was as good as to imply that if they were in the same pocket they would quarrel, but such a position cannot satisfy the logician or the philosopher. He wants all his beliefs to be true, and he cannot conceive incompatible beliefs to be both true. If his science and religion appear incompatible, he cannot be content with keeping them in different pockets. First of all, he must ask whether they are really incompatible, and, if so, he must find out which is true and renounce the other. In its place he may find a different form of religion or a different form of science which, properly considered, is found to be compatible with its fellow.

Truth and Truth can Never be Opposed. Thus, he may finally reach a position where he does not need to shut his eyes to the law of contradiction or fight against the necessities of his own mind. He will neither declare that religion is superstition, nor assert that the face of Nature is false to the soul of Nature, or, in other words, that science does not express the truth. He will the rather subscribe to these sublime words of Herbert Spencer:

"Religion, everywhere present as a warp running through the weft of human history, expresses some eternal fact; while Science is an organised body of truths, ever growing, and ever being purified from errors. And if both have bases in the reality of things, then between them there must be a fundamental harmony. It is impossible that there should be two orders of truth in absolute and everlasting opposition."

LOGIC *concluded; followed by* PHILOSOPHY

DRAWING FOR THE PRESS

The Seriousness of the Press Illustrator's Art. His Masters Among the Moderns. The Law of Page-decoration. Medium, Materials, and Means

By HALDANE MACFALL

THE illustrating of books, magazines, and papers has produced some of the finest art of the last fifty years; it has, besides, been the means of livelihood for many artists who must have failed to earn either a living or fame in the painting of easel pictures. But to-day the art of illustration is sinking under the rivalry of photography, and except for the best class work it is in the hands of the most wretched artists. Nevertheless, if the student have a marked individuality in his style, he will—in illustration as in all art—inevitably come to the front. Indeed, the last ten years have given us the work of some of our most remarkable men.

Limitations and Greatness of Press Illustration. In designing an illustration or decoration for the Press, the student must above all things remember that he is working for what is called the process block—that is to say, he must so use his tools that his drawing may suit the rough treatment required for a daily paper, if he be drawing for a newspaper, or he may allow himself a more elaborate style if drawing for a handsomely printed magazine.

In other words he must simplify his style to suit the conditions under which it must be printed. Phil May evolved a marvellously simple and powerful style in order to get the best results from the rude conditions under which he had to work. Randolph Caldecott is the supreme master of the simple use of line and colour-wash in combination for the purposes of illustration, but it should also be noted that his works come out equally well in half-tone process blocks when required, without colour. No student should be without Joseph Pennell's book, "Pen Drawing and Pen Draughtsmen," which is a mine of illustration and contains much sound advice to the illustrator.

It is well to be clear upon one most important factor in the art of illustration from the start; the illustrator must take his art as seriously as though he were the best of painters or sculptors. By no other means may he achieve distinction in, perhaps, the most far-reaching of all the pictorial arts. Many men have but used the art of illustration as a means of pot-boiling, but this is sheer artistic suicide. Some of the artistic genius of our day has reached its highest achievement in this province, and one has only to think of Steinlen, of Charles Keene, of Randolph Caldecott, of Aubrey Beardsley, of Howard Pyle, of Sime, or Edwin Abbey to grasp the great reach of the art of the illustrator.

Media and Tools. In speaking of the art of illustration it should be clearly understood that the vulgar use of the term "etching" as applied to pen-work is absolutely wrong. Etching is a method allied to engraving on a metal plate. The art of etching and engraving, which is dealt with in a separate article [page 6111], is quite apart from process work, and is not very successful in illustration. Illustration can be—and in the case of Howard Pyle, for instance is—done from paintings, but the more ordinary media are pen and ink, or crayons, or a painting-brush, using charcoal grey and Chinese white for the values.

The tools and materials, then, are of the simplest; their use is dependent on the end required. For the roughest work, line is absolutely necessary. And it has the great advantage over wash-work (or paint) that every stroke of the artist's tool comes out exactly in the reproduction from his work. In speaking of line, the pen-line may be generally understood, but it must be remembered that many men get their line with a brush used as a pen; on the other hand the crayon, though a point, makes so blurred an arrangement of lines, that it has to be reproduced by the more expensive method of half-tone process, just as a wash-drawing has.

The wash-drawing is, in these days of process, marvellously closely rendered when the paper has a smooth surface and the printing is not too rough—as, for instance, in magazines and weekly and other periodical picture papers.

Modern, not Old Masters. Let us first of all take the art of pen-drawing for illustration. A smooth white Bristol board, a pen, and a bottle of liquid Indian ink, are the only materials necessary. What a vast range of technique lies in the use of such simple materials the student may see by comparing pen-and-ink drawings by Charles Keene, Randolph Caldecott, Walter Crane, William Nicholson, Aubrey Beardsley, S. H. Sime, Edgar Wilson, Edwin A. Abbey, Phil May [12], and many of the modern Frenchmen, in whose works we may see that almost any emotional effect may be got, for the gamut of expression ranges from Nicholson's sombre, resonant deep blacks to the light, gay movements of Abbey's sunlit Italian romantic designs for Shakespeare's comedies.

The student of pen-drawing will get little help from the old masters, unless perhaps he try to use the pen as Holbein used a pencil, or as Rembrandt used the etching needle. His masters will be among the moderns. And the student has the advantage that he may procure at a very small price the works of some of the greatest men in his art. In Spain there is the work of Vierge and of Casanova and of Fortuny. All three of these men use a light gay technique that wonderfully represents the sunlit atmosphere of their land. In France we have such fine penmen as Willette,

Steinlen, Rivière, Gerbault, Grasset, Helleu (whose etchings are fine lessons for the penman in musical, swinging line), Caran d'Ache, and a score of others. In Germany we have Menzel, Dietz, Stuck, Max Klinger, Sattler, and Vogel. In Danish work Hans Tegner is particularly fine. In American magazines particularly the student will find rich education.

The superb work of E. A. Abbey, Howard Pyle, Dana Gibson, Blum, and Pennell, to mention only a few of the brilliant army of American illustrators, is in itself an education in black-and-white work. In English books, magazines, and picture-weeklies may be found the finest work in the world, which includes Leighton's illustrations to the Dalziel Bible, Charles Keene in "Punch," Sir John Gilbert and Birket Foster, Millais, Rossetti, Fred Walker, Boyd Houghton, and Pinwell; and Fred Barnard, Charles Green, Randolph Caldecott, William Small, Fred Sandys, Holl, Mahoney, Tenniel, Sambourne, Du Maurier amongst the older men; whilst the nineties were glorified by the work of Aubrey Beardsley, Sime, Edgar Wilson, Gordon Craig, Phil May, Raven-Hill [10], Hugh Thomson, Maurice Greiffenhagen, E. J. Sullivan, Anning Bell, the Beggarstaff Brothers (W. Nicholson and J. Pryde), Byam Shaw, F. H. Townsend [11], and Bernard Partridge [13].

10. SMALL REPRODUCTION OF PEN-DRAWING BY L. RAVEN-HILL

Extract fr n Mabel's Corr ondence: "We had a scratch game with the Black and ue Club yest rday, but had a wful job to get any men. Enid's brother and a friend his turned u at the last m ent; but they didn't do much except call 'Off-side' or Foul every other minute, and they were ll as nervous as cats:

Crayon and Wash. What can be done with the crayon, even under the rough and ready conditions of an ordinary French paper, may be seen in the master work of Steinlen. His work for the "Gil Blas Illustré" should be in the hands of every illustrator, and his influence has produced in America two or three of its greatest living women artists, particularly Elizabeth Shippen Green and Jessie Wilcox Smith. In France we have also the fine journalistic work of Paul Renouard, and the dainty technique of the caricaturist Léandre, and the romantic work of Balluriau. In wash-work, the student will find superb examples in the work of Edwin Abbey, Howard Pyle, S. H. Sime, W. Nicholson, J. Pryde, Raven-Hill, Gordon Craig, Vierge, Stuck, Steinlen, and Greiffenhagen, and from the productions in black-and-white of the pictures of such masters as Frank Brangwyn, Whistler, Manet, Turner, Sargent, and the masters of painting, more particularly Velasquez, and the Japanese.

11. SMALL REPRODUCTION OF PEN-DRAWING BY F. H. TOWNSEND

LADY (*calling on new vicar's young ife*): "Have you seen the library at the Hall? Sir George is quite a bibliophile, kn "

VICAR'S WIFE (*warmly*): "Oh, I'n glad to hear that! So y of these wealthy men have *no* religion!"

The supreme law of the decoration of the printed page is that the print cannot be too simple and pure and clear. The decoration should be so placed on the printed page as to enhance the beauty of the page without in the least detracting from the simplicity, purity, and clearness of the print.

Decoration of the Printed Page. One of the worst evils that ever fell upon the English printed page was the Morris type and decoration. No human being, surely, can read the pages of these expensive editions with the slightest sense of pleasure or profit. The illustrating of certain French books with little senseless drawings dotted all over the page, particularly in the margin and in and out of the text, is a particular abomination that has found favour far too readily in inferior English magazines and books. It is a nice question whether the decoration of a page should ever go down the side of it—it seems to destroy the interest of the print. At the top or bottom, placed clear of the print, it enhances the page. Edwin A. Abbey (sometimes in collaboration with A. Parsons) is particularly happy in his placing of both the illustration and the decoration on the printed page, as may be seen in his edition of Goldsmith's "She Stoops to Conquer," or of his many illustrated old songs. Hugh Thomson, again, is most happy in his

treatment of the page. And both these men teach a splendid lesson as regards the decoration of the covers of their books and of the title-pages. The decoration of a page should have as close a relation to the subject of that page as though it were an illustration of the subject.

Fitness in Design. Another point for the student to remember is that mere geometrical lines, or meaningless designs, have no particular virtue for decoration; and any subject, no matter how real, may be decoratively treated. Above all, the student should remember to utter his decorative work in the spirit of his own day, and not filch inappropriate technique and style from Dürer and the dead centuries. The aim of decoration is fitness of design to the subject.

In working for Press illustration, then, especially for pen-and-ink work, or "line," as it is called, the tools and materials are very few and very simple. For pen drawing, the student needs a smooth, white paper—white paper on a card is better—and it cannot be too white. A hard pencil, a pen, a bottle of liquid black ink, complete his needs, in addition, perhaps, to a sharp knife and a piece of indiarubber. White Bristol board is excellent stuff. On Bristol board the pen moves freely in all directions, when the student is sufficiently master of his pen. Any hot-pressed paper of good quality will also prove useful. Even good lineless thin writing paper will be found excellent for pen work, when a drawing beneath it is to be traced as one draws—only it requires neat handling to paste it to a cardboard afterwards.

When a line is too thick, or there is a blot, if a sharp knife will not cut it away, Chinese white will blot it out. Or if you wish to redraw the line, paste a piece of white paper over it, and draw over it. If you wish to get a tone, or flat wash of shade, anywhere, simply run it on the drawing with a blue pencil, and the process engraver will fill it in with a stipple tint by mechanical methods. Being blue, it does not interfere with the photographic facsimile of your drawing upon the zinc block.

12. SMALL REPRODUCTION OF A PEN-DRAWING BY PHIL MAY

Overheard at a country fair: "'Ere y'are! All the jolly fun! Lidies' tormentors, two a penny!"

As regards ink, ordinary writing inks should be avoided. The artist needs the blackest of inks if he would get the best results from the process-engravers. Newman's, or Winsor & Newton's liquid lampblack, and Higgins's American drawing ink, can be recommended. The ink should dry dead, without shine, should flow easily, and not fur the pen. *Encre de Chine Liquide* is also much used. Except Higgins's, most of the inks tend to drop to the bottom as sediment. This must be guarded against. Indian ink shines, and is a trouble to make.

In pencil drawing, outline in pencil and then work over all freely in ink, making every ink line tell. But remember that every pencil line must be rubbed out afterwards, and that the rubbing has a tendency to "lift" the ink that is over it. If you are making the drawing to be much reduced, remember that in the reduction the lines tend to blur, especially when they cross in several directions. Altogether, it is advisable to avoid cross-hatching as much as possible, and to get the gradations of shading by thinner or thicker lines at wider or narrower distances, but always drawn in one direction.

Wash drawing is really painting in monochrome, the drawing in transparent washes being akin to water-colour painting, and the drawing in body colour to oil-painting. The two methods should be kept strictly apart. The values of body-colour—that is, black or sepia mixed with white—are not always accurately rendered by the camera, especially under the rays of electric light; and if solid white or body-colour is introduced into transparent wash-drawings, the result will frequently be vastly different from the artist's intention.

Working Hints. The artist should, above all things, avoid hard, rigid, mechanical effects of line. There is a tendency to do this from nervousness in the earlier years of one's apprenticeship to one's art; but it should be avoided like the plague. An excellent short cut to copying the main forms of any design which is to be treated in freehand, and so translated into the artist's

own style, is to trace the main lines on a piece of tracing-paper. Then turn the tracing-paper over and re-trace it on the back. You now get a sort of negative or drawing in reverse. Fix this down to the paper or Bristol board on which the drawing is to be inked or painted by sticking down the four corners with pieces of stamp paper. Though you now see the drawing right side up, the back of it holds a transfer which can be rapidly passed on to the board by running over its lines with the edge of a paper-knife, rubbed fairly hard upon the design on the tracing-paper.

It is best, before inking in, to do a little rough sketching with the pen on a scrap of paper, so as to start upon the drawing free from nervousness. The student will find that he "goes at it" with a will, instead of uttering his first few passages in a state of "stage fright." But when the tracing is employed, or a rough pencil sketch made, the student should never allow it to cramp his drawing, employing it always as a ghost to keep him right in his forms and proportions rather than as a taskmaster.

13. REDUCED FROM A PEN-DRAWING BY BERNARD PARTRIDGE

HOTEL-KEEPER (*who has let his "Assembly Room" for a concert*): "Well, sir, I 'ope you found the arrangement of the 'all satisfactory last night?"
MR. BAWLINGTON: "Oh, yes; everything was all right. There was only one thing to object to. I found the acoustics of the building not quite —"
HOTEL-KEEPER: "No, sir; excuse me. *What you smelt was the stabl next door!*"

Another word of warning. Individuality of style is everything; therefore, whilst the student is recommended to take certain modern masters of black-and-white as his model rather than go through the numbing grind of the antique, or the paralysing effect of "art schooliness," he should take *several* masters as his model, not one alone. Try and see life for oneself. For a hundred artists who can copy others there is but one who can state a pictorial idea in terms of self.

14. REDUCED FROM A PEN-DRAWING BY C. E. BROCK

THE VICAR'S DAUGHTER: "Awfully cold, isn't it, Mrs. Muggles?"
MRS. MUGGLES: "Yes, my dear. But, bless ye, I'm *lovely* and warm!"

15. SMALL REPRODUCTION OF A PEN-DRAWING BY TOM BROWNE

MISS HOBBS (*who dislikes tobacco*): "I see you are at your idol again!"
SMOKER: "Yes; I'm burning it!"

[Our illustrations of pen-drawing are reproduced by permission of the proprietors of "Punch," Messrs. Bradbury & Agnew]

BRUSHES AND BRUSHMAKING

Fibres, Hairs, and Bristles Used in Brushmaking. Modes of Drawing Brushes. Painting and Painters' Brushes. Machine Brushmaking

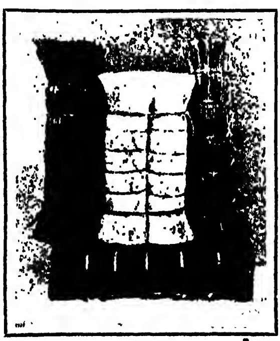
By J. C. VINCENT

THE all but infinite variety of brushes, each in its own way fulfilling the object of its being, performing a great variety of services, entitle this commodity to be called "legion." Brushes for the teeth, hands, hair, clothes, etc., are not luxuries, but necessities, and ourselves, our clothes, our houses, our cities, would not only be unsightly, but positively unhealthy, but for the friendly offices of the brush.

The materials used in brushmaking are as varied as brushes themselves. For the handles we use silver, pearl, tortoiseshell, ivory, horn, bone, various woods, and the quill or "stem part" of feathers, according to taste in some instances, in others to utility. For the brush, the important part, both animal and vegetable substances are used.

Fibres Used in Brushmaking. The least valuable are the vegetable products, known under the general term of fibre [1]. This includes *piassava*, known in the brush world as *bass*—a stiff chocolate-coloured weed which forms a kind of long, tangled undergrowth. The best of this comes from Bahia in Brazil. It is also exported from Para in the same country, while a less valuable quality is found in the forests of Central Africa. In its countries of origin, piassava is used for rope-making, but we shall recognise it best in the scavenger brooms of our borough councils and stables. The illustration [2] shows on the right the bass in length and in the rough state of importation; this is very often 6 ft. long. The three bundles on the left have been dressed, and cut to the lengths required for use.

Whisk is another important fibre. This has somewhat the appearance of straw, but is much stronger. It grows in Italy, the United States, and Canada. Two kinds of whisk are the Italian sorgho, or rice root, and the chiendent, or dandy whisk. The various kinds are used for making carpet brooms, furniture and clothes brushes, and the dandy brush for stable use.



1. FIBRE MIXTURES

Mexican fibres is the name given to those white and grey vegetable products which are used for making lime brushes, nail, bath, and other brushes used in water, and also for mixing with the hair and lowering the prices of baluster brushes and broomheads. This is the fibre of the Mexican aloe (*Agave rigida*).

Coconut fibre is also used in brushmaking, but only in very common brooms, clothes, carpet and a few other kinds of brushware. The illustration [1] of fibres shows the appearance after they have been dressed, and tied up with many strings in order to facilitate cutting to the required lengths with a block knife or guillotine.

Hairs for Brushes. Different brushes are made of different hairs, and the number of animals which lose their coats (to say nothing of their lives) in supplying these is very large. Among them are the horse, goat, bear, badger, beaver, mink, marten, sable, skunk, squirrel, kolinsky, and last, but most important, the hog.

Horsehair is used in making the lower-priced "all hair" brooms, scrubbing brushes, etc., and for adulterating the bristles of paint-brushes.

Badger hair is used principally in the manufacture of shaving-brushes. The best hair grows along the middle of the back, the least valuable on the underside and flanks. The Russian skins produce the shortest, and the German skins the longest hair. The value of badger hair lies not only in the length, but also in the colour. The value increases with the whiteness of the tip and the blackness of the rim of colour just below the tip. After the hair has been removed from the badger skins and the wool combed out, it is tied up in little tufts or knots and immersed in hot water to remove the grease and dirt. The knots are then tied up, each in a separate roll of paper, the whole resembling a boy's kite-tail. The hair is straightened in the subsequent process of drying in a hot room.

Artists' Brush Hairs. The other hairs (the most important of which are sable, kolinsky, and squirrel) are used for artists' brushes. The *sable* and *kolinsky* are indigenous to Siberia, and it is in the tails alone that brushmakers are interested. The finished brush in each case is known as sable, but brown sable is alone rightly so-called. Red sable is the hair of the Siberian pole-cat (kolinsky). Sable tails are imported by the "timbre," or bundle of forty tails. To cleanse, they are separated and placed in a bag of bran, with the mouth tied, and an operation performed similar to kneading dough. The same process is carried out in cleansing squirrel tails. The article known to the brushmaker as *camel hair* is the product, not of the camel's body, but of the squirrel's tail. The wool, fur, or hair of the camel is quite useless in brushmaking.

Brush Bristles. Many persons confound hair and bristles and regard the two terms as interchangeable. But while it is true that all bristle is hair, all hair is not bristle. Bristle is the hair of the pig, not the pork-producer of our farms, but his cousin, the "bristle producer," who lives a freer, and therefore more valuable, life in the forests of Germany and the wilds of Russia. The value of the bristle producer increases as his distance in relationship from the farmyard hog increases; the more northerly his habitation, the longer and thicker his coat. The bristles are marketed in Russia at St. Petersburg and in Germany at Leipzig. At the latter place bristles form the staple commodity during the earlier days of the great Easter Fair.

The bristles arrive in England in immense variety, and an important part of a brushmaker's business is to blend and sort and dress them to the required length, stiffness, and colour for the kind of brush to be made. The hairs are sorted

on a bench fitted with a series of "engines," or steel combs, the teeth of which are graded so as to separate from the handful the bristles of the various stiffnesses. The bundles of bristles, however, contain various lengths as well as various stiffnesses, and the sorting into lengths is known as "dragging."

Bristle Dressing. A handful of mixed bristles is stood up against a "size-stick," or measure, marked with inches and parts of inches. Then the bunch is held in the left hand, and, with the right finger and thumb, bristles above the indicated length are gently pulled from the handful.

These processes are called "beating down on the root" and "dragging," and are repeated until the residue is as solid or "even" as requisite. The handful, now only, perhaps, half the original size, is at the bottom of a series of lengths, graded in quarter inches—say, from 3 in. to 6 in. or even 7 in.

Washing the bristles is another very important process. Tubs with vent pegs in the bottoms (to enable the water to be run off readily) are lined with bristles, layer on layer; soap is then chipped into the tubs, and boiling water poured on. We now take a handful of bristles from the tub, and, after well soaping a flat stone about 18 in. square, rub, or "grind" the bristles on its surface [4]. This looks easy, but the easiness of washing bristles comes only by experience. Notice, in passing, the curve on the bristle. This is seen in the unwashed bundles and in the washed handfuls, but is most pronounced in the layers on the rack which are ready for the drying-room. This curve is known technically as "the bend," and it plays a most important part in the brushmaker's handicraft, especially in that section devoted to painting brushes.

2. BASS DRESSING

Bleaching Bristles. The bristle is now ready for bleaching, where this is necessary. It should be noted, however, that this only gives tone to and increases the whiteness of the bristle. It is impossible by bleaching to turn black or grey bristles white. The bleach in general use among brushmakers is the fumes of sulphur. To bleach bristle we lay it out on a rack, which slides into a groove in the bleach-house, the arrangement being a series of racks in this place which resembles somewhat the series of racks in which a printer keeps his founts of type. All ventilators of the bleach-house are closed, and an iron crucible is placed on the floor. A piece of iron, which has been made red hot, is placed in the crucible, and sticks of sulphur thrown in with it. The door (which, of course, fits tightly) is shut and the sulphur fumes do the rest.

Classes of Brushware. Brushmaking is divisible into four classes—drawn work, set work, painters' brushes, and machine work.

In the drawn work class are grouped scrubbing, nail, cloth, hair and tooth brushes. We may take the tooth-brush as a good representative of the class. The bones are first "cropped"—that is, have the large ends sawn off, and slit lengthwise into several pieces. Each of these is then "profiled," or cut roughly to the shape for which each piece of bone is best adapted. Next they are "fashioned" to the perfect shape, and holes are bored in the head to take the bristle. The boring of tooth-brushes differs from most other kinds in that the holes are not bored quite through the stock or handle. They are then turned over and cut, or "graved," at the back with a fine circular saw in three, four, or five lines according to the number of rows of holes in the face.

The common mode of drawing brushes is shown in the illustration [8], although this is by foot power as well as by hand power. The stock is held in a vice, and a loop of wire or other material is pushed through from the back. Now we take a pinch of bristle, half the size of the hole to be filled, pass it half way through the loop, and, while holding it in position with the left hand, pull the wire with the right. The effect is to force it into the hole by bending the bristle in half, and the first knot will be completed. Now we double the wire again and the loop is formed in readiness to repeat the operation, until all the holes are filled.

The tooth-brush has now to be filled in at the back with white, blue, or red wax, the latter being the most generally used. The finishing of wood brushes, such as those for the hair and clothes, is necessarily different. When we have filled the stock, the brush is open at the back, revealing quite a maze of wire. We must well glue this side of the board, and place upon it the back of rosewood, satinwood, etc. These are then clamped tightly together with wooden screws and put by until the glue has quite set. It will then be possible with spokeshave, bow-saw, and glasspaper, to complete the shape and finish the brush [7]. Finally, the back of the brush is polished.

Trepanning Brushes. Another mode of brush drawing is known as *trepanning*. For this purpose the boards are bored in a similar manner to the tooth-brush stocks, but instead of graving the backs with a circular saw they are "long-holed." In this case, the holes comprising each row are connected inside the back by a hole bored through from the front of the head. A double thread is now passed down the "long-hole" on a needle or bodkin, and pulled out of the end hole of a series, or row, on the face of the stock. The loop thus formed is now ready for the reception of the tuft of bristle, which is drawn into the hole by pulling the ends of the thread.

This operation is repeated till all the holes in each row are filled. The long-hole is now pegged up, preferably with a sharp point of ivory, and the brush is ready for finishing and polishing. The system of trepanning brushes is very largely used in France, but the practice has grown very considerably in England during the last few years, and the firm of G. B. Kent & Sons—to whom we are indebted for the illustrations used in this article—have found it necessary during the past year to increase very considerably the number of employes engaged in this department of brush drawing.

3. BROOM-MAKING

Pan work derives its name from the "pan" round which the makers of this class of brushware sit. It is filled with pitch, kept fluid by the heat of a gas-ring beneath it. The illustration [3] shows the process observed. The stock, or wood part of the brush, is bored with holes of the required size and number. These, however, are not bored right through, but sufficiently deep to take enough material to make the brush effective and the knots secure. Again, all the holes are not bored upright. In boring some of the holes, the stock is held so that the drills enter at a slight angle, in order to effect the "spread" of the bristle, so much desired in the finished article. Notice the ball of whiting on the bench. This is rubbed on the hands to prevent the pitch from sticking to them.

4. WASHING BRISTLES

We now take the material of which the broom is to be made, and select enough to fill a hole; dip it into the pan (the root end, of course), and after scraping off the superfluous pitch, bind it round tightly with a piece of hemp or yarn Again dip into the pan, and, with a turn of the wrist, push the knot into the hole and the thing is done. The man on the left has the knot ready for the hole; the next man is binding a thread round the dipped roots of the knot, while the other workmen are setting the knots in the stocks of a broom and a baluster respectively. It is obvious that the ability to select just the right amount of material to fill the hole is the mark of the accomplished pan-hand. If too much be selected, waste ensues; while the broom is insecure if an insufficient amount be taken.

The most effective hair broom is made of pure bristles; it not only sweeps cleaner, but entails less labour, and for durability will outlast two of inferior quality. The best stable or scavenger broom is made of pure Bahia piassava, with which there is a pliancy and spring far surpassing that of African bass, though a very good broom can be made with 50 per cent. each of Bahia and of African bass.

Painting Brushes. These fall into two main divisions—those for artists and those for painters and decorators. Artists' brushes comprise those of camel hair and sable, and also many made with bristle. Painting brushes comprise such well-known varieties as sash tools, ground brushes, and stock brushes, either one knot, or compound. There are, of course, many other varieties, but they are, in general, only modifications of these.

In making the pencils for artists, we must use quills of various feathers. The sizes are known neither in numerical nor alphabetical sequence, but by name, from the smallest to the largest—lark, crow, duck, goose, swan, and for special purposes, even eagle and pelican. The quill cannot be manipulated in its native state, but by boiling it becomes soft, and the ends can be cut off without splitting the quill. We now remove the "pith" from the inside and place the cleaned quills in a basin of cold water, which keeps them quite soft and pliable, ready for use.

Artists' Pencils. A small bunch of hair from the tail of the sable, marten, kolinsky, or squirrel, is taken hold of at the point, or end opposite to the root, and by passing a comb (a metal one for preference) through it, the "flue," or wool, which surrounds the roots and grows close to the skin of the animals, is removed.

This hair cannot be handled as bristles are, because it is too fine. To get it quite even, it is divided into small bundles, and each bunch encircled with a cardboard tube. When we have about a hundred of these tubes—all standing on end with the roots uppermost—we take a piece of leather, about 5 in. wide, and long enough to encircle the whole, and strap it round them fairly tightly. The technical name for this is the "beater." If we now lift the beater the bottom will present the appearance of a round honeycomb, with cells rather large and circular in shape.

Great care must be exercised here, or the whole will shoot out, and much labour and time will be expended in gathering up the contents and getting them straight again. We now gently lift the beater about ½ in. from the bench, and just as gently drop it down again, holding it with both hands all the time. Repeat this operation smoothly and quickly, making a continual tapping noise, and, sooner or later, all the hair will have become quite "solid," or even, and ready for use.

We now take a "pinch" of hair—regulating the quantity according to the quill to be used—and tie the root tightly with hemp, covering this with coloured silk; wet the flag to keep it together and

5. MAKING PAINT-BRUSHES

bring it to a point, and insert it into the quill at the large end. A piece of wire of suitable thickness, known as a "driver," is now used to push the knot to the other end of the quill. The whole is put to dry, and the brush is made, the drying, and, therefore, hardening of the quill, affording an extra security to the knot.

Sable and Hog Hair Brushes. The best hair for artists' pencils is that of the kolinsky, known as "red" sable and "brown" sable, or sable proper. Sable is becoming so scarce and valuable, and therefore so expensive, that various martens and the mink have taken its place with many brushmakers. Sable hair is worth more per ounce than camel hair is per pound; moreover the former works to a much finer point, and has much more spring and durability.

Hog-hair artists' brushes, to be effective, must possess a good "dome," and the learner must remember that this must be produced without the aid of scissors, for if we trim the brush to a dome with these, we destroy the flag or split end of the bristle, and render the brush unsuitable and ineffective so far as "fine" or artists' work is concerned. A tool called a "canon" is used here. Its shape resembles a large thimble, with the sides straight, instead of converging; the head is shaped to the required dome and the tuft of bristle is placed in this, flag downwards. Now, while the left hand keeps the bristle in position, with the right we give the canon a succession of even taps on the bench, the result being that, when the tuft is removed, it has taken on the shape of the canon.

7. FINISHING HAIR-BRUSHES

Making Painters' Brushes. In dealing with the washing of bristles, attention was called to the "bend." It is most important for the painting-brush maker to keep the bend of the bristle one way, so that as the bunch is on the bench, it presents the appearance of a concave line [see the bristle on the drying rack—4]. The *sine quâ non* in making a paint-brush knot is to tie it together so that the bend of all the bristles faces inwards, and the flags, while not interlocking, form concentric rings.

The sash tool is a good representative of the single-knot paint-brushes. It is generally made on a "forked" or pronged handle, though sometimes the

8. DRAWING MACHINE

6. FINISHING SCRUBBING BRUSHES

handle is bored at the end, making a socket in which to insert the bristles. The knot is dipped in cement (generally made of resin and linseed oil). It is then placed between the forks of the handle and bound tightly round with string. The knots which are to be cemented are kept on a hot-plate to facilitate the penetration of the cement.

Another system of paint-brush making is known as tied work. The workman to the right in the illustration [5] is seen making a compound stock brush. The knot in this instance is divided in the middle, so as to fit on to the handle. It is then tied with copper wire to keep it in position. Though the majority of stock brushes have two knots only, there is quite a large number made with three and four knots, and some even with five.

The driven brush is another form. The knot in this case is pulled into a socket or binding. Sometimes this is a plain band of metal, at others it is made of copper or iron wire, or, again, of string. These bindings are made taper, or smaller at the top than they are at the bottom. After the cemented knot has been pulled into the binding, the handle is pushed through the centre of the brush and driven home with the pointed head of a hammer made for the purpose. The workman on the left of the illustration [5] is seen driving the handle home, the block at which he is working having a series of holes, varying in size, to admit the handle, and at the same time to give a solid bed on which the head of the brush can rest while the handle is driven home.

Grinding and Pointing. After the brushes have been made, certain of them—known as ground brushes—are ground on a stone in a way similar to that described in connection with washing the bristles. Before the brushes are taken to the drying-room they are pointed—that is, a piece of hemp is bound round the bristles in such a way as to keep them in shape. This is put on rather loosely, and great care must be exercised, in order that the brush shall dry in a presentable condition. It is very easy when pointing a brush to completely alter the set of the bristles, and therefore to render it less effective than it should be. An exception to the general rule of "turning in" the bend of painters' brushes occurs in making the painters' duster. In this, the flag of the bristle is made to turn to the circumference of the brush.

Testing Adulterated Brushes. In the manufacture of painting brushes, the brush made with pure bristles only, although the most expensive in initial outlay, is cheapest in the end. The pure bristle brush enables the workman to put the paint on evenly and effectively, while for wear and tear it will outlast several made from a mixture of bristle and horsehair. It is often difficult for a journeyman brushmaker to decide whether a painting brush is adulterated with horsehair, and therefore to the tyro it is well nigh impossible, except in those cases where adulteration is flagrant. One test is the existence of the flag (split end) in bristles, and its non-existence in horsehair. Another test is the greater flexibility and spring in bristle than in hair, and a further difference is that bristle tapers from root to flag, while horsehair is uniform in size all the way up. But the infallible, and therefore the best, test of all is to take a magnifying glass, when it will be observed that while the horsehair is cylindrical in section, the bristle is elliptical.

9. BONING AND FILLING MACHINE FOR TOOTH-BRUSHES

There are two tests to distinguish fibre from hair. One is to bend a piece of each, when the fibre, lacking the elasticity of hair or bristle, will have a tendency to crack, while the animal product will assume its previous position, none the worse for the operation. The other test is to set fire to a piece of each, when the fibre will burn quite readily, while the bristle will only splutter and curl.

The Care of Painters' Brushes. As these are so valuable, it behoves us to be careful in the manner of keeping them when not in use. A varnish brush must, on no account, be soaked in water, because this will destroy the cement used in manufacture, and thus render the brush unsound. For the same reason, a paint-brush should never be soaked in turpentine. A varnish brush may be kept in oil when not in use, and a paint-brush, after having been cleansed in turpentine, may be kept in water. On no account should a brush be allowed to rest on the bottom of a paint kettle. If brushes are allowed to rest on their bristles, the latter become twisted and quite unfit for effective work. A brush should be suspended from a hook on the side of the kettle. Sometimes a brush is put on one side uncleaned, and consequently it becomes quite hard. It can be rendered usable again by soaking it in linseed oil, but prevention is better than cure. New paint or distemper brushes should always be soaked in water before they are put into use.

10. FILLING NAIL-BRUSH BOARDS WITH FIBRE

Brushmaking by Machinery. The simplest of the machine-made brushes are flue and bottle brushes. They are made by taking a double length of wire and inserting the ends in a vice. The doubled end or loop is now put on a hook, fitted with a handle. We now take the weight of bristle allowed, and distribute it as a thin and even layer between the double wire at the end nearest the vice. Turn the handle, which, twisting the wire together, will give the spiral form distinctive of this class of brushware. There are, however, machines very much more complicated than this, and while we cannot go into the intricate mechanical questions involved, we would draw attention to one illustrated [10]. This shows the operator filling nail-brush boards with fibre by a principle known as "punching." The modus operandi is to drive a knot into the hole, and at the same time to "anchor" it into position with a metal clip arrangement. One may best liken it to a double-pointed staple. The punching not only forces it into the board, but opens the clip inside the brush, and thus secures the knot in position. In the hand-drawn brush the knots in each row are drawn (and therefore connected together) on a continuous wire; in the machine-punched brush each knot is isolated, and therefore self-contained. Dandy brushes for stable use are very frequently made on the "punched" principle, and so, too, are many forms of scrubbing brushes.

Bevelling and finishing scrubbing brushes by machinery has to-day been reduced to a fine art, and at the Hertfordshire factories of G. B. Kent & Sons gresses of these brushes are finished in the time that would be taken to finish dozens by hand labour. When we say finished, we do not mean made to shape only, but produced as eminently marketable commodities [6]. Another engineering triumph may be seen at the same factories. This is so remarkable that if it were possible for a mediæval brushmaker to visit again "the plane of his former triumphs," he would not only say that the machine was living and functional, but that it was endowed with reason. A bone handle is placed on the carrier, and the holes are bored evenly and regularly. Just the right quantity of bristle is picked out and wired to the stock, and the brush is made in a few seconds [9].

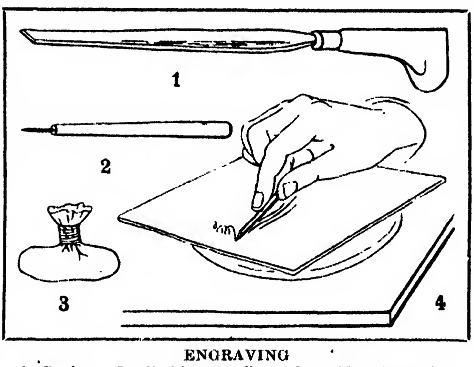
ACID AND LINE ENGRAVING

Copper-plate Etching and Dry-Point. Etching in Tones. The Old and Beautiful Art of Line Engraving and its Masters. Prints in Colour

By EDWARD F. STRANGE

AN etching is a print taken by the method known as "copper-plate printing" direct from a metal plate on which lines have been bitten by an acid or other mordant. The plate may be of any metal; but iron, steel, zinc or copper have generally been used by artists; and the latter so greatly exceeds the others in suitability that it is almost invariably chosen. Zinc, however, has certain qualities of its own, producing a strong, rich line which is excellent for broad effects. Its treatment in no way differs from that required by copper, and the description of the process which follows applies to both metals.

Preparing the Plate. The plate used should be of good and even quality and its upper surface given a fine polish—circular. Such plates can be purchased ready for use. The polished surface must be overlaid with a ground, composed, as a rule, of beeswax, asphaltum, Burgundy pitch, and gum-mastic in varying proportions; but equal parts of each may be taken as a good formula for general use. The ground may be applied: (1) hot, by means of a dabber; (2) cold, as a paste dissolved in oil of lavender, by means of a roller; (3) as a solution in chloroform poured over the plate. The dabber [3] is made of horsehair, enclosed in cotton-wool, with an outside covering of silk or kid; and it is advisable to keep the stock of ground in a silk wrapper to prevent grit from getting into it. The grounded plate should next be smoked to a perfectly even blackness, by being clamped in a hand vice and moved to and fro over the flame of a bundle of wax tapers.



ENGRAVING
1. Burin 2. Etching needle 3. Dabber for laying etching ground 4. Engraving on metal

The subject of an etching is drawn in line alone, the tool used being of steel, and called a needle [2]. This usually has a fine point and need not be otherwise, for though some etchers have employed a blunt tool for making broad lines, a better result is obtained by relying on the action of the acid for this purpose. The drawing may be made direct on the ground, in fine lines of uniform thickness, with pressure just sufficient to penetrate the ground but not to cut the copper; or, if desired, it may be transferred, either from a lead-pencil sketch made on thin paper, damped, laid upon the ground, and then passed through the press with a little less than ordinary printing pressure; or, again, it may be scratched upon gelatine with a needle, red chalk or some other pigment rubbed into the lines, and the transfer made in the press, as above, or by rubbing the back of the gelatine with a burnisher. In this case the gelatine should not be damped. When the drawing is finished, the back of the plate must be varnished with Brunswick black, to protect it against the action of the acid.

The Etching Bath. The drawing having been thus put upon the plate, the next step is that of subjecting it to the action of an acid bath which performs the function of etching—or eating out in the copper—the lines drawn with the needle. It need scarcely be pointed out that on the success of this delicate operation depends the whole merit of the final result, no matter how good may have been the original design. The bath is of porcelain, sufficiently large to enable the plate to lie conveniently within it, and shallow enough for the upper surface of the copper to be easily accessible. Various liquids—mordants—are used for biting-in at the discretion of the artist, who may, however, be advised to confine his attention at first to one only of the following, in order that he may become thoroughly well acquainted with its qualities and arrange the successive stages of the operation with certainty.

(1) *Nitric Bath.* Nitric acid, of specific gravity 1·42, and water in proportions varying from equal parts of each to $\frac{1}{3}$ of acid and $\frac{2}{3}$ of water, for copper. For zinc or steel much less acid should be used. Nitrous may be substituted for nitric acid.

(2) *Dutch Bath.* Hydrochloric acid, 10 parts; chlorate of potash, 2 parts; water, 88 parts.

(3) *Perchloride of Iron Bath.* A 40° Beaumé solution of perchloride of iron in water.

The plate is now immersed in the bath, and in the course of a few minutes the bright lines of the drawing will be seen to cloud over with minute bubbles of gas, produced by the action of the acid upon the metal. If the plate be removed from the bath, and the ground cleaned away with turpentine, it will be seen that every line drawn with the needle has been faintly eaten into the plate. If a proof be taken at this stage, the whole drawing will appear in fine lines such as are required for the lightest portion only of the print. Those portions which are destined to remain in this state must be covered again with ground. Stopping out, as this is called, is effected by a careful use of the dabber, leaving exposed all those parts which require strengthening. The plate is immersed again in the acid, and the whole operation repeated as often as necessary, until the proof shows a gradation, as nearly as possible perfect, from lines almost as fine as the needle-point itself to the deep

blackness which gives an etching its peculiar richness of effect. In the course of this proceeding it may be found, that the whole design is too light.

Re-biting and Retouching. To darken the design "re-biting" is necessary. The dabber cannot conveniently be used, as it is difficult with it to keep the ground out of the already bitten lines. The difficulty is overcome in the following manner. Some ground is laid thinly and evenly on a piece of plate glass, and a roller alternately passed over this and over the plate, until the latter bears a sufficient ground. This should be done with the plates cold, until the operation is completed, when the oil of lavender can be driven off the copper by a gentle application of heat until the plate shines and the ground becomes hard. In carrying out this operation, the nature of the line made on the copper by the mordant must be borne in mind. This is not V-shaped, but, in section, somewhat wider at the base than on the surface of the plate, the edges being undercut to some extent by the acid. Advantage may be taken of this quality when the lines are over-bitten and print too dark; for, with a burnisher used with oil, their edges may be squeezed together and so made to hold less ink and print lighter. Additional work may, at any stage, be put on the plate with the needle, after re-grounding, and a local effect can be produced by applying the acid with a feather instead of placing the whole plate in the bath.

5. FROM A LINE ENGRAVING BY B. P. GIBBON, AFTER A. COOPER, R.A. (Working proof from unfinished plate)

Ink Distribution. The plate should now be ready for printing, which is done in a copperplate printing-press, exerting such pressure as to drive the paper into every depression in the copper, and extract the ink therefrom. The ink used is made from any pigment with sufficient body, ground rather stiffly with burnt linseed oil; umbers or ochres being preferred for colour, and Frankfort black, heavy French black, or a lighter black, made from the smoke of burning paraffin oil, for the blacks. The two former are used for giving "body" to the ink, and the latter for blending to obtain special qualities of printing. A great deal depends on the printing of an etching. If the plate is cleaned as bright as possible, by means of the palm of the hand charged with ink and whiting, only the bare lines show, as in a visiting-card. But it is perfectly legitimate and very valuable to arrange the ink on the plate in such a manner as to get much richer effects. In such a case, the ink is again worked with the palm of the hand, but with a gentler pressure so as to leave more of it on the plate outside the lines.

A further effect may be obtained by *retroussage*, the dragging of the ink into desired directions with a piece of soft muslin, which is lightly drawn over the heated plate along the lines, following the hand and bringing a portion of the ink over the edges of the lines. This process softens them and makes them print darker than would otherwise happen. By careful arrangement of the ink in these ways, a considerable amount of tone may be produced, but the process has to be repeated, necessarily, for each print. The plate must be kept warm over a "heater" in order to soften the ink, which is first applied thickly with a dabber; the surplus ink is then removed with a pad, and the final arrangement of it given with the palm of the hand as just stated. The paper should be of good quality—old hand-made rag paper is the best—and both soft and tough. It is used damp. At every stage of etching, the temperature must be taken into account. The student should study carefully the etchings of Rembrandt, Vandyck, Hollar, Méryon [7], Whistler (the "Thames Set" in particular), and Sir Francis Seymour Haden, P.R.E.

6. WINDSOR FROM ETON (From an aquatint by Paul Sandby, 1777)

In the soft-ground etching process, ordinary etching ground is used, mixed with half its weight of lard or tallow. The ground is laid and smoked, as already described. When cold, a sheet of thin paper is strained over it, and upon this the drawing is made with a lead-pencil, which causes the ground to adhere to the paper in a broken line, depending upon the grain of the paper, the hardness of the pencil, and the pressure used. The plate is then bitten and printed in the same manner as an ordinary etching, the result being a singularly faithful reproduction of a pencil line. Some good examples of this method can be seen in

the work of Samuel Prout, but, at the present time, it has almost ceased to be practised.

Dry-point. A form of engraving which is usually classed with etching is produced by ploughing up the copper with a steel or diamond point in such a manner as to leave the upturned metal in a ragged edge or " burr " on the side of a furrow. For this purpose the tool is sharpened to an obtuse angle. No acid is used, the burr holding most of the ink which gives the printing quality to the plate; if the latter were removed, the line would print sharp and clean. Dry-point is sometimes used alone, but more often as a means of finishing an ordinary etching, it being capable of an effect of great richness of black. The plate worked in this manner is only capable of comparatively few impressions, as the pressure of printing soon flattens out and destroys the burr.

Etching Limited to Pure Line. In all the processes of etching it should be remembered by the beginner that he is dealing with pure line, and that, within this limit, the art registers the precise work of the artist. In a reproduction of a picture the aim should be to express in line the intention of the painter, and not to imitate the texture of paint. In the selection of a subject, one lending itself to a bold or graceful arrangement of line rather than of mass, or tone, will always be more satisfactory, and the merit of an etching lies more often in what is omitted, but still suggested, rather than in an extreme of finish. If the right hint is given by the etcher, the eye of the beholder cannot fail to fill in the scheme offered to him with absolute certainty and rare pleasure. The mistake must never be made of confusing an etching with a pen-drawing.

7. LA POMPE NOTRE DAME, 1852
(From an etching by C. Méryon)

Aquatint Etching. This is a method of etching which resembles that already described, so far as it is the result of biting-in a drawing upon copper with acid, and when once the plate is prepared, it exactly resembles it in the process of printing. But the essential difference between this class of print and etchings lies in the fact that in pure aquatint there are no lines. Everything is expressed in tones, as in a wash drawing, of which, indeed, it may be considered the engraved equivalent, as etching is that of pen drawing. This being so, there is no use for needle or graver. The biting-in is done by washes of acid applied with a brush, on a ground having certain necessary characteristics. And the preparation of this ground is, therefore, the first thing to be considered.

The principle underlying the various ways of obtaining an aquatint ground will easily be understood when it is remembered that the smooth surface of an unused plate will not hold ink for printing. It must be roughened in some way. To begin with, therefore, we require, for the purpose of painting acid on the plate, an even printing surface all over it. This is obtained by breaking up the surface into minute dots or reticula- and can be effected by several methods of laying a preliminary ground, followed by acid biting.

Grounding the Plate. In one case, an ordinary etching ground is first laid upon the plate, which is then heated till the ground becomes soft. Upon this finely powdered salt is next sprinkled evenly. The salt sinks through the soft ground, until it reaches the copper. The ground is then allowed to become cold and hard again, when the salt can be dissolved out with water, leaving the ground pitted minutely wherever it rested. If the plate is now bitten in the acid bath, each of these pittings will produce a black dot. Another method, conveniently known as sand-ground aquatint, is to cover the hard ground with sand, or, better, with emery paper, and pass the plate two or three times through a printing press.

But more convenient than these are the processes known as the " resinous dust ground," and the " spirit ground." In the former, finely powdered resin or asphaltum is placed in a box, which is then shaken rapidly or revolved until a smother of the dust is produced inside. The plate is then inserted at the bottom of the box—and allowed to remain until the dust has settled in an even layer on its upper surface. It is carefully withdrawn, and heated gently, but not enough to melt the dust, a proportion of which will be found to adhere to the plate. The superfluous dust is blown away, and the plate, if bitten, will show a covering of infinitesimal white dots where the particles of resin or asphaltum adhering to it have protected its surface against the action of the acid. This method gives good results, but requires careful manipulation and a specially-made box, with an aperture and door for the insertion of the plate.

The most convenient of all ways of making an aquatint ground is by taking advantage of a curious property of resin. This is dissolved in rectified spirit, and flooded evenly over the plate. As it dries, the resin held in solution is again deposited, and contracts into a series of reticulations, each of which, if bitten, will be represented by a fine line where the acid has penetrated the " crackle " of the resin. The granulations produced will become coarser as the proportion of resin used is increased.

The Aquatint Picture and its Limits. In the making of the picture the high lights are first stopped out with Brunswick black. Acid, as already stated, is applied with a brush, each tint being similarly protected as finished, and the whole completed by successive steps in this manner, leaving the deepest shadows to the last. The method of printing is identical with that of an etching. Pure aquatint, as thus described, is by no means capable of a wide range of expression, although, for certain effects of landscape, it has unrivalled qualities. But its flatness of tone limits it to a considerable extent, and many artists have reinforced this by using a preliminary basis of strongly etched lines, put upon the plate before the

aquatint ground was laid. The history of the art begins with Jean Baptiste Leprince about 1750, although earlier suggestions of it are to be found. It was introduced into this country by the Hon. Charles Greville, who communicated it to Paul Sandby, R.A. This artist made the first English aquatint, in 1774, and his work [6], together with that of William Daniell, R.A., J. C. Stadler, R. and D. Havell, and F. C. Lewis, may usefully be referred to by the student. An aquatint plate, it may be noted, has good printing powers, and is capable of producing a large number of impressions without serious deterioration.

Line Engraving. The old and beautiful art of line engraving is now almost entirely abandoned; but its revival always remains possible. The technique of it is quite simple, but it requires a patient skill only attainable by long practice. It is to be remarked, in the first place, that the term "line engraving" is used to denote only engraving upon a metal plate, made with a special instrument—the burin [1]—which may be described as a short steel tool, curved upwards towards the point, square in section, but grooved on each face, and fitted with a knob handle suitable for holding within the palm of the hand. In the ordinary meaning of the words "line engraving," they might be applied to etching, dry point, or woodcuts; but the custom of ages sanctions the above limitation, which is universally accepted.

All the old engravings were made upon plates of copper until the early part of the nineteenth century, when steel was largely substituted for the softer metal, the term "steel engraving" thus coming into vulgar use almost as a synonym for that forming the title of this section. In pure line engraving no tool other than the burin was used. The subject was first lightly sketched upon the plate, and then gradually finished, the practice of most engravers having been to work from light to dark, gradually filling in the shading as the task progressed [5]. The burin was held in the palm of the hand, guided by the finger and thumb, and driven forward against a pad with considerable pressure, cutting a line almost free from burr [4]. But many engravers made use of the process of etching as a convenient means of getting the outlines of their subjects upon the plate, biting-in lightly, and re-working the lines with the burin.

How the Masters of Line Used its Limitations. At a very early period in the history of the art the dot makes its appearance as an adjunct to the pure line, and this is most easily made with a burin having its point curved downwards instead of up. The old masters kept their work open, using simple shading only to express form. Close cross-hatching—that is, lines crossing and re-crossing each other closely at varying angles—was a development due to attempts at realising the tone, and light and shade, of a painting or wash drawing. In this later work, the dot is used to strengthen, or as a substitute for the cross-hatching, instead of being simply a device to secure a softer effect than line was capable of giving.

The great characteristic of burin work is that it produces only a formal line or line and dot, as compared with the unfettered freedom of the etching. It will turn only in a curve, and thus imposes severe limitations on the skill of the engraver. The great masters of line, such as Dürer, Lucas Van Leyden, Mantegna, Marc Antonio, and our own William Rogers, were able to use this characteristic to splendid advantage, and the leaders of the Dutch and French schools—as, for example, Cornelius Visscher, Nanteuil, and the Drevets—while losing much of the intrinsic value of line, quite compensated therefor by the superb modelling and light and shade with which they invested their portraits. After the close of the sixteenth century line engraving was chiefly devoted to the reproduction of paintings; and the student of this class of work should not rest content until he has made himself acquainted with the admirable engravings which were produced in England by the artists associated with J. M. W. Turner, absolutely the finest landscape engraving the world has ever seen. It was usual to take proofs of the plates in various stages of completion. An interesting series of these can be referred to in the collection of prints and drawings in the Victoria and Albert Museum.

Stipple Engraving. This was a method much used in the second half of the eighteenth century. In it the whole of the picture is represented by dots, carefully placed, at wide or close intervals, to express the modelling and light and shade of the design. These dots were generally made with a needle upon a plate covered with an etching ground, and, when bitten in, deepened and finished with the burin. For this purpose, as already remarked, the burin has a downward point. The roulette, a small wheel with toothed surface, and tools consisting of groups of two or more points, were also employed. A combination of cut line and stipple is also frequently met with. A special form of stipple used particularly for the facsimile reproduction of drawings has received the name of "chalk engraving." It was executed partly with soft ground etching and partly with roulettes and punches. The best examples of stipple engraving—which was frequently printed in red or brown—are to be found in the work of F. Bartolozzi, W. W. Ryland, A. Cardon, G. Vendramini, and L. Schiavonetti.

Colour Prints. Mezzotint, aquatint and stipple, and even line engravings, were frequently printed in colours, the inks used being of the same nature as described above, but with the addition of pigment. Too often the use of colours was merely a device to disguise the wearing of the plate, and although a pleasing effect is produced in the best examples, this defect should always be watched for by the collector. The colours were arranged, as required, on the plate for each separate impression, and it is impossible, as a consequence, to find two prints in colour from the same plate, that exactly correspond in the minutest details.

It is fairly easy to detect the extent of handwork which appears on a coloured aquatint or engraving. If it be examined with a lens, the spaces between the engraved dots or lines will appear white in those parts wherein the colour was printed; but where applied by hand, the wash covers everything. Good examples of coloured mezzotint and stipple are to be found in prints by the Wards and J. R. Smith—especially those after Morland; of coloured aquatint by W. Daniell and the Havells; and a good print of pure line engraving, printed entirely in colours, may be referred to—"A Sleeping Venus," by P. W. Tomkins, after Titian. In France and Germany a good deal of attention is now being given to the production of coloured etchings. In these, the method of printing is that already indicated, but it should be borne in mind that the colour is an integral part of the composition from its inception, and the actual etching is subordinated thereto accordingly.

How and Why the Stars Rise and Set. When and Where the Principal Constellations may be Found. The Solar System

By W. E. GARRETT FISHER

ASTRONOMY deals with the celestial bodies, among which the earth is one of the least; it teaches us their physical constitution, and traces the history of their development. It is probably the oldest of the physical sciences. Its foundations were laid when shepherds watched their flocks by night on the plains of Chaldea, and occupied their nocturnal leisure by studying the recurrent march of the stars. As good a way as any to begin the study of this fascinating science is to put oneself in the place, as far as possible, of these earliest astronomers. Those who live in a town, which in our modern civilisation is the lot of the majority, are less favourably placed for this study than those whose life is passed under the clear and open skies of the country; but there are few towns so foggy or so shut in that the diligent student cannot find some point of vantage in his near neighbourhood from which, on a cloudless night, an open view can be obtained of a large part of the sky.

The Motion of the Starry Sphere. After watching the starry heavens for a few consecutive nights during the same hours—say, from nine to twelve—the student will realise, first of all, that there is an apparent revolution of the whole heavens. He will notice that the bright stars, which are scattered irregularly over the whole visible sky, appear to form themselves into certain more or less definite patterns, known as *constellations*, and that these patterns continue to preserve the same relative arrangement from night to night [1]. But careful observation for even so short a time as three hours in a single evening will further show him that the whole starry sphere is in steady motion.

Stars which appear early in the evening low down near the eastern *horizon*, or boundary line of our vision, gradually climb up into the sky, whilst those which were originally sloping towards the west sink further and further down, and ultimately disappear below the western horizon. Their motion is precisely the same as that of the sun, which, as everybody knows, rises in the morning above the eastern horizon, gradually ascends until it has reached its highest point, and is practically due south at noon, and then descends until it sets or sinks again out of sight behind the western horizon.

The Daily Revolution of the Earth. We are familiar with this apparent motion of the sun, but so little accustomed to watch that of the stars through anything like the same space of time, that at first we hardly associate the two. But the first lesson which should be learnt by the watcher of the sky is that the stars behave just like the sun, and pass from the eastern to the western horizon in a space of time which is constant for each of them, though it differs in the case of every individual star. The real meaning of this fact is, of course, that the earth revolves on its own axis once in about twenty-four hours. We who live on its surface are unconscious of the motion which we partake, and consequently are apt to talk of the sun and the stars as if they moved round the earth. This was the theory actually held by all men till the middle of the sixteenth century, and all early systems of astronomy were occupied in accounting for the motion of the stars as if the earth was at rest in the centre of the universe.

The Sidereal Day. After observing the stars for a number of nights—not necessarily consecutive, for a great deal may be learnt by taking a single evening a week for the purpose — the young astronomer will next notice that he has to distinguish between two distinct kinds of heavenly bodies. The great majority of the stars which bedeck the evening sky remain always fixed in the same relative positions to one another. They swing steadily round the earth at such a rate as to complete one revolution in rather less than twenty-four hours. That the period of their revolution does not exactly coincide with the measure of time which we call a day is clear, indeed, from the fact that the configuration of the stars is not the same at the same hour on every night throughout the year, as it would be if this were the case. The stars which at one time are high up in the sky are seen at another low down on the horizon, whilst some of the brightest stars are visible in winter but not in summer. The *sidereal day*, or period during which any particular star completes its revolution and comes back to the same place is about four minutes—exactly 3 minutes 55·91 seconds—shorter than the *solar day*, or interval of time between successive noons. This sidereal day is the rotation-period of the earth. Consequently, any particular star comes back to its place each night rather earlier than on the night before.

For convenience, we measure the apparent motion of the stars from the moment at which they cross the *meridian*, an imaginary great circle which is drawn on the celestial sphere through the pole of the heavens and that point of the horizon which is due south of the observer. If a particular star happens to cross the meridian at ten o'clock on a particular evening, the next night it will cross the meridian about four minutes earlier. The actual difference between the sidereal and the solar day is such that, after a year has elapsed, any star coming to the meridian four minutes earlier every night will then have returned to the place which it occupied a year before at the same hour of the night. In other words, the year contains 365¼ solar, and 366¼ sidereal days. Hence the configuration of the stars as seen at the same instant of time on a particular night in every year is the same; or at least it would be so if there were not other small but long-continued variations to take into account, with which the student need not trouble himself at present.

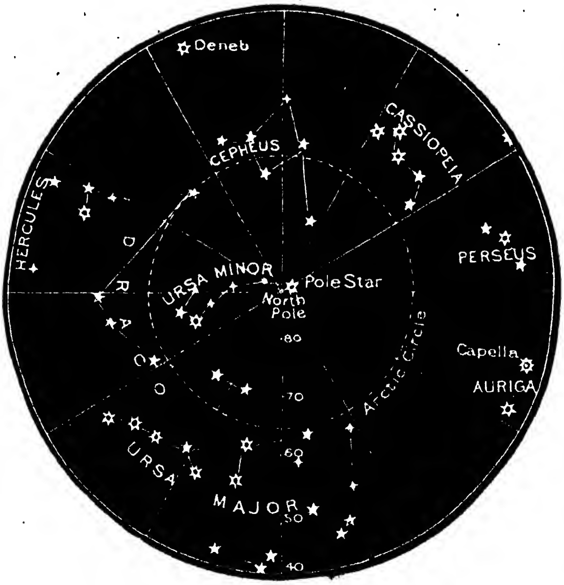
Planets and Other Wanderers. This is the rule with most of the stars visible in the sky. But there are a few exceptions to it. The student will soon find that there are about half-a-dozen stars, and those among the brightest which he can see, which do not obey this otherwise universal law. Instead of returning night after night to the same position, they appear to wander among the other stars, and to occupy positions which differ

considerably at different seasons. These are known as *planets*, or wandering stars. Venus, the brightest of them all, is known to everybody as the Evening Star or the Morning Star, occupying both positions at different times of the year. Jupiter, which is the brightest star in the sky after Venus, is another of the conspicuous planets. Mars, the red planet, is also well known to everybody who watches the night sky. Mercury and Saturn are less familiar, whilst Uranus and Neptune and the minor planets, nearly 600 in number, are never seen without a telescope.

The moon, which is far brighter and larger than any of the stars, also holds a wandering course, both its position and its brightness varying from day to day through the month. Comets and shooting stars, which also appear in the sky, show themselves at apparently quite irregular intervals, though we shall see later that they also are subject to the reign of universal law.

Nightly Motions of the Fixed Stars. We shall now confine ourselves to studying the so-called *fixed stars*, those stars, namely, which preserve the same relative position and configuration from night to night, only varying, and that with perfect regularity, in the times at which they reach the meridian. For this reason they have been known from the dawn of astronomy as fixed stars, in contrast with the planets or wandering stars. The student who watches the nightly changes in the sky with close attention will soon perceive that all these fixed stars appear to move in circles or parts of circles. Some of them describe larger circles than others, and the further south a star is when it passes the meridian, the larger circle will it describe.

If we look north, it will not be long before we satisfy ourselves that the *constellations*, or groups of stars, in that quarter of the sky describe circles which would be complete could we watch them through the twenty-four hours. The brilliant light of the sun blots them out of sight when it is above the horizon, and thus we can only follow them through a part of their diurnal path. But this part is always a segment of a circle, and at different times of the year we can watch them in different parts of the same circle, so that we infer that they actually complete the circle daily in somewhat less than twenty-four hours. They can actually be watched doing this by Arctic travellers in latitudes where the sun remains out of sight, and there is perpetual night, for several months at a time.



1. CIRCUMPOLAR CONSTELLATIONS

The Pole Star. There is one star, however, which appears to the naked eye never to move at all. This is known as the Pole Star, and the first aim of the student should be to discover it for himself. It lies due north, and its height above the horizon is always equal to the latitude of the observer's position. Thus, at the North Pole, the Pole Star would appear to be directly overhead, or in the *zenith*; at the Equator, it would be exactly on the horizon, though practically it would always be invisible; to a London observer, it appears to hang at an altitude of a little more than 51°. If the student will now procure a small model of the terrestrial globe, he will speedily perceive the meaning of this fact observed about the Pole Star.

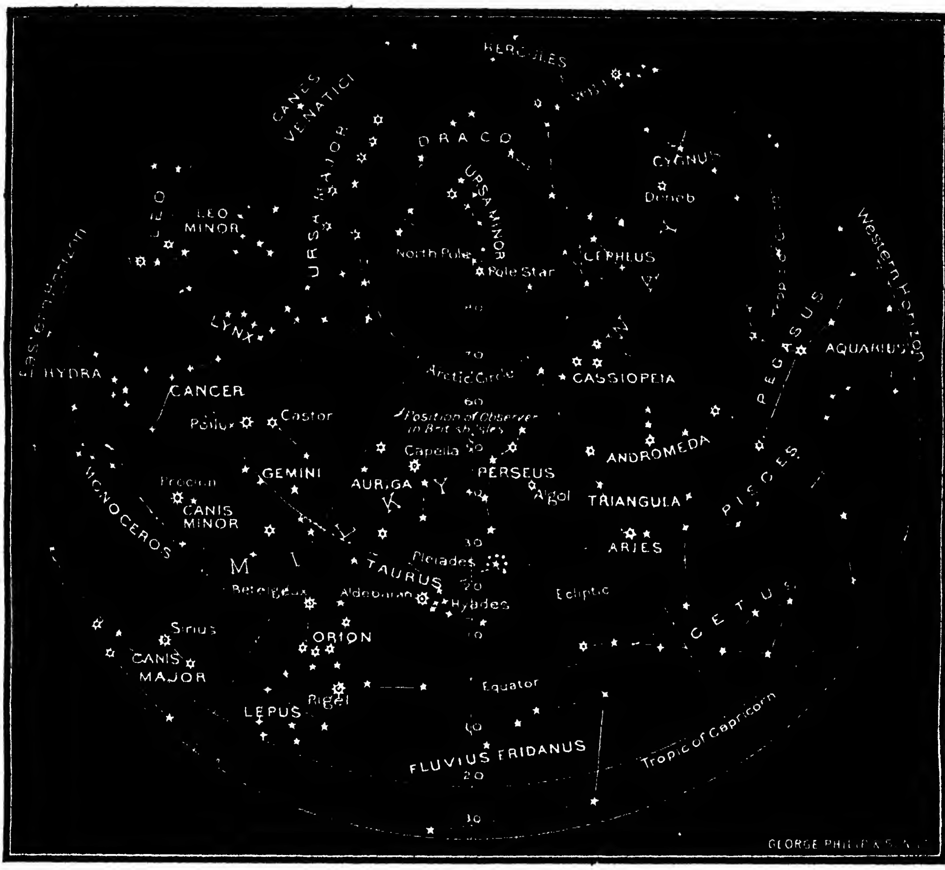
The Celestial Poles. The *poles* of the earth are the points at which its imaginary axis emerges, and when prolonged indefinitely this axis cuts the imaginary sphere of the heavens in two points, which are known respectively as the *north* and *south celestial poles*. If we now cause our model globe to rotate, keeping the axis pointing in the same direction, a little thought will make it clear that, to an observer on its surface, the stars, which are supposed for convenience to be fixed on the surface of an exterior globe, will all appear to describe circles round these celestial poles. These circles will vary in size with the star's distance from the pole; and if one of these stars happens to occupy a position corresponding to a celestial pole, it will appear to remain stationary to the terrestrial observer.

That is the case with the Pole Star, which, indeed, is not absolutely coincident with the celestial North Pole, but is so near to it that the tiny circle which it describes in its motion can be measured only with the aid of a telescope. To the naked eye it appears to remain motionless night after night, and thus provides us with a simple method of ascertaining the true North, as well as fixing the centre round which all the other stars appear to revolve.

It cannot be too often repeated that this motion of the stars is only *apparent*, being due to the *real* rotation of the earth, along with the observer on its surface, in the contrary direction.

There are about three thousand stars visible to the naked eye in our latitude, though not all these are visible at the same time, many of them being below the horizon whilst others are elevated in the sky at different times and seasons.

From a very early period they have been mapped out for convenience into definite figures, or *constellations*, to which more or less fanciful names have been adapted. The student must familiarise himself with the general names of these constellations, which he can easily do with the aid of any good star atlas, many of which are now published. Messrs. Philip's planispheres may be specially recommended. It is frequently by no means easy to recognise why these constellations have received their individual names, which often involve a great



2. CONSTELLATIONS VISIBLE IN AUTUMN

deal of imagination on the part of the observer. Most of them have come down to us from the earliest times when astronomy was studied in the valley of the Euphrates.

The Circumpolar Constellations. We shall begin by describing the *circumpolar* constellations, which are nearest to the Pole Star, and which never set in our latitude. In other words, they are visible at all times of the night and at all seasons of the year, though in different months they occupy different positions.

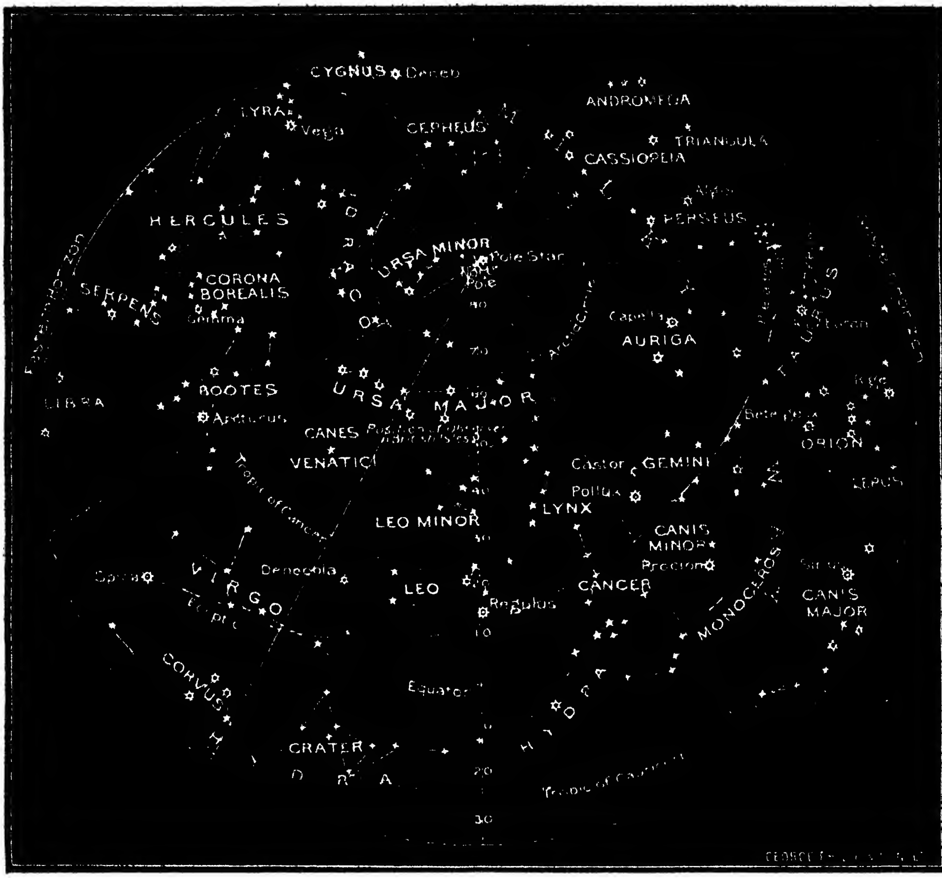
The most famous and familiar of these constellations is the Great Bear, which is also known as the Plough or Charles's Wain. It consists of seven bright stars arranged in the shape of a saucepan with a bent handle, from which our Transatlantic cousins have given it the more comprehensible name of the Dipper—American for saucepan. The two stars which form the side of the saucepan farthest away from the handle are known as the Pointers, because they furnish a ready means of finding the Pole Star, which lies in a straight line with them. On the opposite side of the Pole Star, and about equally distant from it, can be seen the constellation of Cassiopeia, shaped like a very irregular W. If we imagine a circle drawn round the Pole Star, passing through the Great Bear and Cassiopeia, and divide its circumference into four parts, we shall find two other conspicuous constellations occupying the two remaining quadrants. These are Auriga, or the Charioteer, and Lyra, or the Lyre. Each of them is distinguished by a star brighter than any which we have yet seen—Capella, in Auriga, and Vega, in Lyra. The latter star may be readily distinguished by its steely blue lustre, whilst Capella is more of a yellowish colour, and both surpass in brightness all other stars in the neighbourhood of the Pole.

The curious river of stars, crowded so closely together as to shine with indistinguishable lustre, which is known as the Galaxy, or the Milky Way, will be noticed meandering round the Pole from Auriga through Cassiopeia till it almost touches Vega, and thence flowing off in both directions to make a great circle in the heavens.

Extrapolar Constellations. The four constellations which encircle the Pole Star are always visible in our latitude, but as we go further south we find that the constellations move in larger and larger circles, until they dip beneath the horizon and disappear from sight. If we draw a circle round the pole at such a distance as just to touch the horizon, all the stars within this circle will be perpetually visible, and it is therefore called the *Circle of Perpetual Apparition.* Its distance from the pole depends upon the latitude of the observer.

It is quite impossible within our limits to give a detailed account of all the constellations which lie outside this circle and are visible to us at one time of the year but not at another. We may simply name some of the most conspicuous of these constellations, with the time of year at which

175



8. THE CONSTELLATIONS OF WINTER

they are visible in our latitude and the most brilliant stars which they contain.

Seasonal Constellations. The chief constellations visible in autumn are Taurus, or the Bull, containing Aldebaran and the Pleiades; Orion, the most splendid of all constellations visible in this country; Canis Major, marked by Sirius, or the Dog Star [2].

Constellations visible in winter are Canis Minor, the Little Dog, containing the brilliant star Procyon: Gemini, or the Twins, containing the bright stars Castor and Pollux; Leo, or the Lion, marked by the bright star Regulus [3].

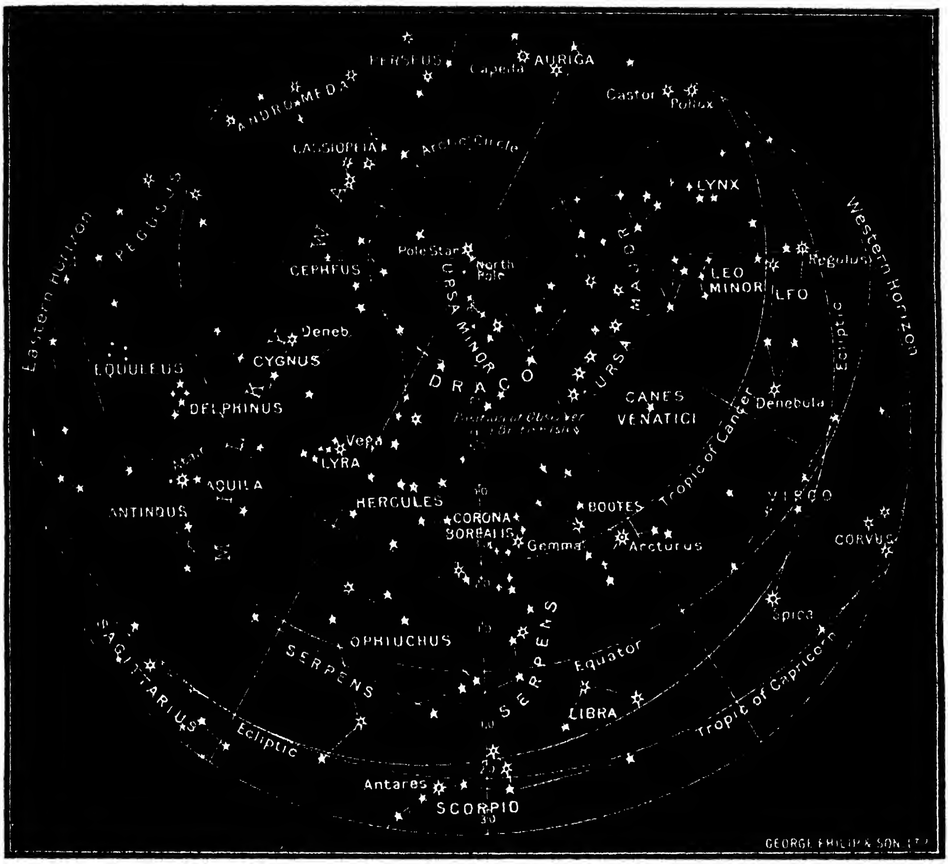
Constellations visible in spring are Boötes, or the Herdsman, marked by the bright star Arcturus, lying in the prolongation of the curved handle of the Dipper, or tail of the Great Bear; Virgo, or the Virgin, containing the bright star Spica; Scorpio, the Scorpion, with the red star Antares [4].

Constellations visible in summer are Aquila, the Eagle, marked by the bright star Altair in the Milky Way; Pegasus, the Flying Horse, with its characteristic square pattern of stars [5].

These are only a few of the constellations into which the visible stars have been mapped out, and are mentioned here because they contain the brightest and most conspicuous stars. It is no very difficult task to learn to distinguish them, but this can be done so easily with the help of a star map that it would be a waste of space to give further directions here for their identification.

The student has by this time elucidated nearly as much practical astronomy as was known to the ancients. They discovered, by observations of the same kind as he has made, that the fixed stars appeared to revolve daily round the earth, that the Pole Star alone remained in the same place, and that this revolution was completed in a little less than twenty-four hours—the time occupied by the sun from noon to noon—so that a different set of constellations occupied the same part of the sky at different times of the year.

The Ptolemaic System. They accounted for these phenomena, however, by supposing that the stars were really in motion round the earth, and were fastened on to the surface of a vast transparent or crystalline sphere with the earth in its centre. Other concentric and invisible spheres were introduced to account for the apparent movements of the sun, moon and planets, each of which was supposed to have a sphere of its own, moving in some curious fashion which accounted for the observed facts. In this way Ptolemy of Alexandria and his successors formed a highly ingenious and complicated system of astronomy, which was quite competent to explain the actual motions of the various planets with as much accuracy as was required by observations made entirely with the naked eye, and even to predict their future places. Ptolemy was quite aware that the earth was a globe, and that it was exceedingly small in comparison with the distances between it and the



4. CONSTELLATIONS VISIBLE IN SPRING

stars. But it never seems to have occurred to him that it was very much simpler to suppose that the earth was itself rotating than that these gigantic spheres, bearing the fixed stars and all the planets, were sweeping round it with the terrific speed that would be necessary for the outermost of them to complete one revolution in every day.

The Copernican System. The real state of things with regard to the planetary and stellar motions was first taught by Copernicus, a Prussian monk, who was born in 1473 and died in 1543. He was the first who clearly conceived the true system of the universe [6]. He demonstrated that the diurnal revolution of the heavens was only an apparent motion, corresponding to the real rotation of the earth on its own axis in the same period; that the earth, instead of being the centre of all things, was merely one of the planets, revolving in an orbit round the sun; that the sun itself was only one of the numerous stars which bedeck the heavens with light, and that these stars were at a distance from the earth which was very great in comparison with that of the sun or the planets. He also showed that the apparent movement of the sun and moon among the stars could be explained by supposing that the earth revolved round the sun in a year, and that the moon revolved round the earth in a month.

Copernicus first enunciated this great truth, which is now familiar to every schoolboy, but to work it out completely was reserved for a series of astronomers. The accurate observations of the Dane Tycho Brahé, the laws of planetary motion which the German John Kepler based upon them, the discovery of the telescope and the laws of motion by the Italian Galileo Galilei, and finally, the great discovery of the law of universal gravitation by our own Sir Isaac Newton, were all necessary before astronomy could become an exact science.

The Diurnal Motion. A little thought will show the student how it is that the real motion of the earth on its own axis gives us the effect of an apparent motion of the whole universe round the earth. If he stand up in the middle of the room and turn slowly round, the effect will be exactly the same as if the walls of the room stood upon a turntable and had revolved while he stood still. He knows quite well that it is he himself who is turning round. But in the case of the earth we are entirely unconscious of its motion, because we ourselves and all the objects which surround us, including the atmosphere, share in it. Motion, of course, is only relative—that is to say, we can only detect it by reference to some fixed point. So it is with the spinning earth. It is constantly rotating with a speed which, at a point on the equator, amounts to over a thousand miles an hour; but this rapid motion is quite imperceptible to us, since we share it, until we look at some external object like a star. There is really nothing but probability to show us whether we are moving in one direction or the stars are moving in the opposite one. During the greater

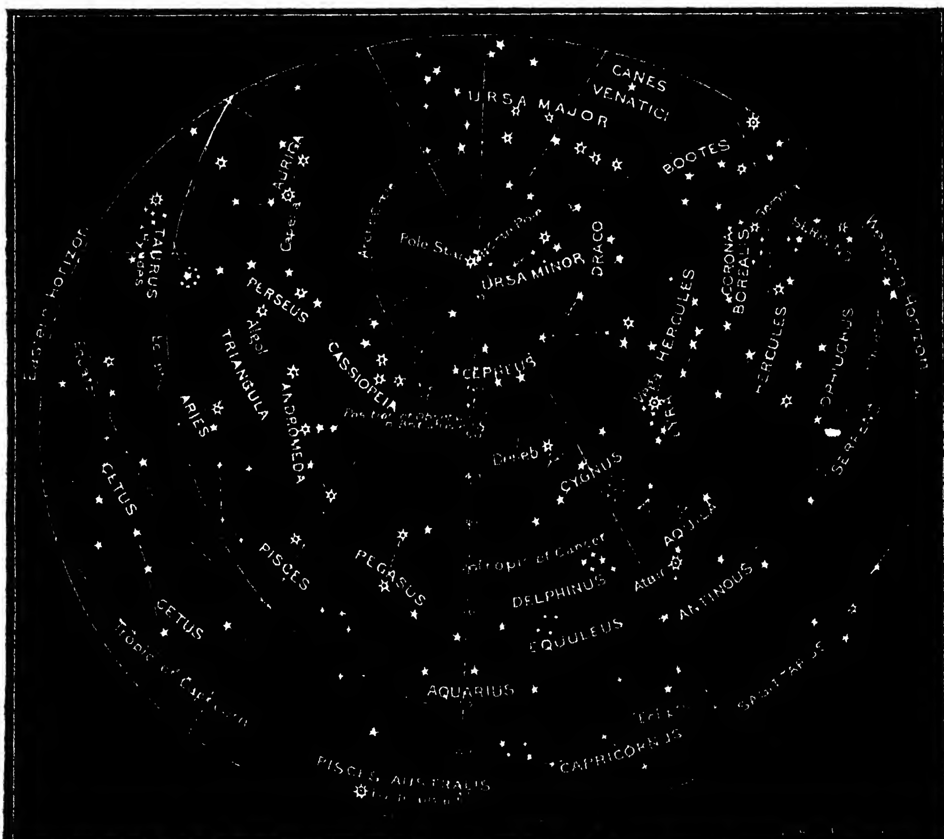
part of the existence of mankind the latter view was universally accepted. Now, however, we are all convinced that the former is the true one.

The earth rotates on its own axis once in 23 hours 56 minutes 4·09 seconds, and consequently in the same period the stars appear to complete a revolution in the opposite direction. The exact length of this period is determined by measuring the interval which elapses between two successive passages of the same star across the meridian, and, of course, it proves to be the same whatever star we may choose.

The Earth's Yearly Journey. In addition to the diurnal motion of rotation, the earth has another quite independent motion. This we deduce from the apparent motion of the sun. Our luminary appears to describe a great circle among the stars in the course of a year; this circle is known as the *ecliptic*. By the same method of reasoning previously employed it will be seen that the appearances would be just the same if, instead of the sun travelling round the earth, the earth travelled round the sun; and this is the explanation now adopted. Its accuracy is proved by certain physical considerations which lie beyond the sphere of this course. The earth, in fact, is one of the planets attendant on the sun, and travels round that star in an orbit which is nearly circular, but is actually an ellipse, at a distance from it which averages rather less than 93,000,000 miles. It always travels in the same plane, which is known as the *plane of the ecliptic*, and is inclined to the plane of the earth's equator at an angle of about $23\frac{1}{2}^\circ$. It is the combination of this orbital motion with the earth's diurnal rotation which, as we have seen, causes the stars to present different configurations in the heavens at the same hour at different times of the year. In the course of its journey round the sun it will be clear that the earth makes one additional revolution on its own axis; in other words, it makes $366\frac{1}{4}$ revolutions with regard to the stars in the same time as it makes $365\frac{1}{4}$ with regard to the sun. Thus, every star comes back to the meridian to-night rather less than four minutes before the solar time at which it arrived last night.

Solar and Sidereal Time. Hence it follows that there are two distinct methods of measuring time. They both depend upon the earth's rotation, which continues at an unvaried rate—or, at least, the variation which is believed to exist is so small that it is quite imperceptible within the span of man's history. The actual period of the earth's rotation, as measured by the interval between two successive appearances of the same star on the meridian, is known as a *sidereal day*, divided into 24 sidereal hours, minutes and seconds.

The *solar day*, however, is measured by the interval between two successive meridian passages of the sun—or, rather, since the sun's motion is not quite uniform, between two meridian passages of a fictitious body known as the *mean sun*, which is never more than a minute or two in front of or behind the real sun, but is so chosen



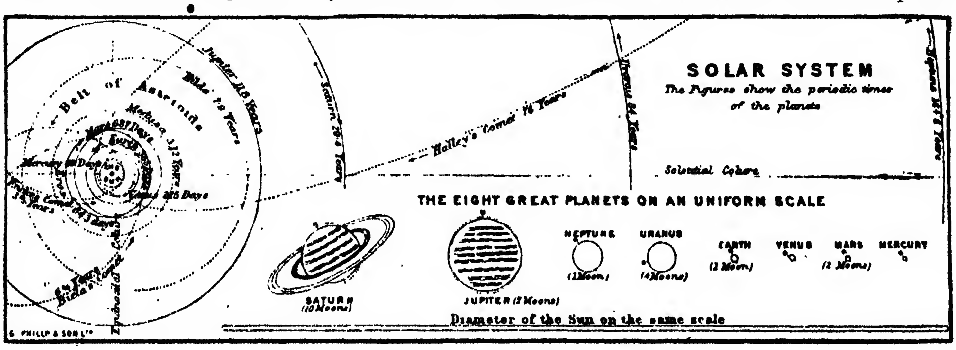
5. THE CONSTELLATIONS OF SUMMER

that every day is of exactly the same length. This day, as every one knows, is divided into 24 solar hours, minutes and seconds, which are those measured by ordinary clocks and watches. Astronomers use clocks which are regulated to keep *sidereal time*, and consequently register 24 hours while an ordinary clock only registers 23 hours, 56 minutes, 4·09 seconds.

The sidereal and mean solar time are in agreement on March 22nd, and for the rest of the year the sidereal clock is steadily gaining until it catches up the solar clock at the same date next year. Thus, the same star always crosses the meridian at the same time by the astronomical or sidereal clock, and a simple calculation—multiplying the number of days which have elapsed since March 22nd by 3 minutes 55·91 seconds, and adding this to the time shown—gives the corresponding solar time. As astronomers do most of their work at night, they reckon the day from noon to noon, and divide it into 24 hours: thus 5 a.m. on June 23rd is spoken of by astronomers

which shine in the midnight sky. Its nearest stellar companion is situated at an almost incredibly vast distance, such that a body moving with the speed of light itself would take more than four years to cross the gap which divides the sun from the nearest star. The sun, with its attendant planets and their satellites, as well as certain comets and shooting stars which also circle round it, make up what we call the *solar system*, the study of which must be the first object of the astronomer. The far-off and innumerable stars form the subject of a later division of the science, known as stellar astronomy, with which we shall deal in a later section. But the greater part of this course will be devoted to the motions, movements, and physical characteristics of the bodies composing the solar system.

The Solar System. The centre of the solar system [6], of course, is the sun, that great luminous orb which supplies us with almost the whole of the light and heat which are necessary for the continuance of life, and which holds all the planets



6. THE COPERNICAN SOLAR SYSTEM

as June 22nd, 17 hours, Greenwich mean time. This must be remembered in consulting astronomical tables.

The Motions of the Moon and Planets. The moon, in addition to sharing the diurnal motion, also describes a circle among the stars, which it completes, from new moon to new moon, in the period known as a lunar month, or about 29½ days. This phenomenon is similarly explained by the fact that the moon describes a nearly circular orbit round the earth, at an average distance of 238,840 miles, in 27 days, 7 hours, 43 minutes, 11·55 seconds. The former period is known as the synodic, the latter as the sidereal month—the difference being due to the earth's orbital motion.

The other planets, like our own earth, describe elliptical orbits round the sun, at distances which vary from about 35,000,000 of miles in the case of Mercury, to 2,775,000,000 of miles in that of Neptune. The time which they take to complete this revolution varies from about 88 days to more than 164 years. It is the composition of these real motions which accounts for the apparent movements of the sun, moon, and planets.

The Sun a Star. The sun itself is a star, and by no means one of the largest among those

in regular motion about it by its vast gravitating energy. The sun is a star of comparatively small magnitude, which is yet so large that if the earth were placed at its centre there would be ample room for the moon to revolve round it inside the sun, and so massive that it outweighs all the planets put together more than 700 times.

The nearest planet to the sun is Mercury, at a distance of 35,000,000 miles. Next comes Venus, the bright evening star, at a distance of 66,000,000 miles. After these inferior planets follows the earth, distant 93,000,000 miles. The remaining planets, being beyond or above the earth, are known as *superior*, and include Mars, at a distance of 141,000,000, Jupiter 480,000,000, Saturn 881,000,000, Uranus 1,771,000,000 and Neptune 2,775,000,000 miles. Between Mars and Jupiter there is a curious swarm of minor planets, of which nearly 600 are known.

The earth has the moon for its single satellite, revolving round it as the planets revolve round the sun; and all the exterior planets have their satellites, varying in number from the one which circles Neptune to the ten which whirl round Saturn. In addition to these planets the sun has for attendants an unknown quantity of comets and meteorites.

SCIENTIFIC INSTRUMENTS

Lens Grinding. Principles and Manufacture of Optical, Meteorological, and Other Scientific Instruments

As lenses are important items in so many optical instruments it will be appropriate to consider them first. Lenses are the chief feature of microscopes, telescopes, lanterns, cameras, and spectacles, and the methods of manufacture of the various lenses have much in common. The material of which lenses are made is generally glass, although for spectacles pebble or quartz has several advantages. Pebble, however, in anything but the thinnest plates, such as are required in spectacle lenses, has a double refraction, hence it cannot be used in many optical instruments. The definition of a lens, as showing the difference between a lens and an ordinary piece of glass, is "a piece of glass or other transparent substance shaped so that rays of light passing through it are made to change their direction and to magnify or diminish objects at a certain distance." The illustration [1] is what is known as a convex lens, the straight lines representing light which, by the action of the lens, is refracted and converged to a point, called the *focus*. The second figure [2] is a concave lens in which the rays of light are diverged. It is obvious that a focus is not formed by this lens, but what is called a "virtual focus" is obtained by following the rays backwards as shown by the dotted lines, V being the point of virtual focus.

The various kinds of lenses must be imagined as segments of glass spheres or cylinders, the different forms being shown in the illustration [3].

The Principle of Lens Making. As stated, the various lenses are segments of spheres, and the chief object in lens grinding is to obtain truly spherical surfaces. This is fortunately comparatively easy on account of the natural tendency of two surfaces to grind each other equally when rubbed together, especially when the surfaces are paired—a concave and a convex surface. In order to grind or polish a lens surface a tool must be made of the exact shape of the lens required, this tool being moved over the surface of the lens in several directions, abrasion being produced by a small quantity of emery powder. It is obvious that in time the tool will have worn the glass away until both are of the same curvature. The comparatively rough surface—it looks like ground glass—is then treated with finer emery powder and finally putty powder until a brilliant surface or polish results. The curvature of the tool determines the curve of the glass and the curve of the glass is the chief factor in the magnifying or diminishing properties of the glass. Lenses made of different glass vary in their properties, so that by picking the kind of glass and the depth of the curves and combining the several lenses different effects are obtained.

Measuring Spheres. The instruments used for measuring spherical lenses are called *spherometers*. One of the oldest is the Ross spherometer, shown in 4. It will be seen that the central index bar is moved up or down according to the convexity or concavity of the cylinder that is being measured. The index bar is provided with a vernier for finer reading. Professor Silvanus P. Thompson has also devised a spherometer, but the one chiefly used by spectacle makers is that invented by Mr. J. T. Brayton, a Chicago optician. This is, in size, like a watch, the appearance of the instrument and the internal works being shown in 5 and 6. It gives by direct reading the focal length of a lens either spherical or cylindrical, the measure in dioptrics being indicated on the dial. The angles of prisms are measured by an instrument called a *goniometer*.

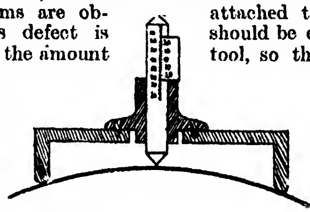
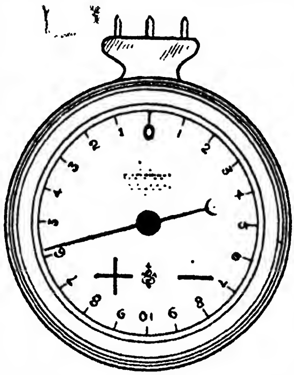
Some Defects of Lenses. When light passes from air into another substance of greater density it is bent or refracted. A familiar illustration of this is obtained when a stick is dipped into water, the refraction of light at the surface of the water giving rise to the impression that the stick is bent. Light is made up of a series of vibrations which together give the sensation of white light, but the component vibrations violet, indigo, blue, green, yellow, orange and red are bent or refracted in an

unequal degree. By means of a prism a beam of light can be separated into its component parts, the experiment being familiar to students of physics. A lens of spherical shape is really a collection of prisms, an idea which can be readily grasped by studying a section of a lens, and hence colour fringes familiar with prisms are obtained with single lenses. This defect is known as "chromatic aberration," the amount of difference between the refraction of the extreme colours being called the "dispersion" of the glass. To correct chromatic aberration is one of the most important functions of the opticians. Different kinds of glass have varying refracting powers, or dispersion, and by putting together differing glasses it is possible to neutralise or correct the defects of either, a lens so produced being *achromatic*—free from colour. Crown and flint glass are the commonest examples. A disc of each glass put together produces a lens free from colour defect, but obviously the positive and negative lenses must not be of corresponding strength or no lens effect will be obtained. The rule is that the foci of the two lenses should be proportional to the relative dispersion. A large number of various kinds of glass are now available, and the requisite proportions can be calculated when certain physical properties of each glass are known. Another defect—spherical aberration—is due to the shape of the lens and cannot be entirely corrected. It can, however, be reduced to a minimum. The nearer the surface tends towards the elliptical form the less aberration there will be, and by properly combining the curves of two lenses most of the aberration can be destroyed. Astigmatism is a defect in which a round point is rendered by an oval, the correction being made by keeping the lens as concentric as possible. Various distortions exist in lenses which are known as *barrel-shaped* or *pin-cushion*, according to the kind. These defects are neutralised by "stops," or diaphragms placed between the two lenses.



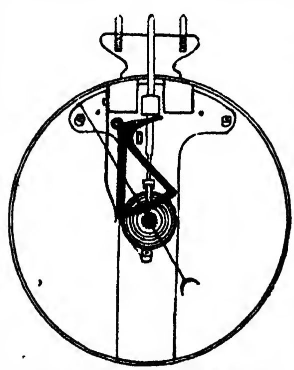
4. ROSS SPHEROMETER



5. BRAYTON LENS MEASURE (OUTSIDE)

The Manufacture of Lenses. The methods of making lenses will now be dealt with, but specific instruction in special classes of lenses will also be referred to under the various optical instruments.

Lenses are worked by hand or machine, the latter arranged to give motions similar to those imparted by the workman in the hand method. For persons who already have a lathe, a useful lens-grinding attachment is shown in **7**. It consists of a wooden box supplied with a curved arm inserted in the tool-rest support. A vertical journal box passes through the bottom of the box, and contains a shaft having upon its upper end a socket for receiving the grinding tool, and on the lower end a grooved wheel surrounded by a rubber friction band, which is revolved by contact with the face-plate of the lathe. The speed of the wheel relatively to that of the lathe can be varied by raising or lowering the shaft by means of the box support in the tool post. The glass to be ground is cemented to the face of a flanged casting, and is held down to the grinding tool by the lever attached to the box. The centre of the lens should be eccentric to the centre of the grinding tool, so that the lens will be revolved on the face of the tool. The point projecting from the lever enters a small cavity in the centre of the casting, to which the lens is attached, and ensures an equal pressure over the entire surface of the lens.



6. INTERIOR OF BRAYTON LENS MEASURE

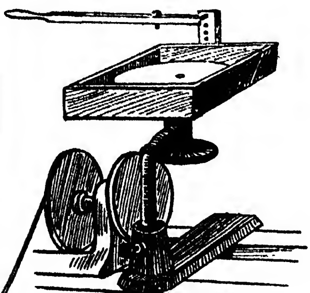
Gauges. The tools which must be provided first are the templates, gauges, or patterns for forming the curves of the grinding tools. For long radii, the gauges are sometimes cut out of thin plate-glass, say about $\frac{1}{16}$ in. thick, by cementing it upon the bench and mounting a good diamond upon the end of a radius bar. In its simplest form, the radius bar may be only a wooden rod, with a bradawl stuck through it into the bench, the diamond being placed from the awl at the distance equivalent to the radius of the curve. The glass is cut and separated, the edges of the two pieces being respectively concave and convex. These edges are ground together with emery and water by being laid upon the bench and rubbed edge to edge till they fit truly. More usually templates of large and medium radii are cut out of sheet brass, or even zinc, either with the radius bar or in the turning lathe. The brass concave and convex gauges are cut at separate operations as it is necessary to adjust the radius to compensate for the thickness of the edge of the cutter. The edges are ground truly together. A gauge made in a turning lathe, with bevel edges, is shown in **8**. The tools are turned to the brass gauge, sometimes only the concave tool, the convex one being turned from the perfect concave. Double calipers and step gauges are used for gauging the thickness of concave lenses in the roughing process.

Grinding and Polishing Tools. Having the templates ready, a concave "roughing" tool is next made. This, called a "shell," is needed for a convex lens, and is turned from wood, being gauged until true. A shell in iron is obtained by casting; at the same time another casting about $\frac{3}{8}$ in. larger is made, which serves later on as a medium for the polisher. A pair of brass tools [9], concave and convex respectively, are next made, and these being the tools that are responsible for the curves of the lenses, a good deal of time must be devoted to their preparation. The two tools must fit each other as accurately as possible. In lens factories this is carried out so exactly that when the two parts are put together the lower tool can

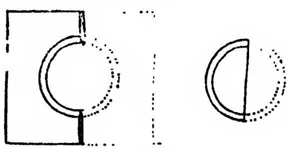
be raised by means of the upper tool. As mentioned above, the gauge is used for the concave tool, and from this the convex portion is shaped. The turning tool, or scraper, shown in **10**, is useful for giving the final shape to the concave tool. It consists of a sharpened steel disc attached to or formed upon the end of a bar. Drawn brass is preferable for the tools, as it is more homogeneous than a casting. The backs of the tools are provided with screws like an ordinary chuck, so that they can be fitted into the lathe mandrel for turning, and when required for grinding, fixed to a "post" or upright in the workshop. The brass tool must be made of sufficient weight to retain its "figure," without risk of flexure. To correct the curvature of the tools, the convex tool is fastened by the screw on the back to the post, and a handle having been fixed to the concave tool, it is placed on the convex tool and the two rubbed together. If now the surfaces are examined, the parts not true will be shown by a brightness which is carefully corrected by the scraper [**10**], until, when the tools are nearly true, a little emery is introduced between the two tools, and by means of a circular swinging motion, continually varied in extent and direction, the two fit each other perfectly. Occasionally, it is necessary to reverse the position of the tools—but always keeping in mind the object of the grinding—to obtain a true spherical figure, and to fit the tools exactly to each other.

Although brass has been recommended as the material for making tools, some workers prefer glass, the chief advantage being that emery does not embed itself in the surface. Amateurs of an inventive turn of mind will have no difficulty in devising other means of shaping the grinding tools. Passable moulds can be made in plaster of Paris by means of the gauges, and type-metal is sufficiently hard for a home-made casting in a plaster mould.

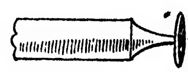
Preparing the Glass. For making an achromatic lens, two discs of glass are needed, one of flint and the other of crown glass. These are sold in pairs, or can be cut out of plate glass (flint for the convex lens) and crown glass (for the concave lens) by means of a revolving iron hoop supplied with sharp sand and water. A pair of "shankers," a tool similar to scissors, and a tool known as a "flonk," made from a piece of a rasp, are also used for chipping or nibbling the glass into shape. The molten glass is sometimes pressed into the approximate shape to minimise work at this stage. The back of the piece of glass is then heaped up with pitch, and the glass cemented to a wooden handle [**11**].



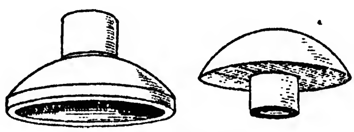
7. LATHE ATTACHMENT FOR LENS GRINDING



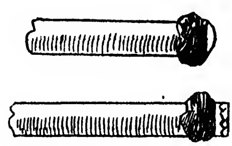
8. BRASS TEMPLATES



10 SCRAPER



9. SPHERICAL GRINDING TOOLS



11. LENS MOUNTED ON HANDLE

Roughing. The next process is called "roughing" or "curving." In this, the lens is approximately shaped by means of a grindstone, emery wheel, or revolving spindle, to which is attached a hardened steel tool, moistened with turpentine. Another method, in which sharp wet sand is allowed to drip on the revolving "shell," against which the glass is pressed, is shown in **12**. The shell is placed in the shallow tray to catch loose sand that flies off during the process. Each side of the glass is roughed, the glass being detached by warming the pitch cement. The parallelism of the two sides is obtained by observing the edge of the glass and the depth of the surfaces by the caliper and step gauges.

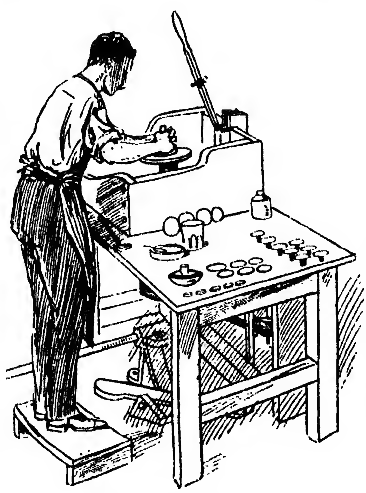
Lens Grinding. The lenses are now ready for grinding in the brass tools. In this operation the lenses are either treated singly or many at a time, according to the size and quality of the work. The lenses are fastened to the tool by means of pitch cement, the process being known as *blocking*. To avoid rounding the edges of each lens it is customary to fill up the spaces between the glass discs with smaller pieces or rings of glass, a certain symmetrical arrangement being preserved to ensure even grinding. Lumps of pitch are placed on the back of each disc, and the glasses pressed into position by means of the cast-iron runner heated sufficiently to melt the pitch. The spaces will now be filled up level with pitch to the surfaces of the lens. The process of grinding now begins. Emery moistened with water is placed on the glass and the tool is worked upon it with a circular swinging stroke, the worker meantime gradually moving round the disc and also turning the tool around. From time to time the tool must be tried with its companion to see that it is not losing figure. From three to six grades of emery are used in the grinding process, from coarsest to finest. Between each grade the lenses are carefully cleaned and care taken that there is no contamination with coarser emery. By examining the surface of the lenses with a magnifier, the operator can judge of the progress of the grinding and detect any scratches. The wetted emery is spread by means of a tool called a "bruiser," a piece of plate glass shaped to the radius of the tool. Excess of emery is wiped off the edges with a sponge. Very little emery is used. When the use of the finest emery is reached, and the lens is true to form, a uniform granular appearance will be presented by the glass. Carborundum, a product of the electric furnace, is coming into use as an abrasive in lens grinding.

Polishing. The next operation is polishing the lens face—that is, converting the milky appearance into a bright, transparent, structureless surface. The polisher is prepared by taking the iron shell made for the purpose, warming it, and coating ⅛ in. thick with pitch cement, pressing the pitch to correct form by the corresponding tool. The surface is now warmed till soft, covered with a piece of broadcloth cut to proper size, which is pressed into place by the counter grinding tool. The cloth adheres and takes the form of the softened pitch. Allow the polisher to get cold, then work into it putty powder to fill up the pores of the cloth and leave a firm, glazed surface. Now, on sprinkling a little water on the surface, the polisher is ready for use. It takes about two hours to polish a lens. In place of broadcloth, silk or other fabric or paper is used for special purposes, and iron oxide may take the place of putty powder. Hand polishing is illustrated in **13**. During polishing the pressure should be very moderate, or the lenses may sink into the surface of the polishing tool and become rounded at the edges. Stress is laid on getting the polisher to begin polishing in the centre of the tool and gradually extending the polish to the edge. A lens that begins to polish at the edges is generally slightly flattened—not truly spherical.

12. ROUGHING LENSES

It will be understood that unless the other side of the lens is to be left plane that the processes above enumerated, grinding and polishing, must be repeated on the second side. The concave lens needed for an achromat is prepared in the same manner, except that the grinding surface is now convex. The convex tool, it should be noted, is always the lower one when several glasses are operated upon together.

Balsaming. The convex and concave lenses are now cemented together. The surfaces fit each other if the lenses have been ground to the same curves. They are freed from all traces of pitch by means of turpentine, and when quite clean are warmed on a "hot-plate." A drop or two of Canada balsam is let fall into the concave lens and the convex lens pressed upon it until all air bubbles are expelled. The lens is left on the hot-plate to bake for an hour, and allowed to cool, when the balsam will have become hard.



13. POLISHING LENSES

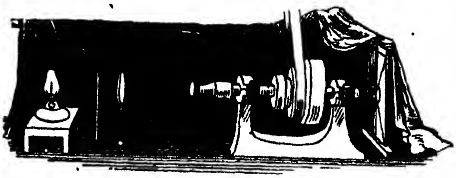
Testing. The method of testing lenses to see that their optical and geometrical centres correspond is shown in **14**. The lens is cemented to a chuck upon one end of a hollow lathe mandrel. Near the opposite end there is a ground-glass surface and in front of the lens a large standard lens. Beyond this is a small vertical rod and lamp. These pieces of apparatus are all in line with the axis of the mandrel, and an image of the rod is cast upon the ground-glass screen. If the image remains stationary while the lathe revolves, the optical centre of the lens corresponds with the centre of rotation. If this is not so, the cement with which the lens is attached is warmed sufficiently to allow the lens to be moved to the correct position. The edges of the lens are finally trimmed to the correct form by holding a brass or iron surface charged with emery or sand against the rapidly revolving lens. The curvatures of the surfaces of high-class lenses are tested by what are known as *contact gauges*. These are pieces of very hard glass the exact counterpart of the surface to be tested. When the two surfaces are placed together and reviewed by reflected light, rainbow or interference colours are shown when the surfaces are exceedingly close together.

Lens Mounting. For mounting or setting lenses for various optical purposes the machines used in other branches of light engineering work are required, such as lathes, milling machines, drilling machines, and presses. The lightness or heaviness of the design will depend upon whether the instrument is for commercial use or for delicate work that can be done only by a skilled operator. It is obvious that in instruments requiring absolute rigidity the construction should not be too flimsy, but, on the other hand, excessive heaviness is an indication of bad design. Fantastic curves should be avoided, and the adjustments made as simple as possible.

The tubes or cells in which lenses are mounted for telescopes, microscopes, and photographic lenses are formed from sheet brass, although some of the newer alloys in which aluminium forms a constituent are coming into use with advantage as regards lightness and incorrodibility. The sheet brass of the necessary size to form the required tube has its edges straightened and brightened by filing. The piece of brass is then rounded upon wood by means of a mallet till the edges are in contact. The edges are then joined by spelter soldering over a coke fire. The tube is then pickled in weak sulphuric acid and sand-scoured. Next it is submitted to a drawing process, by which it is elongated, stiffened, and brightened, the finishing being done on a brass-

turner's lathe with a series of special tools. The brass surfaces which are on the outside of an instrument are lacquered, while internal parts are blacked with either a chemical colouring or a mixture of vegetable black and gold size.

The iris diaphragms fitted to photographic lenses and microscopes are made of eight to sixteen thin semicircular segments of hard-rolled brass. The older pattern of diaphragm—a piece of metal with a hole in the centre—requires no explanation, but it should be noted that the rapidity of the lens depends on the aperture or size of the diaphragm. The size of the diaphragm is calculated as a fraction of the focal length. For example, a diaphragm marked *f*4 means that its diameter is one-fourth of the focal length of the lens, and all lenses having an aperture one-fourth of their focus are assumed to be of equal rapidity. The Royal Photographic Society of Great Britain have standardised a series of apertures as being those most generally useful.

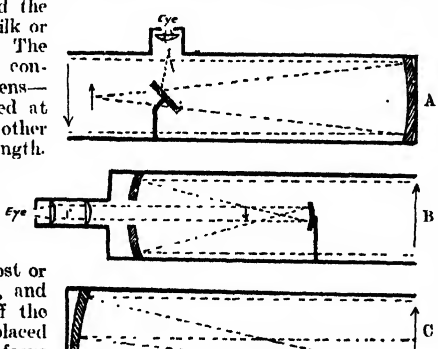


14. TESTING LENSES

Telescopes. There are two classes of telescopes, *refracting* and *reflecting*. The refracting telescopes depend on a system of lenses, the object glass forming the image and the eye-piece magnifying it, while in the reflecting telescopes the rays are reflected on to a speculum or polished mirror, inverted images being formed in both cases in the focus of the lens or mirror.

175.

Refracting Telescopes. These are the oldest form of telescope. In the simplest character they consist of an object glass of one lens and an eye-piece of one lens, but of shorter focus. The best lenses for telescopes are ground and polished by hand. The lens, if small, is held by cement to a handle, and the polishing is done upon silk or with the pitch polisher. The eye-piece of a telescope consists of a compound lens—that is, two lenses placed at a distance from each other equal to half their focal length. The two lenses are usually plano-convex, with the convex faces towards the object glass. The larger lens, called the *field-glass,* is innermost or nearest the object glass, and a diaphragm cutting off the marginal rays is usually placed between them near the focus of the eye-lens, where the image is formed. This eye-piece is generally called the *negative* eye-piece. The Ramsden, or *positive*, eye-piece has the lenses of nearly the same focal length, but the distance from each other is less than the focal distance of the lens nearest the eye. The focusing of the telescope is effected by a rack and pinion motion acting on the tube which carries the eye-piece.



15. REFLECTING TELESCOPES
A. Newtonian B. Gregorian C. Herschellian

Reflecting Telescopes. The advantage of this form of telescope is the great quantity of light which it collects. Faint nebulæ and stars, which are invisible to the observer with a refracting telescope, can be detected by this type of telescope. The three forms of reflecting telescopes are seen in 15. There are, however, many variations. In the Newtonian telescope the real image is formed by a concave mirror, and the reflected rays turned aside through 90° by a plane reflecting surface. The magnifying eye-piece is at the side of the instrument. In the Gregorian form the reflected rays are sent back along the axis of the instrument. These rays, or the central portion, are allowed to pass through a small central hole in the concave mirror, and examined by the eye-piece on the other side of the mirror. The eye-piece is at the end. The Herschellian telescope has the concave mirror tilted slightly to one side. It will, without loss of light, due to the intervention of a second mirror, bring the real image towards one side of the tube, where it is examined by an eye-piece directed obliquely towards the mirror.

Speculum Grinding. The difficulty in making the specula or mirrors for reflecting telescopes is to get a perfect image, owing to the defect of spherical aberration. On this account the polishing is directed towards attaining a parabolic form. Many of the operations of grinding resemble those described in lens making.

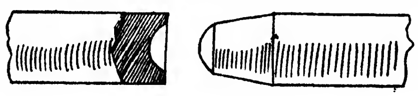
The Microscope. Microscopes are classed as *simple* and *compound*. To the former class belong the lens or combination of lenses such as the reading glass or pocket magnifier. The lenses are of the double convex type. A Coddington lens is such a lens, with a groove cut all round and filled in with black varnish so as to form a diaphragm. The Stanhope lens is similar, except that the two sides of the convex lens are unequally curved. The side with the most convexity is placed next to the eye. Aplanatic magnifiers consist of a convex lens with a thin concave lens on each side, by which means colour is corrected and a flat field obtained up to the margin.

The Compound Microscope. This is a combination of lenses arranged so that the image formed by the objective lens is magnified by the eye piece, or ocular. The parts of a microscope, in addition to the lenses just enumerated, will now be given. Firstly, the foot, or base; this in English microscopes is the tripod or pillar form. The horseshoe form is always made on the Continent, and has advantages when the microscope is used other than in a vertical position. The *stage,* that portion just beneath the objective, is provided with springs to hold the slide in position. It is made of brass and may be faced with vulcanite. The aperture should be sufficiently large to admit the finger. A refinement of the stage is the *mechanical stage,* which is provided with arrangements for giving rectilinear movements horizontally and vertically. The stage is also sometimes graduated so that the position of the slide can be noted for future guidance. For some purposes a *rotary stage* is provided, by which means an object can be rotated to coincide accurately with the optic axis of the microscope.

The *mirror* is carried on a square or circular tail-rod, and is designed to reflect light on the object. The mirror generally has two faces—one plane and the other concave. The sub-stage beneath the stage carries the condenser, which concentrates and focuses the light of the object. The sub-stage is provided with a focusing arrangement. The *diaphragm* is a means of moderating the light, so that it shall bear some ratio to the apertures of the various objectives.

The *limb*, or *pillar*, is the arm carrying the *body tube*, into the lower end of which the objective is screwed. The limb carries the *coarse* and *fine adjustments*—rack and pinion methods of attaining an accurate focus. The size of the body tube varies from 0·9173 in. to 1·41 in. The length of the English tube is 10 in., the Continental tube 6 in. to 7 in. The objectives are specially corrected for the various size tubes. The body tube is made with a *draw-tube* to enable the smaller tubes to be extended. *Binocular microscopes* have two eye-pieces, so that both eyes can be used at the microscope, a prism being used for uniting the images.

Microscope Lenses. These, being so small, have to be made singly. The piece of glass is cemented on the end of a stick, and the roughing is done on a grindstone. The templates are small discs of steel turned in the lathe. The brass "cups," or tools, are charged with emery, and rapidly revolved on the lathe, the lens being formed by holding it against the surface. These tools are shown in **16**.



16. TOOLS FOR GRINDING MICROSCOPE LENSES

The polishing is usually done with crocus mixed with beeswax. The lenses are stuck to the handle by means of shellac. The terms 1 in., ½ in., etc., used to designate the focal power of objectives, represent the approximate initial magnifying powers without eye-piece at a distance of 10 in. from the back lens. As the relative size of object and image vary directly as their distance from the centre of the lens, it follows that the less the equivalent focal distance the greater is the size of the real image. Dry objectives are those which have air between the objective and cover glass. Immersion objectives have a liquid in place of air. This liquid may be water or cedar-wood oil. The adoption of Jena glass has brought forth a new series of microscopes in which many of the aberrations of older forms are quite overcome.

The Oculars or Eye-pieces. The eye-piece most frequently used is the Huyghenian, or negative, eye-piece. It consists of two plano-convex lenses, both with their plane surfaces next the eye. The one nearest the eye is always half the focal length of the other, and the distance between the two lenses must be half the sum of their combined foci. The Ramsden, or positive, eye-piece consists of two plano-convex lenses. The convex surfaces are placed towards each other, the foci of both being the same and the distance of the lenses from each other two-thirds the focal distance of one lens. The Kellner eye-piece consists of a bi-convex field lens, and an achromatic doublet meniscus for the eye lens. Compensating eye-pieces are specially constructed for use with apochromatic objectives, certain corrections being rectified by the eye-piece, which, for optical reasons, were left undone in the objective. The magnification of eye-pieces ranges from 4 to 15, 5 to 6 being about the lowest that can be satisfactorily used on the short tube-length for which achromatic lenses are corrected. A *projection eye-piece* is one used for projecting the image formed by the objective on to a screen for demonstration purposes.

R.M.S. Standards. The Royal Microscopical Society of London in 1857 introduced uniformity in screws for microscopic objectives. The specifications of this standard are as follows: Whitworth thread—Pitch of screw, 36 to 1 in.; length of thread on object glass, 0·125 in.; plain fitting above thread of object glass, 0·15 in. long, to be about the size of the bottom of male thread; length of thread of nose-piece not less than 0·125 in.; diameter of the object-glass screws at the bottom of the screw, 0·7626 in.; diameter of the nose-piece screw at the bottom of the thread, 0·8 in. The Society supplied gauges and a master tap, or "bob," for cutting screw tools, but as the mechanical difficulties in the making of these taps were considerable, there grew up differences in the Society screws. In 1896 the Society again considered the question, and devised a method by which it can be kept to the standard. The new screw is almost exactly the same as the original standard.

The diameter of the draw-tubes of microscopes has also been standardised by the Royal Microscopical Society as follows:

No. 1, 0·9173 in., 23·3 millimetres.
No. 2, 1·04 in., 26·416 millimetres.
No. 3, 1·27 in., 32·258 millimetres.
No. 4, 1·41 in., 35·814 millimetres.

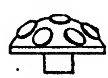
No. 1 is the size in general use on the Continent and in England for students' microscopes; No. 2 is the mean of the sizes in use by English makers; No. 3 is the new size used for the larger English instruments, especially binoculars. No. 4 is used in few English microscopes.

Photographic Lenses. The simplest lens used in photography is known as the *spectacle lens*. As it is non-achromatic, it possesses the defect of chromatic aberration. When used for photographic purposes, a correction has to be made after focusing, as the chemical focus (that observed by the photographic plate) is shorter—that is, lies nearer the lens than the visual focus. The correction is one-fortieth of the focus of the lens. Such lenses are now used only in hand-cameras of fixed focus. The method of correcting colour defect has been dealt with in the manufacture of lenses. These achromatic lenses are excellent for landscape photography, but are not suitable for architectural subjects, owing to the distortion of the marginal lines. This defect is got over by placing between two single lenses a stop, or diaphragm, forming a "rapid aplanat" lens, also known as *rapid rectilinear* or *symmetrical* lens. The lens includes an angle on a certain sized plate which may vary from 45° to 90°; if between 80° and 90° the lens is known as a wide-angle lens. The component parts of the rapid rectilinear lens can obviously be used separately with certain limitations. The "portrait" lens has a front and back combination, the curves of which have been specially calculated to give freedom from spherical aberration and great rapidity. The area of sharpness is, however, restricted. Astigmats are a class of lens rendered possible by the introduction of new kinds of glass. With crown and flint glass achromatism could be corrected, but some of the kinds of spherical aberration (Von Seidel specifies five kinds), astigmatism and coma (defects which occur towards the margin), and curvature of field (the lens gives saucer-shaped or convex fields) could not be attacked. Miethe's astigmat and

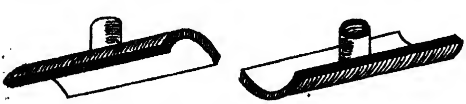
Schroeder's concentric lenses were the first in which the new Jena glasses were used. These were introduced in 1888, but have since been superseded by more modern anastigmats, such as Goerz's double anastigmat, computed by Von Hoegh, in which there are ten lenses and at least four different kinds of glass. Other similar lenses are the Zeiss convertible anastigmat, calculated by Rudolph, Voigtländer's collinear lens, Steinheil's orthostigmat, and Busch's aplanat. An English lens—the Cooke—has only three lenses, but perfect correction of the above named defects has been attained. The Grün lens, which works exceedingly rapidly, is constructed to hold a reservoir of cedar oil between the front and back combination. It is used for photographing in theatres. The telephotographic lens of Dallmeyer is designed for obtaining large images of distant objects. It may be regarded as a combination of a telescope with a photographic lens. The photographic component is placed in front, and takes the form of a "stigmatic" lens.

Lens Adjustment. The adjustment of the various lenses in their cells is a matter of great delicacy. The lenses are first mounted in a trial mount so as to permit of an approximation of the separation of the lenses. The performance of the lens is tested on a watch dial or other similar test object and the exact amount of separation determined and marked for the final adjustment. A deviation of a small fraction of an inch is sufficient to affect the performance of a lens, hence it will be seen that time spent in the adjustment is well spent. Standard lens flanges have been devised by the Royal Photographic Society, but have not been favourably received.

Spectacle Manufacture. In making the lenses used for spectacles a large number of pieces of glass are cemented to the tool [17]. Emery is used for grinding, and a slow rotatory movement is given to the upper tool by machinery. The tool when charged is known as a *form*, and a "bench" of forms is usually attended by one man. The spectacle-maker often grinds special curvatures by hand. The finished discs are cut to shape by shankers or a diamond-cutting machine constructed to yield elliptical figures. The edges of the lenses are ground smooth and to the shape of the frames by revolving emery wheels or grindstones, the lens being held between the finger and thumb. For rimless glasses a polish is imparted to the edges, while grooved edges for "invisible" frames are obtained by revolving angular-edged metal wheels. The tools used in manufacturing cylindrical glasses are shown in **18**; the motion given to them by the machine is backwards and forwards.



17. SPECTACLE LENS GRINDING



18. CYLINDRICAL GRINDING TOOLS

Thermometers. The temperature or hotness of a body is measured by an instrument called a *thermometer*—a glass tube with a bulb on one end partially filled with mercury or alcohol. Alcohol is used because it cannot be solidified, except at a very low temperature, and mercury because it boils only at a moderately high temperature. The mercury thermometer is most extensively used. A piece of glass tubing of fine bore (capillary) is taken, and by means of heat a bulb is formed on one end; the tube is then filled with mercury by dipping the open end into mercury, the end is sealed, and the tube is graduated to show the various temperatures.

Manufacture of Thermometers. The thin glass tubing selected must be of a narrow and uniform bore. This can be ascertained by measuring a short column of mercury at different points of the tube. A bulb, which may be spherical, pear shaped, oval, cylindrical, or tubular, is then blown by strongly heating one end of the tube, and, having fixed an elastic ball to the other end, blowing in sufficient air to give the necessary expansion to the softened glass. The elongated form is to be preferred, as it offers a large surface to the action of the air. The end bulb having been blown, a second is added a short distance from the other end, and when this has half cooled, the open end is dipped into pure, recently distilled mercury, which gradually rises into the tube. In this way the lower bulb is gradually filled. The tube is next held by a wire, as shown in **19**, and heated over a furnace until all the air has been expelled by the boiling mercury. While the mercury is still hot, the open end of the tube is touched with sealing-wax. When quite cool, the mercury fills the lower tube and bulb. The tube is then inclined, and the lower bulb heated to a temperature higher than the thermometer is intended to indicate. Some of the mercury is thus expelled, and as the mercury begins to retreat on cooling, the tube is hermetically sealed just below the upper bulb, which is pulled away. The filled tube is then stored for some time or heated for several days to 50° or 100° above the temperature it is intended to indicate, so as to season the glass.

19. THERMOMETER MAKING

Graduating the Thermometer. The tube is next divided into a number of graduations depending upon the scale selected. The Fahrenheit scale is the oldest, and dates from 1724. It is used in Great Britain and the United States. This scale was primarily divided into 180°: zero was placed at temperate: the point to which the liquid rose when placed under the arm of a healthy man was marked 90°: and the temperature of a mixture of ice and salt, then believed to be the greatest possible cold, was marked 90°. The scale was subsequently altered as follows: 0° was the coldest temperature, and the space between this point and that representing the warmth of the human body was divided into twenty-four degrees. The freezing point of water was then 8°, but as these long degrees were inconvenient, each was divided into four, and 8° became 32°; blood heat, 96°. A mercurial thermometer thus graduated registered 212° as the boiling point of water. In 1730, Réaumur made alcohol thermometers with their zero at the freezing point of water, and the boiling point of water at 80°. The corresponding mercury thermometers were subsequently introduced, and are still used in some parts of the Continent. A centesimal scale was adopted by Celsius in 1742; the boiling point was marked 0°, and the freezing point of water 100°. The points were subsequently reversed by Linnæus, and the scale is now known as *Centigrade*. Such a scale is used for scientific purposes and in many Continental countries. A comparison of the Fahrenheit and Centigrade scales is given on page 1565.

The Freezing Point. Of the two fixed points needed on a thermometer the freezing point is first marked. The whole of the thermometer tube is placed vertically in a vessel of snow or melting ice. After about half an hour, the tube may be raised till the top of the mercury can be seen, which is marked with a file. Thermometers for use in very cold countries have a still lower point indicated, that of the freezing point of mercury. This temperature is obtained by mixing solid carbon dioxide and ether.

The Boiling Point. This is the temperature of water boiling at normal pressure (760 mm.). To determine this, either Regnault's apparatus or a long, narrow-necked flask is used. The former, which is preferable, consists of a cylindrical copper vessel with double sides, between which the vapour of water circulates, there being no possibility of the exterior air reaching the thermometer. To ensure the regular escape of steam, a small manometer communicates with the interior of the boiler, to indicate the least pressure within. The whole of the mercurial column must be exposed to the vapour of the rapidly boiling water, but, after a few minutes, it may be raised just above the cork, and its position noted. As the boiling point of water depends upon the pressure of the atmosphere, the height of the barometer must be taken. If it stands at 760 mm., the temperature is 100° C.; if not, a calculation will be necessary—1° C. or 1·71° F. must be added or subtracted for every 26·7 mm. above or below 760 mm. The interval between the two fixed points is then divided mechanically into the requisite degrees, according to the scale chosen.

Verification. For common use, extreme accuracy is not called for in a thermometer, but if needed for accurate scientific work, the scale readings need checking. The method is by comparison with a thermometer of known accuracy. The freezing and boiling points of both thermometers should correspond, the readings being accurately determined through a lens. The standard thermometers are made at the Kew Observatory of the Royal Society, where elaborate precautions are taken in the selection and seasoning of the glass and graduation of the tube. The limits enforced at Kew for thermometers are that all thermometers are rejected when the largest error at any point is greater than 0·3° F., or when a space of 10° F. is more than 0·3° F. wrong.

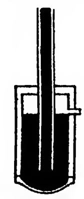
Various Thermometers. Instruments for measuring extremes of temperature are known as maximum and minimum thermometers [see page 1565]. The former is provided with a constriction just above the bulb, so that, although the mercury passes out easily, it cannot recede past the constriction. In other forms, a minute air bubble is left or a plug of porcelain is inserted just above the bulb. The expanding mercury passes the porcelain, but when once past, cannot return. Minimum thermometers are usually spirit thermometers with an index in the stem. If the spirit contracts in consequence of a fall of temperature, it carries the index towards the bulb, but when, subsequently, a rise of temperature occurs, the spirit flows past the index, the latter being left in position to register the lowest temperature. These two thermometers can be combined as a maximum and minimum thermometer. One form consists of a U-tube with a bulb at each extremity: each arm of the tube is half filled with mercury; one bulb and the remaining portion of the tube above the mercury is filled completely with alcohol: the other bulb is only partially filled with this liquid. A steel index, prevented from falling by a hair tied round it, moves on the surface of the mercury in the side tubes. Should a rise of temperature take place, the spirit in the full bulb expands, causing the mercury to push up the index in the other limb. The reverse occurs when a diminution of temperature takes place. The lower ends of the indices nearest the mercury indicate the maximum and minimum temperatures. Clinical thermometers are modified forms of the maximum thermometer with constriction above the bulb. An open scale is obtained by making the bore of the tube very narrow, and the optical properties of the convex edge of the glass are utilised for the purpose of obtaining a magnified image of the exceedingly fine thread of mercury. The range of temperature given in clinical thermometers is from 90° F. and 110° F., so that the length of the instrument is small. The sensitiveness of the thermometer is assured by making the bulb of special shape, but care must be taken that the glass is not so thin as to be elastic to pressure. Thermographs are self-registering thermometers. They consist of a curved metallic tube filled with spirit and hermetically sealed. The tube is firmly fixed at one end, and as changes of temperature alter its curvature, they cause the free end, which is connected to a pen by multiplying levers, to move. Fire alarm thermometers are also made. In this form a thermometer is balanced on a knife-edge, a sliding band having previously been placed at the temperature which has not to be exceeded. When this temperature is reached, the mercury overbalances the thermometer, and causes its upper end to make contact with the wires of a battery; a bell immediate rings to give the alarm. Instruments for measuring very high temperatures are known as *pyrometers*. These depend on the expansion of a rod of metal or other solid substance, the difference in expansion of two solid substances, or the coiling or uncoiling of a spiral composed of two or more metals rolled or welded together to form a ribbon.

Barometers. An instrument for measuring the atmospheric pressure is called a *barometer* [see page 1139], the most usual kind being that in which variations in the height of a column of mercury in a tube are noted. If a glass tube a yard long and a quarter of an inch diameter is sealed at one end and filled with mercury and then inverted in a vessel of the same metal, the mercury in the tube sinks until it is about 30 in. above the surface of the liquid in the reservoir. This is known as Torricelli's experiment [see page 1139], and the observation that the variation of the height of the mercury depends on the pressure of the atmosphere suggested the use of this fact for measuring and recording the changes in pressure. Pascal repeated Torricelli's experiment with water, the tube in this case being 50 ft. long. The atmosphere was found to support a height of 34 ft. of water, which corresponds to the height of the mercury when the difference between the weight of the two liquids is taken into account. Water barometers have been constructed and found extremely accurate, but the disadvantages of such a long tube of water and its liability to damage by frost have prevented its use except as a curiosity.

Types of Barometers. The main types are *mercury* barometers and *aneroid* barometers. Of mercury barometers the chief kinds are (1) the siphon; (2) the Fortin or cistern barometer [**20**]; and (3) the Kew pattern. In addition to these instruments intended for accurate observations there are the weather-glasses as originally suggested by Admiral Fitzroy, which are usually called *wheel barometers* [see page 1140]. The aneroid barometer

does not require the use of mercury. The variations of the atmospheric pressure act on a metal box which has been deprived of air and are communicated to a scale. We shall first deal with the construction of the mercury barometer.

How to Make a Barometer. First of all a piece of tubing 42 in. long is taken: it should be of ¼ in. bore or even slightly larger, and it is better not to use lead-glass tube as the mercury in time acts on the glass and dims the interior. The tube is well cleaned first with sulphuric acid and water, then with several rinsings of water, and finally with alcohol. It is put to dry and carefully protected from dust. One end of the tube is closed by heating it in a Bunsen flame, care being taken to get a nicely rounded finish to the end of the tube. The edges of the open end should be rounded off by carefully heating in the flame. The next step is to make a U-shaped bend 36 in. from the sealed end. The glass must be heated gradually so that the diameter of the tube remains the same throughout the bend. This will leave a short limb of about 3 in. and a long tube of 36 in. The U-shaped bend should not be quite parallel; it is better to make a slight inclination, as this facilitates the introduction of the mercury at the subsequent stage.



20. BAROMETER CISTERN

Reference to page 1139 will show the form of the tube, which is, after bending, fastened on the support, a piece of hard wood 38 in. long, 3½ in. wide, and at least ⅝ in. thick. Various items, such as means for hanging up the board, will suggest themselves to the worker, and there is no objection to bevelling the stand and rounding off the corners. The space where the mercury tube is to lie is hollowed out, and when it fits nicely in its place the tube is fastened there by brass clips. Along the tube is placed a sliding scale, which next needs to be considered. This is best made of cherry-wood or mahogany and is 32 in. long, while in the upper and lower part slits are cut and through these brass screws with milled heads are inserted, the object being to allow of sliding the scale upwards and downwards in a certain constricted sphere. The scale, which is usually of ivory or one of its substitutes, is fastened near the top of the sliding scale just described. It is 4 in. long and divided into inches and tenths, the lowest inch mark being 29, the next 30, and the upper one 31. The scale is placed so that the 30 in. mark is exactly 30 in. from the bottom of the slide, which is furnished with a brass edge, the purpose of which is to make easier the adjustments required when the barometer is read.

Filling the Barometer Tube. The next step is to introduce the mercury, which should have previously been purified by being squeezed through chamois leather. The tube is laid on its side with the short limb uppermost. The mercury is put into a glass flask and boiled to expel moisture and air: then, when still hot, poured little by little into the short limb of the tube through a glass funnel with L-shaped tube. By manipulating the tube the air in the tube is partly dislodged, and this is completed by corking the open end and passing the tube gradually through a flame so as to boil the mercury from end to end. The result is a perfectly bright tube of mercury free from air. The mercury is allowed to cool and the tube raised to the vertical position—the closed end uppermost. The mercury will sink a little as in the Torricellian experiment, the excess of mercury running out of the short limb. Enough mercury is expelled from the short limb, by inserting the finger or a wooden plug, to leave 2 in. empty. The bottom of the sliding scale is brought opposite to the top of the mercury in the short limb, and the height of the column—the atmospheric pressure—is shown on the scale at the other end. A cover is fitted on the open end of the mercury.

Wheel Barometers. Another variety of the siphon barometer is especially intended to indicate good or bad weather. This is managed by means of a float on the top of the mercury in the short limb. A string attached to this float passes round a pulley and at the other end there is a weight somewhat lighter than the float. A needle fixed to the pulley moves round a graduated circle on which is marked "stormy," "rain," etc. Admiral Fitzroy, who wrote a much used treatise on the weather gives the following as the indications. When the mercury stands at:

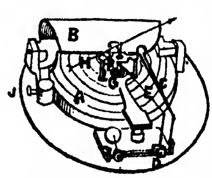
31 in.	it indicates	very dry	weather
30·5	,,	settled fair	,,
30	,,	fair	,,
29·5	,,	changeable	,,
29	,,	rain	,,
28·5	,,	much rain	,,
28	,,	stormy	,,

The following directions are also usually given on one of this type of barometer; they were originally drawn up by Admiral Fitzroy:

Rise for North NW—N—E Dry or less Wind	Fall for South SE—S—W Wet or more Wind
Except Wet from North	Except Wet from North
Long foretold, long last; Short notice, soon past.	First rise after low Foretells stronger blow.

It must be confessed, however, that the indications of the wheel barometer are only approximate, as the height of the mercury depends on the height of the place where the barometer is above the sea-level. The weather also depends on other circumstances than atmospheric pressure. A thermometer is usually fitted on the case of a barometer.

Aneroid Barometers. The principle of the aneroid barometer has been explained on page 1139. The illustration [21] will be described in detail as it serves to explain the exact working of an aneroid. The outer case and the face of the instrument are removed, but the hand is attached by its collet to the arbor. A is the corrugated box which has been exhausted of air through the tube J, and hermetically sealed by soldering. B is a curved spring resting in gudgeons fixed on the frame-plate and attached to a socket behind F, in the top of the box. A lever, C, joined to the stout edge of the spring is connected by the bent lever at D with the chain E, the other end of which is coiled round and



21. ANEROID BAROMETER

fastened to the arbor F. As the box A is compressed by the weight of the atmosphere increasing, the spring B is tightened, the lever C depressed, and the chain E uncoiled from F, which is thereby turned so that the hand H moves to the right. In the meantime the spiral spring G, coiled round F and fixed at one extremity to the framework and by the other to F, is compressed. When, therefore, the pressure decreases, A and B relax by virtue of their elasticity; E slackens, G unwinds, turning F, which carries H to the left. Near J is shown an iron pillar cast as part of the stock of the spring B. A screw works in this pillar through the bottom of the plate by means of which the spring B may be adjusted to the box A so as to set the hand H to read on the scale according to the indications of a mercurial barometer.

Barographs. These are self-registering barometers. The principle of registration is either (1) photographic; (2) mechanical; (3) electrical; or (4) by balance. The photographic method consists in moving a strip of sensitive paper at a given rate behind the top of the mercury column of a barometer. The mechanical method is by means of a float as in the wheel barometer, the motions being communicated to a pen passing over a revolving drum of ruled paper. The electrical method has one pole of a battery in contact with the mercury in a siphon barometer, and at fixed intervals of time the platinum contact point at the other pole of the battery is made to descend the open limb of the barometer until it comes into contact with the exposed mercury or a metallic float, when the circuit will be closed. The current caused by this closing of the circuit can be utilised in several ways to record the height of the mercury column. The balance method works by gravity and is known as the *steelyard barograph.* The balance arm resting on the mercury is counterpoised, the differences or movements being recorded. These are for accurate determinations, but the barographs working on the aneroid principle are the most popular and are accurate if precautions are taken occasionally to check the records by a mercury barometer. The instruments have from two to six exhausted boxes coupled up, and the combined motion of the vacuum boxes is communicated to a recording pen by means of multiplying levers.

Chemical Weather-glass. The chemical weather-glass or camphor barometer is a tube of a chemical solution which thickens or clears up according to the variations in the weather conditions. Glass tubes 10 in. long and $\frac{3}{4}$ in. diameter are nearly filled with the following liquid: camphor, 2 dr.; potassium nitrate, $\frac{1}{2}$ dr.; ammonium chloride, $\frac{1}{2}$ dr.; dissolved in absolute alcohol 2 oz., water 2 oz. The contents of the tube must be uniform when filled. The tube is fastened to a flat piece of wood in the same manner as a thermometer. This weather-glass should be exposed to the north, shaded from the sun. A good deal of the changes which take place in the liquid depend on the temperature, but that is not the only factor in affecting the chemical solution. The changes of the solution signify the following:

Clear liquid, bright weather.

Crystals at bottom, thick air, frost in winter.

Dim liquid, rain.

Dim liquid with small stars, thunderstorms.

Large flakes, heavy air, overcast sky, snow in winter.

Threads in upper portion of liquid, windy weather.

Small dots, damp weather, fog.

Rising flakes which remain high, wind in upper air regions.

Small stars, in winter on bright, sunny days, snow in one or two days.

Another form of chemical barometer consists of a figure wearing a dress saturated with a solution of cobalt chloride. In damp weather the dress changes to a pink; in fine, dry weather to a blue. A piece of catgut on tension is also very sensitive to changes of moisture and this fact is taken advantage of in the weather indicator which consists of two little figures. One of the figures carries an umbrella, and, when the catgut is affected in a certain direction, this figure comes out of an aperture and indicates wet weather. When the catgut is twisted in the opposite direction a figure in summer attire appears from another aperture. The familiar changes in the feel of a piece of seaweed which is popularly used as a weather guide depends on the quantity of salt in the tissues of the seaweed.

Measurement of Atmospheric Motion. The direction of the wind is indicated by a wind vane or common weathercock, while the effect of the wind is shown by anemometers, the pressure suction or power of rotation being made apparent. Of the various types of anemometer the most frequently used is that known as the Robinson, one pattern being shown in 22. Four hemispherical cups are mounted at the ends of two crossed arms supported horizontally on a spindle. When exposed to the wind the unequal pressure on the convex and concave surfaces of the cups causes the arms to rotate, and the number of revolutions is recorded by a simple counting apparatus. The dial is graduated to show the number of feet or miles of air which has passed. The diameter of the cups is from 4 in. to 9 in. and the spindle rotates on ball bearings. Another type depends on the suction which the air produces as it blows past an orifice, or the pressure which it exerts when blowing into a tubular opening which is turned by a vane so as to be always facing the wind. These instruments are also made self-recording.

22 ROBINSON ANEMOMETER

Measurement of Aqueous Vapour. Absolute moisture in the air is measured by chemical means, or by determining the temperature of saturation known as the dew point. The instrument is called a *hygrometer.* The wet bulb thermometer gives a rough indication of the humidity or dryness of the air. The measurement of the rain is done in a rain gauge or pluviometer. To measure the fall of snow it is usual to reckon that a foot of snow equals an inch of rain. Recording rain gauges are of two types. In one the rain collects in a bucket which tilts over each time it is filled, the number of tilts being recorded on a revolving drum. The other pattern depends on the employment of a float which as it rises on the water records its motion on a revolving drum. An instrument which automatically records the direction of the wind, velocity of the wind, temperature of the air, pressure of the atmosphere, and rainfall is known as a *meteorograph.*

RESPIRATORY ILL-HEALTH

Some Common Diseases of the Respiratory Organs. Their Causes and Symptoms. Nose and Throat Troubles. The Growth of Consumption

By Dr. A. T. SCHOFIELD

THE respiratory organs are peculiarly complicated, delicate, and sensitive in structure and function. Forced to inspire seventeen times a minute whatever air is next the mouth and nose, they are the first to be affected by the endless impurities, poison, and bacteria with which the air swarms; and very many of those respiratory affections that at one time were put down to catching cold are now proved to be due to infectious germs inhaled in ordinary respiration.

Causes of Respiratory Troubles. The climate of these islands, so capricious and variable, has, of course, a great deal to answer for in these diseases.

Then, again, there are the vagaries of fashion to consider. Disturbances, too, of the circulation in the lungs and mucous membrane of the air passage are very common owing to the complex nature of the blood supply to their parts.

The delicate lung tissue itself is peculiarly liable to degenerative changes; the respiratory system as a whole is specially under nervous influence, so that a large number of its diseases are directly or indirectly of nervous origin.

We may now pass on to consider some respiratory diseases in detail. We will begin with the nose, and the first respiratory trouble that may be referred to is not using it for inspiration. Breathing through the nose is a safeguard against many respiratory diseases. It warms, moistens, filters and perfectly purifies the air, so that it cannot injure the delicate lungs; and yet by a strange perversity nearly one-third of the population, perhaps more, cannot habitually inspire through the nose, but take in all the air through the mouth, to the destruction of the teeth, the drying of the tongue, and the swallowing of the disgusting dust with which town air is so often laden, to say nothing of the admission of this raw, dirty fluid direct to the lungs. There are, of course, in some cases obstacles to breathing through the nose, but in most people it is simply a bad habit.

Diseases of the Nose. The most common obstructions nowadays are adenoids, or growths at the back of the nose, reaching from the throat, that obstruct the passage of the air. They are common in school-children, and not only obstruct the breathing, but exercise a prejudicial effect on the mental development, making the child heavy and stupid. They should, therefore, be removed as soon as possible.

Polypi in the nose are softer growths. Both cause the speech to be nasal, and if large may induce deafness. The nose may also be obstructed by a thickened or crooked septum between the two nostrils. This also requires operation. Bleeding from the nose, resulting from congestion and bursting of the small veins, is sometimes violent. It is seldom as dangerous as it looks, and is often a relief to the congested brain.

The nose has a very sensitive mucous membrane and is liable to inflammation not only from catarrhs, of which we shall speak, but from special irritants, as in hay fever or hay asthma. In this the mucous membrane of the nose is specially affected, but the eyes and throat often suffer as well. The general irritant is the pollen of grass and flowers. There is constant sneezing (Nature's effort to get rid of the irritant), running at the nose, cough and sore eyes. The cure consists in stopping all irritation by living in towns or by the sea, and in a little cocaine solution on cotton wool being inserted in the nose. Bad cases require medical advice.

Diseases of the Tongue. In the tongue we have several diseases. Glossitis is a rare inflammation of the tongue, but ulcers of the tongue are common and not very easy to heal. If they are small and not hard round the base they are not dangerous; but if they are hard with a bad discharge a doctor should be seen at once.

Cracked tongue is very common in dyspepsia, and is troublesome to cure, though in all affections of the mouth and tongue it must ever be remembered that the saliva itself has a very healing effect. The mouth itself, apart from the tongue, may be ulcerated, and the same importance attaches here to a hard base and a foul discharge which indicates medical treatment. In children small ulcers are common, caused by not cleansing the mouth after feeding. A white coating to the tongue and mouth called "thrush" is also common from the same cause. The home treatment is to rub the tongue well with glycerine and borax.

Throat Troubles. Sore throats are of great variety. They may arise from indigestion, colds, debility, infection, etc. We get pharyngitis, or inflammation of the back of the throat, in scarlet fever and from colds, and from much speaking; also laryngitis, or inflammation of the larynx, which lies just in front of the gullet and may be acute or chronic. It arises from infection, colds, and over-use of the voice. There is in fever loss of voice, some difficulty in breathing and swallowing, with often a hard, brassy cough. When this occurs in children it is sometimes called false croup. True croup (so-called), with the formation of membrane, is really diphtheria. The danger, of course, in acute laryngitis is suffocation, and for this surgical interference by tracheotomy may be necessary. Chronic laryngitis often

accompanies consumption, and, in these cases, is tubercular in character. The simple form is the result of continual catarrhs or of voice strain. The variety common to public speakers, and very hard to cure, extending up into the pharynx, is called "Clergyman's Sore Throat." Mild laryngitis, acute or chronic, is relieved by inhaling a teaspoonful of Friar's Balsam in half a pint of *boiling* water.

Tonsilitis. Tonsilitis, or quinsy, is a painful affection of the mouth, mainly involving one or both tonsils. The inflammation is generally so severe that an abscess forms in the tonsils which is exceedingly painful until it bursts. It is caused by some poison or by cold, and is common in youth. There is fever, redness and swelling, pain in swallowing, and it generally takes from a week to a fortnight to run its course. Even when swallowing seems almost impossible a little warm milk can be trickled down, for the throat never really closes. Quinsy is much relieved by holding in the mouth hot water in which poppy heads have been steeped. All food taken should be very soft.

There may also be a chronic enlargement of the tonsils that calls for operation. This does not consist, as is often thought, in removing the tonsils, but in cutting a slice off the front of each, which both reduces the size, and, owing to the harder scar tissue that forms, renders them less liable to inflame. Occasionally a relaxed uvula requires shortening, which can be done without pain with a pair of *clean* scissors.

Aphonia, or loss of voice, is not only, as we have shown, a symptom of laryngitis, but may occur independently as the result of the paralysis of one of the vocal cords on which phonation depends.

Catarrh. We now come to a larger class of diseases that involve more extended tracts of the respiratory passages.

Catarrh is the most common of all diseases affecting the respiratory organs and the passages leading to them. It is an inflammation of the mucous membrane that lines all these tracts. If neglected it steals down the windpipe and produces hoarseness and soreness of the chest; if still neglected it may travel along the lungs and become bronchitis, and it may continue still further and become inflammation of the lungs, so that a neglected catarrh may in weak persons end in pneumonia.

The causes are generally a mild specific germ that invades the air passages, coupled with a chill of some sort which lowers the resisting power.

The symptoms are weakness, aching of head, pain across the forehead, running at nose, and perhaps eyes; hoarseness, sore throat, furred tongue, slight rise of temperature, no appetite, and thirst. The mucous membrane is in a state of great irritation, and pours forth a copious liquid secretion at first, which, as the disease advances, gets scantier and thicker, the whole course of the disease, if it does not extend, being from ten days to a fortnight. It can be cut short by treatment in simple cases, which consists mainly in staying in a warm temperature of 60° F. to 65° F. till it is cured. A little paregoric elixir will stop excessive discharge.

Bronchitis. Bronchitis is an inflammation of the bronchial tubes of the lungs as distinguished from the lung tissue inflammation, which is called pneumonia. Distinguishing broadly from leading pulmonary diseases one might say that pleurisy (properly, by analogy, pleuritis—"itis" signifies inflammation) is an inflammation of the outer covering of the lungs; bronchitis, of the air-tubes of the lungs; pneumonia (properly pneumonitis), of the air cells of the lungs; while phthisis is consumption of the air cells coupled with actual destruction of the lung tissues, which does not take place in any of the other three cases.

Bronchitis may well be divided into acute, chronic and capillary. Acute bronchitis is a somewhat dangerous disorder owing to the tendency to spread to the cells and become bronchopneumonia. There is always some fever, ranging to about 102° F.; there is tightness of the chest and short breathing with wheezing. There is a constant, troublesome cough, with some frothy mucous expectoration. The pulse becomes more rapid; there is headache and a general feeling of weakness and illness. It is not common in old people. The cough in bronchitis is of the greatest value in clearing the lungs, and no attempt should be made to stop it. Sometimes there is but little expectoration; the chest is very tight, and the expectoration is dry; in either case the air requires to be moistened with steam from bronchitis kettles.

One form of acute bronchitis is very dangerous, because it principally attacks the very smallest tubes leading to the air cells. It is called capillary bronchitis. It attacks very young children, who die very rapidly from sheer inability to breathe. In these cases the promptest measures are alone of any avail. It is readily distinguished by the bluish colour of the child, and its gasping and fighting for breath.

Chronic Bronchitis. Chronic bronchitis is a common and distressing affection in this country owing to its constant recurrence in the autumn and winter of each year. In chronic bronchitis, or with bronchitis only, there is little or no rise of temperature, but a constant hacking cough, made worse on any exposure or change of temperature and often lasting for months, and not disappearing till the spring. If it be dry, and the expectoration scanty, it becomes more distressing, and may produce emphysema. This consists of the bursting, through strain, of the air cells, so that they form small cavities in the lungs full of air. In this disease, the result of chronic bronchitis, the breath becomes permanently short, and the condition remains even when the bronchitis is gone, from which the lung does not get destroyed. On the other hand there is no restoration of the cells, so that the lungs get overfull of air and over expanded. Such people cannot run or even walk fast. This condition once established persists through life.

The miseries connected with chronic bronchitis are so many that it is a great pity to let

it get firmly established; when any form of bronchitis attacks a person, every effort should be taken to cure it as quickly as possible lest it extend or become chronic. In all these varieties of bronchitis a doctor must be seen.

Pneumonia. Pneumonia is of two distinct varieties—lobar pneumonia, which is a distinct disease, due to a specific germ, and broncho-pneumonia, which generally arises from an extension of bronchitis to the air cells of the lung.

Lobar pneumonia generally attacks one lung, the right twice as often as the left, and the lower lobes more frequently than the upper, whereas consumption almost invariably attacks the upper lobe first. It has a definite cause, and begins quite suddenly like one of the infectious fevers. There is a sudden rise of temperature to 103° F. or more. There is little or no cough or expectoration, but the breathing is hurried, and the face flushed. The whole lung is congested, and but little air reaches the affected lobe or perhaps the whole side. Simple congestion resembles this pneumonia except that there is no fever. The breathing becomes increasingly difficult until the cough begins; with this there is a little scanty expectoration of a rusty colour. It is tinged with blood, which gets more copious as the cough increases. On the tenth day, or thereabouts, a change generally takes place for the better; the temperature falls, and the disease gradually abates till in a fortnight or three weeks the patient's lung is comparatively well again (there being no distinction of tissue in this disease), though the patient remains very weak for weeks after. This disease does not spring from bronchitis, nor does it tend to return like it, nor does it continue indefinitely.

Broncho-pneumonia differs in all respects from lobar pneumonia. It generally invades both lungs and extends gradually. It is nearly always preceded by bronchitis, and is common among children. It runs no certain course, and may continue a long time, and even become chronic. It is more liable to recur than lobar pneumonia.

Pleurisy. Pleurisy is constantly associated with pneumonia, through the inflammation extending through the lung wall to the membrane covering it, but it often arises alone. Between the lung and the chest wall is a double bag on each side called the pleura, containing a small quantity of fluid, so that one surface slides on the other and thus forms a sort of joint as the lung moves. If this membrane gets inflamed the two layers tend to stick together, and when the lung moves a sharp pain or "stitch" is felt at the spot, which is very significant of pleurisy. If the inflammation continues a quantity of fluid is poured out into this closed bag and may amount to several pints, which is generally drawn off by tapping it through the chest wall, as otherwise it takes such a very long time to absorb.

Sometimes a sharp pain is felt in the ribs that is very like pleurisy, which is only neuralgia of one of the veins that run round the ribs to the breast-bone, and is called "pleurodynia."

Asthma. Asthma is a distressing disease which consists of spasmodic contractions of the bronchial tubes for central nervous causes. Fits of asthma commonly occur in the night, when the patient is suddenly aroused from sleeping, and a feeling of suffocation ensues. He is obliged to spring out of bed and rush to the window for more air. The eyes are staring, and the patient feels that he is dying, although asthmatic patients are long lived. The frequency and violence of the attacks depend a good deal on where the patient lives. The disease is often distressing in clear country air, and disappears in a smoky town. A change to the other side of the street even may cause it to disappear. Between the attacks the lungs are healthy and the patient well. When the disease has lasted a long time the patient gets high shoulders from a forced effort at respiration. It is often hereditary, and may last for years.

Phthisis. We now come to phthisis, that dread disease that alone destroys the lung it attacks. This is the most dreadful and fatal disease in this country. Its ravages are still terrible; over 50,000 young people die of it annually. It advances in the patient with noiseless tread, and deceives him with hopes of recovery to the last day of his life. It kills by inches.

The seed, through which alone consumption is propagated, is a tiny micro-organism called the bacillus tuberculosis. It is a small fungus like a rod; 600,000,000 can lie on one square inch, and, if placed in a continuous line, would extend ten miles. They multiply at the rate of 1,000,000 an hour. They are coughed up in countless myriads and expectorated, and as they dry, are blown about to infect all around who are susceptible.

Consumption is now being most vigorously combated, and may be made a notifiable disease. We have already given full information respecting its ravages in different countries in the section on Health [page 5409], under the head of Endemics, and will only add a few particulars about its cause.

It nearly always begins at the tops of the lungs, and there can be no doubt that the exposure of the neck, and, above all, the way in which it is sometimes overheated with furs and at other times left bare, greatly weakens the resisting power of this part.

The left side is that most commonly attacked. The temperature is never steady, but goes up at night, and falls in the morning. The expectoration and cough is frequent. Emaciation rapidly sets in as soon as the lung begins to break down. Cavities are formed, sometimes taking the place of an entire lobe. In this connection, however, the greatest exaggeration prevails, and patients are said to have "lost a lung" when only a few inches of tissue have been destroyed. The tendency of the disease is to spread until death ensues from exhaustion. The spirits, however, keep up to the last, and the patient is seldom gloomy or downcast, while the hectic flush on the cheek gives a deceptive appearance of health.

CARVING IN RELIEF

The Most Interesting Form of Wood-carving. The Sweep Strokes. How Relief Carving is "Faked." Intaglio and Perforated Work. Foliage

Group 2
CARVING
3

Continued from page 6046

By F. WELLESLEY KENDLE

WE now come to the most interesting of all styles of wood-carving, which consists of rounding down the surface to make it look like a natural object, whether a leaf, an animal, or a landscape.

A Panel in Relief. Set out the panel on white deal [52]. Firm the outline as usual. Ground out and complete the lozenges and ribbons. Sink the grooves BBB between the leaves to their full depth with a V tool. Leaning the tool first to one side and then the other, rough out the curved surfaces. With a flattish gouge model it still more perfectly, furnishing each leaf with a double convex contour, working all the margins to nearly ground level and letting each blend at its root with its fellows. It is better not to attempt to smooth the work piecemeal at this stage, rather strive to get the general effect as a whole; then, and not till then, add the finishing touches with gouges that more nearly fit the curves.

Now chip down the N.E., N.W., S.E., and S.W. corners of the balls CCC (if we may apply the term corner to a circular figure); next, with the concave surface of a flattish gouge lower the wood N and S nearly to ground level; with a tool whose radius is nearly as quick as the circumference of the ball, round it off with a series of sweeping strokes, never making them quite in the direction of the grain, but with a forward, gliding, rotating and ever downward movement of the tool, so that the butt of the handle describes an upward spiral sweep.

50. SWEEP STROKE, FIRST POSITION

51. SWEEP STROKE, SECOND POSITION

The Carver's Freehand Stroke. It is impossible to devote too much time to the acquisition of this particular stroke, which is to the carver what freehand is to the artist. An adept will produce excellent effects with a turn or two of the wrist, while the amateur will flounder about trying to round off a figure by nibbling away at it with straight, pushing cuts; added to this its employment reduces the troubles caused by grain to a minimum.

Having studied the effects of the sweep stroke made with the concave surface of the tool, the reverse must be practised. Again a remarkably bold design is selected [54]. The general moulding is too well indicated to require any explanation; it need only be said that the original fifteenth century font from which it is taken is only carved to the depth of about ⅛ in., the delusive appearance of solidity being suggested by broad bevels, and slight undercuts.

The Reverse Freehand Stroke. Firm the outline and ground out as usual. Rough out the twisted leaf. Take a gouge with an arc corresponding to the curvature of the leaf and not more than ½ in. wide. Let the back of the tool rest nearly flat at A, A¹ [50]. Sweep it onwards with a double curve that leaves the handle perpendicular and the blade at right angles to its first position by the time it reaches B, B¹ [51]. Do this with a continually gliding cut, so that whereas at A¹ the portion of the edge nearest the carver had most of the cutting to do, by the time it has reached B¹ it is practically free, and the other end of the blade is making the final downright cut. If too quick a gouge be used an awkward looking notch is left at the tail of the stroke; if too flat a one, it will probably hitch in the wood half way through the sweep. If the gouge be too small, the manœuvre will have to be repeated once or twice; if it be too large, the feat is almost impossible.

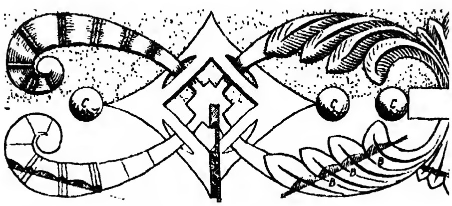
Round the outside of the turnovers. Leave the edges of the leaf high, except at CCCC, where they must be lowered almost to ground level. The notches are cut with gouges held on the slant, bevelling one side and undercutting the other. Model the wavings of the leaves with gouges, noting particularly the rich double wrinkle at DD. Round off the balls, hollow their sockets, and complete by carving the bosses around them, and adding the veins with a V tool.

So all-important are these sweep strokes that a second example has been figured with more numerous but smaller turnovers [53].

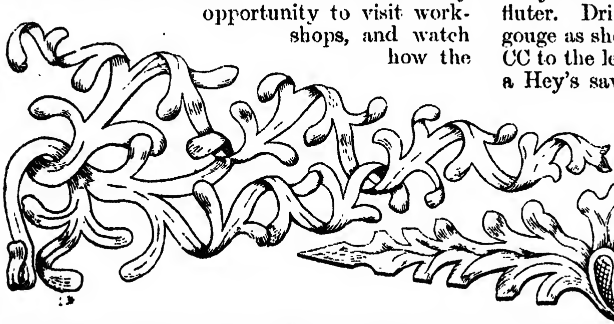
Knowledge of Clay Modelling and Shading. Should doubts arise as to how a subject should be treated, model it first in clay or plasticine. If this be done now it will be noticed that many of the folds in the copy are

out of drawing. This is a common fault, for the carver is not always a first-class artist, and the medium he works in is not the most tractable. So useful are models at this stage that a course of modelling in clay should invariably precede that of carving in wood; the student should also be able to convert an outline drawing into a shaded study [see ART, page 1217, and DRAWING, page 1533].

The More Complicated Designs. Having learned to vein, flute, firm, ground, slope, round, and turnover, the execution of more complicated designs, such as are shown in [56], is simply a matter of combining these several methods. If a man can carve a single leaf or petal, he can, with patience, execute an entire flower. He should seize every opportunity to visit workshops, and watch how the trick is done; he will learn more in half an hour by so doing than in half a lifetime from manuals.



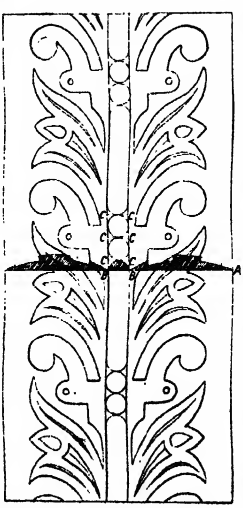
52. JACOBEAN RELIEF CARVING



53 AND 54. CARVING FROM FIFTEENTH CENTURY FONT (PILTON) SHOWING REVERSE FREEHAND STROKE WORK

Modern Fakes. Relief carving nowadays is frequently "faked" by gluing a fret of the design to the panel, and rounding off afterwards. This saves all the trouble of laboriously reducing a large portion of the surface to ground level. A more legitimate application of this was the practice of augmenting the effectiveness of a simple panel by adding a boss or mask, such as may be seen in the panelled room from Exeter, now in the darkest corner of South Kensington Museum. Much of the work executed by Grinling Gibbons's pupils and imitators was not true carving but *appliqué*. Many of the elaborate Devonian mantelpieces, decorated with flowers and drooping sprays, have had each leaf, stem and flower carved separately, glued into position, touched up with putty, and finished off with paint. The French brought this style to great perfection, and adopted *sculpture à la scie* for the reduplication *ad infinitum* of floral wreaths and garlands. Further particulars will be found in "Sculpture sur Bois," one of the *Encyclopédie-Roret* series.

Mouldings and Friezes. For mouldings and friezes the pattern is generally a repeat, and may run either vertically or horizontally. An easy example [55] of the former, taken from the same source as 45, 46, 47, 50, and 52, is given. The shaded portion shows the section. Run out a strip of oak with the moulding plane. Stencil the pattern on the wood. In firming the outline, the tool should always be pointed at the centre of the circle of which the face of the moulding happens to be the arc; by this means a clean edge throwing a pleasant shadow is ensured. At the extremities of the chord, AA, let the ground die away to the level of the surface. Vein with V or fluter. Drill the small holes with a very quick gouge as shown in 33 [page 6043]. Saw down at CC to the level shown in the section at BB, with a Hey's saw; round the balls and the ends of the bolsters as described.



55. JACOBEAN PANEL MOULDING

When cutting mouldings to occupy a horizontal position, this fact must be remembered when the work is on the bench. Take, for example, the familiar "egg and tongue." The sinking cuts, which are necessary to free the wood scooped from the hollow in which the egg lies, must be parallel with the horizon, and each upward sweep must meet it at right angles.

Flutings of pillars and pilasters may be carved with gouges, though it is far easier to run them out with a moulding plane, or a travelling *bur*, leaving the carving tool nothing to do but to trim up the extremities of each. Spirals, which were formerly carved with gouges from start to finish, are now simply turned on a lathe.

A symmetrical twist may be easily obtained by winding a strip of paper, down the centre of which a line has been drawn, round the post to be carved, and marking the wood at its edges. Sink a furrow along this line with a V, keeping it on an even keel, and always at the same inclination to the axis of the cylinder.

56. PANEL IN RELIEF CARVING FROM A SIXTEENTH CENTURY ITALIAN MARRIAGE COFFER

It is most important that this groove should be the same depth throughout if the post is of the same thickness all the way up, or taper gradually should it do likewise. Rough out the curves with flat gouges from the bottom of the furrow to the central line on the paper. Smooth with a gouge that is just a shade flatter than the curve of the spiral; this will give more play, and is less likely to get hitched than one which fits exactly.

Intaglio Work. Still another method of ornamentation is *deep, intaglio* or *die sinking*. This is the exact reverse of relief carving, for the surface remains plain and the pattern is sunk. It is quite easy for any one who has been accustomed to relief work. The main features of the design are scooped out with bent gouges, details are added with quicker tools, and veins added last of all. It is of great assistance to the carver if he takes a squeeze of his work in plasticine from time to time, in order to judge of the general effect. By disarranging the lighting, and causing shadows to fall in a contrary direction, a casual glance will receive the false idea of relief.

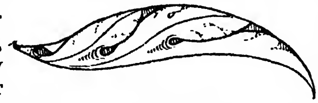
The Value of Keeping Records. Whenever possible, copies should be taken of good work. Putting on one side the obvious methods of sketching and photography, this may be done with a "squeeze." Oil the panel well, and proceed to cover it with sheets of very wet paper, pressing them thoroughly into every crevice; add layer upon layer of coarse brown paper soaked in size or very thin glue. Squeeze out all superfluous moisture. Leave in position to set sufficiently well to permit of removal without danger. When this is dry, plaster of Paris casts can be obtained from it, or others having the appearance of wood itself, by using a mixture of equal parts by weight of gelatine, wood sawdust, and phosphate of lime, moistened sufficiently to make into a stiff paste. Leather well soaked in hot water may be used, or a lump of soap, clay, or putty. Flat carvings may be "rubbed" with heelball or black lead. This procedure is inapplicable to relief; still, a very good general idea of a panel can be obtained by the aid of a newspaper and a rather greasy rag. Press the paper down on the pattern, gently moulding it as much as possible with the fingers; on going over it with the greasy rag the printing ink will be smudged most wherever the relief is highest.

Work in the round is erroneously believed to be the most difficult of all styles to accomplish; in reality it is nothing more than panels in relief carved on both sides. To minimise labour and to prepare the block, it is useful to take a profile of the copy with a strip of lead or malleable zinc. Apply this to the wood, and pencil the outline. Take the opposite profile and transfer as before; then treat the sides similarly.

Carving in the Round. Remove with the saw as much of the waste wood as possible. Next whittle away superfluous material with mallet and gouge, proving progress with the metal guide or with callipers. Should any detail cause anxiety, model it over and over again, or work it out on a soft piece of wood; it is better to devote a few minutes to this than to waste the labour of weeks by perpetrating an irremediable error. Take off too little rather than too much; superfluous wood can be removed, but additions are not so easy.

If he should be nervous about starting—and most novices are—let him begin on some ridiculously easy task, such as sharpening a pencil very neatly or carving animals such as those in a Noah's Ark. Afterwards he may try a poppy head ornament, which he will find to be nothing but two studies of foliage in high relief placed back to back. The human figure and drapery are the most advanced style of all, just as is the case with relief, but the student will find it far easier to hack out a head, or other figure work, in high relief than in low relief.

Tracery and Perforated Work. Tracery and perforated work is an advance upon fret cutting. The ground is entirely removed, leaving lights. It presents no difficulties to the good wood-carver; but it does not pay him nowadays to execute it. Modern machinery with its lathes, planes, bits and burs, can rip out tracery mouldings in a hundredth part of the time in which an expert workman can carve it. So with panel reduplication by mechanical means. It is wonderful to watch a species of glorified pantograph, armed with a revolving bur, copy the design with hardly any manual assistance; but it is not wood-carving, and its servile imitation destroys half its charm.



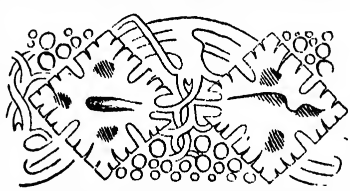
57. ACANTHUS LEAF DESIGN

Foliage. Veins of leaves are frequently carved in relief instead of being sunk with a V tool or fluter. Twin furrows are run along with a V, leaving a medium ridge; the surface is worked down to the foot of this, which is trimmed to shape, tapered at its extremity, neatly joined

at its branchings, and made to die away into the leaf stalk. The macaroni is a handy tool for this work, though it cannot be used close to a junction.

Though the flora of the wood-carver often bears but slight resemblance to that of the botanist, there are certain well-defined points common to each. Thus, veins, though showing as depressions on the upper surface of a leaf, appear as ridges below; remember this when treating a turnover. Noting the general characteristics of a plant, the student will the better appreciate the skill with which the mediæval artist selected and treated his subjects, and will see why it was that the lily, vine, thistle, oak, passion flower, poppy, dandelion, rose, and, above all, the acanthus [**57**] were such universal favourites, and why the coarse and perishable nature of his material led him to limit his efforts to purely decorative adaptations.

The Vine and the Rose. The vine, not only because of its adaptability for ornamental purposes, but also because its religious symbolism, was constantly utilised in ecclesiastical architecture. The carver treated it in two distinct ways. Sometimes the leaf was inscribed within the limits of a symmetrical pentagon, its four eyes and the point of junction with the leaf stalk being arranged at the corners of a similarly shaped but inverted figure. At other times the leaf was placed within the area of a square or lozenge, as may be often noticed on the friezes and crochets of late Gothic work [**58**]. The thistle and dandelion are adapted to follow the lines of acute angled triangles. Both are invaluable for filling in odd corners of tracery.



58. VINE CARVING (ATHERINGTON CHURCH, N. DEVON)

Ivy falls within the lines of a pentagon, and occasionally those of a isosceles triangle.

The rose is conventionally depicted as a symmetrical five-petalled flower, each petal furnished with a fold-over having a bracket-shaped edge. A common sixteenth century ornament was the Tudor rose, the union of the Houses of York and Lancaster being symbolised by the exhibition of both flowers in one boss, one superimposed upon the other, their petals alternating.

The Oak Leaf. Perhaps no other leaf had so many liberties taken with it by German carvers as the oak; they more than conventionalised it, they exaggerated, elongated, stunted, twisted, and folded it, till it became almost unrecognisable. They left it with widely indented margin, rectangular lobes, rugged and misshapen, stunted, gnarled, and bent like its parent tree and yet effective and picturesque.

The acanthus [**57**] is a characteristic feature of renaissance design; at first sight it appears a difficult and complicated subject, but on dissecting its structure it is found to be contained within the limits of two concavo-convex lines, which start from a common point, separate gracefully, and finally coalesce, the leaf bellying and swelling between them. This simplicity of outline is now broken by subdividing each leaf into a number of lobes, the junction of each with its fellow being marked by an "eye." Each lobe in turn is deeply serrated. A vein runs down the centre of each lobe and pipings start from every eye, all losing themselves at a common point. Whether viewed in full or in profile its main lines are always the same, never parallel, never crossing, but each a graceful curve radiating from a common point and strictly subservient to an outline of the greatest beauty and simplicity.

Finishing and Ageing. It cannot be impressed too strongly upon the novice that sandpapering carved work to "make it look smooth" is an unpardonable crime; a few touches with the scraper or rubbing down with a bone are bad enough, but "papering" is the rankest of all heresies. There is nothing to be ashamed of in tool-marks, for at least they show the work is genuine hand-wrought stuff.

To keep the carvings clean light woods may be given a thin coat or two of "egg-shell" varnish; oak and chestnut should be treated to a soaking in boiled linseed oil, followed by plenty of "elbow-grease," using a stiff brush. Beeswax and turpentine should be avoided; they clog the corners of the work and destroy its sharpness. Most other hard woods may be French polished.

It is frequently necessary to stain new wood in order to make it match older work. Apple, pear, and box can be aged with a weak infusion of saffron; lime, ash, kauri and white wood with turmeric or a solution of chloride of tin; mahogany with Brazil-wood. Oak can be slowly darkened with a 2 per cent. solution of bichromate of potash to which ½ per cent. of dilute nitric acid has been added. The process takes a few months, but the tone gained is particularly rich and warm. Veining and figure work can be brought into strong relief by treating first with a weak decoction of madder, and, when this is dry, painting with a solution of acetate of lead.

Blue-black is attained by a decoction of oak galls followed by a solution of green vitrol; jet black by a decoction of oak bark and then perchloride of iron; purple-black by logwood; brown-black by madder and acetate of copper.

Fuming. Oak, and other woods in a smaller degree, can be darkened very rapidly by exposing them, in an airtight box or cupboard, to the fumes of ammonia; but the weaker the dose and the longer the time allowed, the better the result. Storage for several years in a badly ventilated stable loft imparts a tone that cannot be equalled by any other method.

Wood-carvings may be preserved from the ravages of worm and rot by fumigating with calomel, formalin, or corrosive sublimate, by dressing with a solution of alum or of water glass, or, best of all, by impregnating the panel with hard paraffin under heavy pressure at a temperature of about 180° F.

LINK MOTIONS OF ENGINE VALVES

Action of the Link and its Imperfections. Zeuner's Diagrams. Their Value and Application

Continued from page 6072

By JOSEPH G. HORNER

THE method of operation of the slide valve illustrated on page 5642 is of a simple and elementary kind. No large, high-class engines have such a simple arrangement. But it is necessary to understand the principles, because the more or less intricate valve gears embody the elementary cycle of operations. The most familiar modifications are the various link motions, of which there are about half a dozen good and well-tried types. In England the Stephenson is the best known, but on the Continent the Walschäert is more common. The elements of the link motion may be studied in the Stephenson.

The link—the central feature—is a curved piece, the function of which is to bring about variations in the relations of the eccentrics to the slide valve. Two eccentrics are used, for forward and backward running respectively, and the engine so fitted, therefore, can not only be reversed, but worked at different degrees of expansion. In the extreme end positions of the link, the eccentric and valve rods are practically in line, so that the relations between whichever eccentric happens to be in gear to the valve are identical with those which exist in the simple valve gear without a link. But when the link is in mid-gear, the engine is inoperative. At intermediate positions from full towards mid-gear the cut-off is effected at earlier stages, and with increased expansive working. This is termed by the railway men *notching up*, because the reversing lever is held in notches which are arranged for graduated rates of expansion. When an engine is running light on a level the links are notched up, with economy of steam consumption.

The Elements. The elements of the motion [42] are the two *eccentrics* and sheaves, A, B, the eccentric *rods* C, D, attached to the *link* E, the *die block*, or sliding block, F, over which the link is movable, and connected to the valve rod. To shift the position of the link relatively to the die block, so bringing either eccentric rod with more or less approximation into line with the valve rod, *lifting links*, G, when vertical, or *drag links* when horizontal, are attached to one end of the link. The lifting, or drag links are pulled, or pushed by the *reversing lever*, H, acting through a bell-crank lever on the lifting links. The fulcrum of the bell-crank lever is in the axis of the *weigh shaft*, or rocking shaft J, on which the lever is keyed.

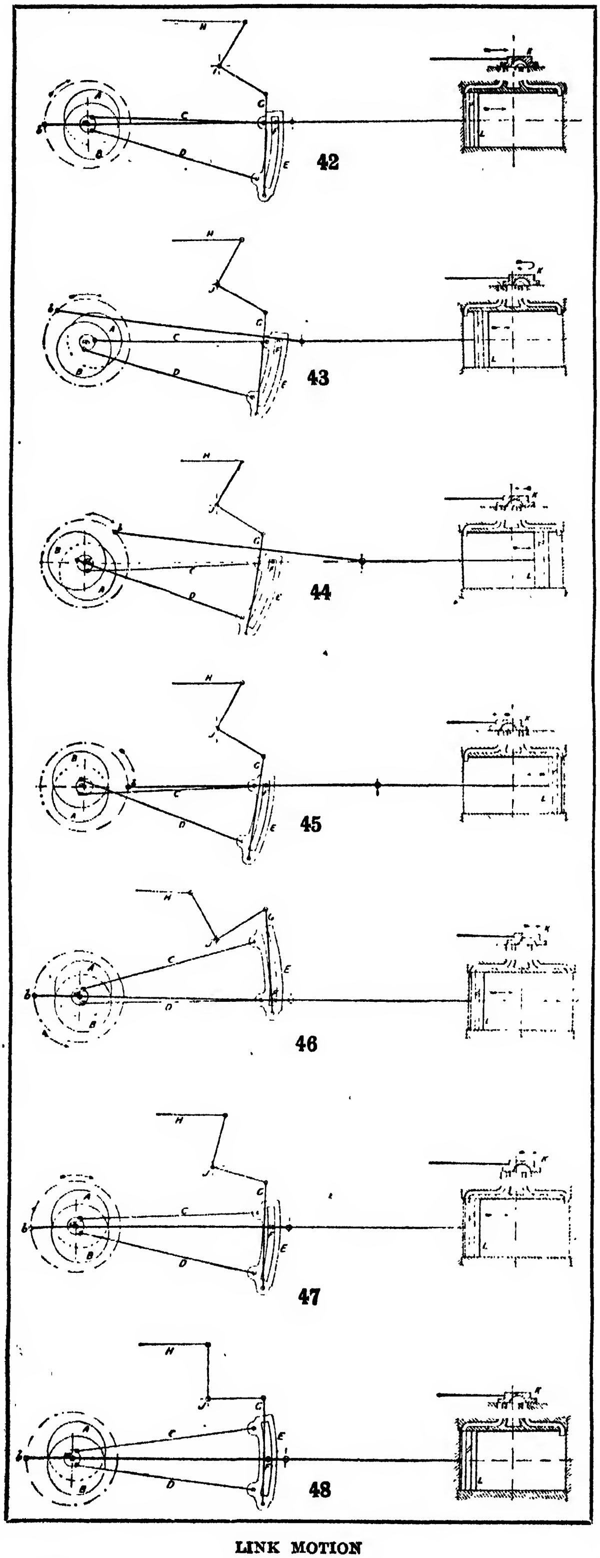
Action of the Link Motion. We shall trace out the action of the mechanism: In 42, in which the engine is on *dead centres*, *a* being the centre of the crank-shaft, and *b* the crank-*pin*, the forward eccentric A will come into operation, and lead, and the engine will run in the direction of the arrow drawn on the circle of the crank-pin. The reason is that the valve K being open to lead—that is, by the amount allowed for lead, say, from $\frac{1}{32}$ in. to $\frac{1}{16}$ in.—steam enters the cylinder behind the piston L, and causes it to move in the direction of the arrow. But in so doing, the crank-pin *b* must move in the direction of the arrow drawn on the crank circle. The full part of the eccentric A still pushes the valve wider open, and more steam enters behind the piston. This goes on until, in 43, the eccentric has advanced far enough to open the steam port to its widest, and then, the centre of the sheave being in line with the valve rod, the valve begins to return. It will be noted that steam is exhausting from the cylinder on the opposite side of the piston. In 44 the valve has returned, and closed the port, cutting off the steam at about three-fourths the stroke, after which the remainder of the stroke is accomplished by the expansive force of the steam enclosed behind the piston. The exhaust port is about to close. In the final stage of the stroke, when the crank-pin *b* is on dead centres, at the opposite side of the path from which it started [45], or 180° therefrom, the forward eccentric A is still 90° in advance plus the amounts of lap and lead on the other side of the centre *a*. The piston has reached the end of its stroke; it is cushioned by the steam entering by the opening to lead, and is about to return. The arch of the valve has opened the port to exhaust, so completing the cycle of one stroke of the piston.

Reversal. If now the link is lifted to bring the backward eccentric into line with the line of dead centres [46], the full part of the eccentric will lead the crank in the opposite direction to that in 42, or backward. This is clear, for though the valve is opened to lead exactly as it was in 42, the eccentric B, in opening the valve, leads and pulls the crank-pin *b* in the direction of the arrow. With the exception that the rotation is in the opposite direction, the sequence of events in the cycle is identical with that in 42 to 45. The opposite end of the link, that which is not brought into gear, is inoperative. It wobbles about, but does not affect the movements of the valve.

The effect of sliding the link in relation to the die-block [47], *notching up*, is to shorten the stroke of the valve, with the result that steam is cut off earlier, and worked at a higher ratio of expansion. But it also increases the opening to lead, and with it the amount of back pressure or cushioning.

If the link is brought into mid-gear [48] the valve will be open to lead at the termination of a stroke, but no motion can ensue, because the port becomes covered at once. But for the lead and lap no motion at all would ensue. An engine with the link in mid-gear would not run, though the throttle valve or regulator were wide open.

Imperfections. Around this common link motion much variety in practice exists, for it is only a compromise, and it lies mostly round the allowances for lap and lead, and especially the latter. Too much lead would be an evil in a slowly-running engine. The obliquity of the rods exercises a considerable influence, and to this is due the fact that the aim is generally to make the rods as long as is convenient, to lessen this obliquity, just as connecting-rods are made long preferably to being short. For the same reason the links are made as short as convenient, because bringing the centres of attachment of the rods closer together lessens their



LINK MOTION

obliquity. For the same reason, rods are made *open*, rather than *crossed*, when the full part of the sheaves comes between the crank axle and the link. They become crossed when the full part of the sheaves lies on the side of the crank-axle which is farthest from the link. The effect of crossing is to shorten their radius, because of their greater obliquity. This explains why the lead is greater at one end of the cylinder than at the other, greater in **45** than in **42**. This increase will be minimised the more the length of the rods is increased. The reason why lead is increased by crossing the rods is illustrated in **49**, where the rods, open, are shown at C, D, and the same crossed at C′, D′; *a* being equal to twice the lap and lead, *b* is the extra amount of lead due to crossing the rods. The reason why lead is increased by moving the link from full gear towards mid-gear is apparent from the diagram in **50**. When the engine is in full gear forward, the centre of the pin of the forward eccentric rod is at *a*, and that of the backward rod at *b*. By lifting the link to the centre, the rods describe arcs round their sheaves. The centre of the link is thus thrown farther away from the crank-axle by the distance *c*, with corresponding increase of lead.

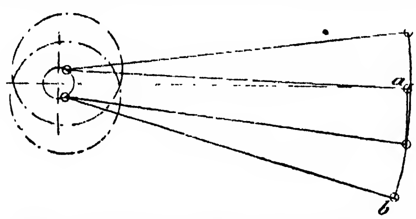
To neutralise the effects of increase of lead at one end of the stroke the general rule holds good: "Draw the centre line of the link with a radius equal to the length of the eccentric rods, measured from the centre of the joint at the other end."

Zeuner's Diagrams. The relative positions of crank and slide valve can be obtained by means of Zeuner's diagrams as follows. The principle is shown in **51**. Here *ab* represents the length of the connecting-rod, and *bo* that of the crank, *o* being the centre of revolution of the crank shaft: *cd* represents the length of the eccentric rod; and *od* the eccentricity or throw of the eccentric, *d* being in advance of the crank-pin *b* by 90° plus the angle of advance θ of the eccentric sheave. The length *ab* of the connecting rod may be set off from the extremes of the crank circle at *ef* to *e′f′*, which will give the length of the piston stroke. By setting off the length *dc* of the eccentric rod from the valve circle at *hi* to *h′i′*, the length of the valve stroke can be obtained.

Now draw *bj*, *dk* perpendicular to the line which represents the axis of movement of the piston-rod. Neglecting the obliquity of the connecting rod, *ej* will represent with sufficient approximation the distance *e′j′* through which the piston has moved at the position *b* of the crank. Set off *oc′* equal to *dc*, and *c′* will correspond with the mid-stroke of the valve. The valve has moved a distance of *cc′* from its mid-position for the position *d* of the eccentric sheave. Since *oc′* equals *dc* very approximately, therefore *ok* is

approximately equal to cc'. Next take half the radius od in **51**, and with it draw two circles in contact [**52**]. Draw ok' parallel with od in **51**, and join $d'k'$. Then, in **51** and **52** od equals od; the angle $d'ok'$ equals the angle dok, and the right angle $ok'd'$ equals okd. Therefore $d'k'$ is the radius vector, which is the line from the centre of the force to the point of the orbit where the body is supposed to be. This, if drawn parallel with any position of the eccentric will be approximately equal to the travel of the valve from its mid-position. In other words, the amount of movement of the valve is the same as the radius vector corresponding with that angle. Hence, by the embodiment of this diagram, the distance between the centre of the valve and its centre of movement for any position of the crank can be measured without calculation.

To apply the principle embodied in the diagram, the circles are rotated back through an angle of 90° plus θ, the angle of advance of the eccentric, as in **53**. This is done as a matter of convenience. The angularity of the eccentric rod being so small as to be negligible, as is evident in **51**, which is drawn to scale, and the radius vector being, therefore, approximately equal to the travel of the valve from its mid-position, all that



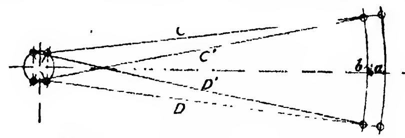
50. INCREASE OF LEAD TOWARDS MID-GEAR

remains is to bring this into line with the line of the crank. In **53**, take two lines at right angles with each other, aa, bb, and from aa set off the angle of advance θ towards the initial position of the crank, and draw the line cc at that angle. Then draw two circles in contact from centres $o'o'$, oo' being equal to half the radius of the eccentric. Then the radius vector od of the valve circles, drawn from o parallel with any position of the crank corresponds with the travel of the valve from its mid-position.

Completed Diagrams. The foregoing are drawn to the same relations and scale as the diagrams in **51** and **52**. But as it is impossible to be quite accurate when the valve circles are so small it is usual to draw these to an enlarged scale. The next figure, **54**, therefore shows them four times larger than the previous figures do. The valve diagram is here shown completed; bb' is in the path of the piston-rod, and aa is at right angles thereto; bb' is the crank circle, and the crank is moving from b' to b.

Draw the line cc at the angle of advance θ from $b'b$. Measure off od, oe, each equal in length to half the travel of the valve, and with centres $o'o'$ on these lines draw the two valve circles. The crank circle bb' is drawn to any scale or to full size. With centre o and radius equal to the outside lap draw the outside lap circle ll. If inside lap is put, then, with centre o and radius equal to the inside lap, draw the inside lap circle 2.

The port opens to steam when the valve has moved from its mid-position through a distance equal to its outside lap. A line, the radius vector,

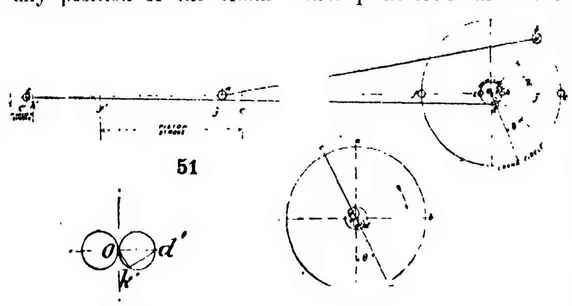


49. OPEN AND CROSSED RODS

drawn from o through the point i on the valve circle to cut the crank circle at i' shows the position of the crank when the valve opens. o 3 4 is the position of the crank when the valve closes, and the steam begins to work expansively. o 5 6 is the position of the crank when the valve opens to exhaust, and o 7 8 that of the crank when the valve closes to exhaust, and compression begins. On the lines drawn below **54**, the proportionate lengths of stroke of the valve rod are shown; o 4 is the period of admission, 4 6 that of expansion, 6 8 that of exhaust, and 8 2 that of compression.

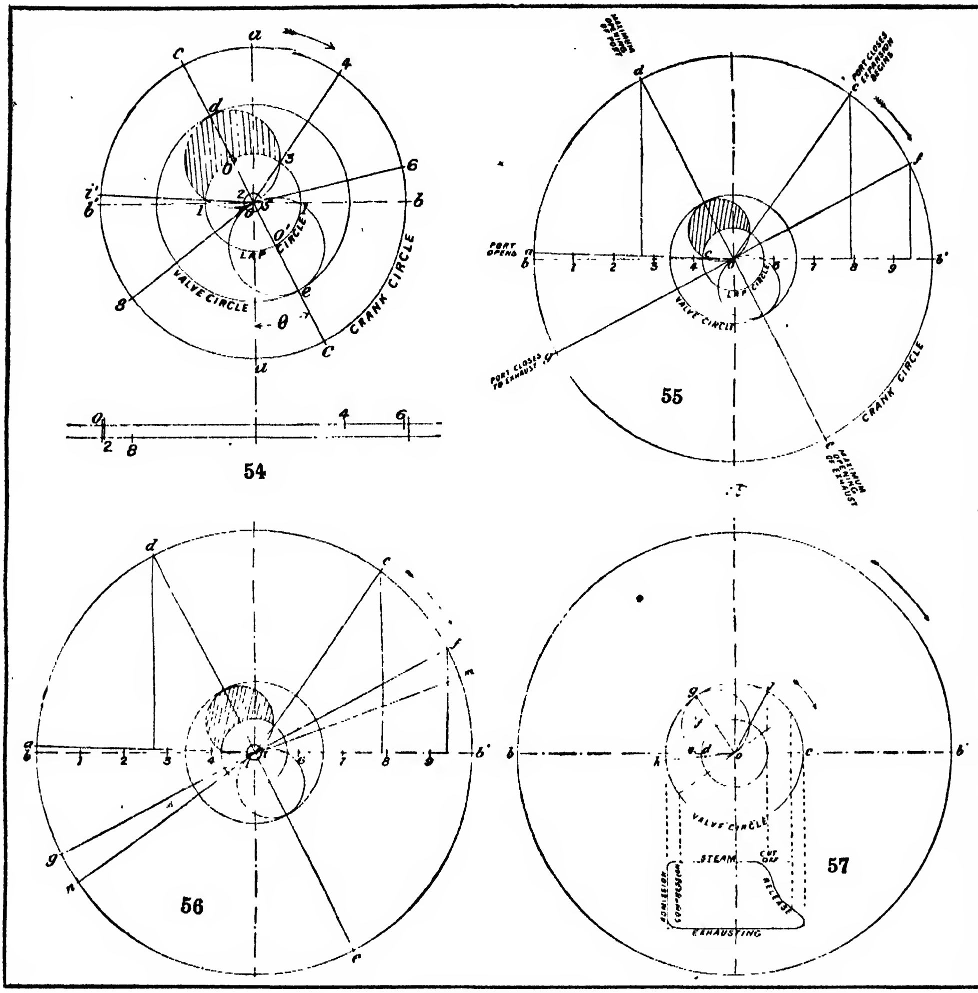
Another way of illustrating the valve diagram, though identical in principle, is shown in **55**. Draw the crank circle bb' of the same diameter as the stroke of the piston, and mark a line bb' across its diameter. From the same centre describe a circle, the "valve circle," the diameter of which represents the length of travel of the valve. From the same centre describe the "lap circle," the diameter of which equals twice the lap.

When in the plane bb' the crank is on dead centres. But if lead is allowed the port opens before the crank arrives at dead centres—namely, at the point a on the crank circle. This can be obtained by setting down on the valve circle the proportion which the lead bears to the total travel of the valve—it may be one-fortieth, or one-fiftieth, or other proportion of the travel—and drawing a line through that point from the centre o to cut the crank circle at a. This line will cut the lap circle at c. A circle is now drawn of half the diameter of the lap circle cutting the lap circle at c. The portion of the circle lying outside the lap circle is shaded in order to indicate the amount of opening of the port, as separated from that of the lap, and the two extremities, as shown in the previous diagram, mark the points of opening and closing up the ports. The line oa is that which corresponds with opening, and the line oc with closing. On the radius od on the centre of the shaded portion the maximum width of port opening is measured. And in any position included by the arc of admission the width of opening of the port can be measured on any radius on the shaded area. Similarly, the line od prolonged to e gives



51 52 53

PRINCIPLE OF VALVE DIAGRAMS



VALVE DIAGRAMS

the maximum exhaust opening. And if there is no lap to exhaust, the exhaust will remain open during half a revolution, and therefore a half circle measured equidistantly from *e* will give the entire exhaust opening, being at its maximum at *e*, and closing at *g*, beyond which compression takes place to *a*.

Uses of Diagrams. It is easy to ascertain from the diagram the distance which the piston has travelled corresponding with any width of port opening. Suppose the length of stroke is divided into ten equal parts, as shown. Then perpendiculars dropped from any points in the crank circle indicate at what positions of the piston the various stages in the valve cycle take place. If there is no exhaust lap, the edges of the arch of the valve coincide with the inner edges of the steam ports when the valve is in the middle travel. Then the opening and closing of the exhaust ports will be represented by lines at exact right angles with those representing the maximum port opening, as in the present figure [**55**]. If exhaust lap is added, the diagram is modified, as in **56**. A circle is struck from the common centre with a radius equal to that of the lap. A second circle is drawn equal to the upper circle, which will indicate the port opening for the return stroke. Through the points *i* and *i* where this circle cuts the exhaust lap circle lines are drawn cutting the crank circle at *m* and *n*; *m* represents the opening to exhaust and *n* its closing.

Another way to draw the diagram is shown in **57**. Draw the centre lines *bb'*, and from a centre *o* describe a circle *c*, the diameter of which is equal to the travel of the valve. Mark off from the centre *o* the lap *d* and lead *e*. From *e* erect a perpendicular *f*, cutting the valve circle at *g*; join *og*, and on the line *og* describe a circle in contact with *o* and *g*. From the centre *o* draw the lap circle *cd*. Draw lines from *o* passing through the points of intersection of the two circles, and cutting the valve circle at *hj*; *oh* then represents the position of the crank when the valve begins to open the port to steam, and *oj* corresponds with the cut-off. To render the relations more clear, an indicator diagram is drawn below, showing admission, and full opening, cut-off, expansion, release, exhaust, and compression.

CIRCULAR SAWS

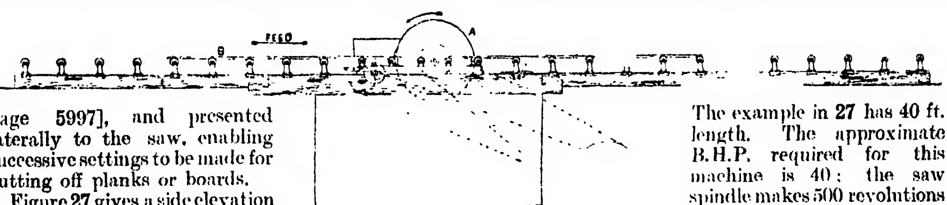
Rack Benches. Re-sawing Machines. Benches with Rope, Chain, and Roller Feeds

Continued from page 5997

By FRED HORNER

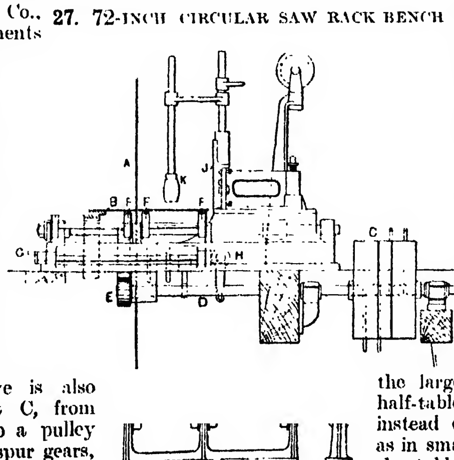
WE shall now consider the circular saw as a log-converting machine. It possesses the advantage of great speed of cutting, and outdistances the reciprocating saws easily in this respect. As a set-off, however, two objections are found: there is a considerable waste of wood in the kerf, and the saw takes an excessive amount of power to drive it, due to the leverage of the teeth acting on the periphery of the disc. Notwithstanding these objections, circular saws are employed when logs have to be cut into heavy scantlings, such as sleepers, posts, and various framings of square or other sections, which involves taking off the outside portions. They are not used to such an extent for the cutting of logs into very thin boards or strips of different sections, although the smaller saws are adapted to deal with pieces that have already been broken out from logs. The Americans are fond of using circular saws for log work, and manufacturers devote more attention to these machines than they do over here.

Rack Benches. The log saws are constructed with travelling tables, which carry the logs past the projecting saws. There are two patterns: one in which the tables are divided to embrace the saw on each side, the other in which the logs are held on dog-carriages resembling those in **26** [see page 5997], and presented laterally to the saw, enabling successive settings to be made for cutting off planks or boards.



27. 72-INCH CIRCULAR SAW RACK BENCH

Figure **27** gives a side elevation of a *rack bench* for a 72-in. saw (Messrs. W. B. Haigh & Co., Ltd.), from which the elements of such machines may be studied. In **28** some of the details are illustrated. The saw, A, runs in fixed bearings, and the timber rests upon the table, B, which has a longitudinal opening to receive the saw. The table is made of steel plate, and moves upon a series of rollers, seen underneath, resting upon a timber framing. The driving of the saw is effected through the line shaft and pulley at C, belted up to the saw mandrel; the table drive is also derived from a pulley at C, from which a belt goes up to a pulley connected to a train of spur gears, coupled with the rack underneath the table. The rates of feed can be varied from 10 ft. to 40 ft. per minute, with a quick return movement at 120 ft. per minute. Some details of the machine are illustrated in **28**, the saw being seen at A, the table at B. The feed is from pulleys at C, carrying open and crossed belts, either of which is shifted on to the central fast pulley, driving the shaft D, and thence a train of spur wheels, which end in a pinion meshing with the rack fastened underneath the table, B, to the left. The four rollers supporting the table across its width are seen at F F F F, all of these being mounted upon a common spindle. There is a foot pedal at G, which, when depressed one way or the other, turns a short shaft, having mitre gears communicating motion to a rocking lever at H, which operates a rod connected to the striking forks on the pulleys at C, thus giving the attendant perfect control over the feeds and return. The *fence* at J is for guiding timber in a straight line past the saw, and to keep the timber against the fence the *pressure roller*, K, is brought into use. It is held on an upright bar that can be pivoted in its socket, and pulled over by a cord attached to a balance weight, the cord passing over the pulley adjacent. In this manner the timber is pressed up to the fence, and the resulting cut is parallel and smooth. The length of the tables in these rack benches ranges between 20 ft. and 40 ft. The example in **27** has 40 ft. length. The approximate B.H.P. required for this machine is 40; the saw spindle makes 500 revolutions per minute, and the greatest possible depth of cut which the saw can make is 32 in. In the case of a 42 in. saw machine the capacity in depth is 18 in., and the H.P. 20. These saws are speeded to give about 9,000 ft. peripheral speed.



28 DETAILS OF RACK BENCH

Figure **29** shows the general appearance of a rack bench (Thomas Robinson & Son, Ltd.), in which the rollers at one end are seen exposed as the table is travelling towards them, carrying a log upon it. The tables in this type of machine are of steel, and in the largest sizes of machines each half-table is driven by its own rack, instead of employing a single rack, as in smaller machines. Parallel with the table, and at the same level, are a series of plain rollers for shifting the timber about, both before and

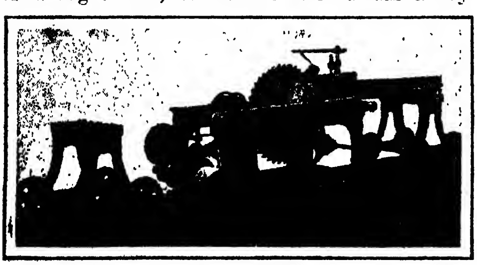
29. CIRCULAR SAW RACK BENCH

after it is sawn. These may be noted at the left-hand side of the table rollers in the picture.

Hand-fed rack-tables are made only to a moderate extent, the motion being obtained from a crank handle turning the rack pinion. The table is made of wood, with iron guide rails bolted beneath, and the framing is of wood, made in such portions that they can be conveniently transported to out-of-the-way districts. The tables are shorter than those for the largest power-fed machines, ranging from 12 ft. to 20 ft. The term *colonial* is often applied to these classes of machines. The sawmill engineers simply supply the iron portions of the machine, leaving the purchaser to construct the timber work on the spot, or within convenient reach of the forest.

The reason for the adoption of wrought-iron or steel plates in these rack benches is chiefly one of strength, because cast iron is liable to be fractured through the concussion of heavy logs rolled on to them. No fastenings are necessary for the logs, as the weight is sufficient to keep them steady. Round logs are flattened a little on the bottom to make them stand firmly, or else wedged and packed to keep them from shifting.

Rack Benches with Dog-carriages. In what are erroneously called American rack benches the log is not carried upon a flat table, like the foregoing, but is held in a dog-carriage, by which it may be fed up to cut off planks and boards of various thicknesses, the operation being similar to that of the vertical log band-saws described in the previous article. These machines are used more extensively in America than over here, but the band-saws are gradually displacing them, for the reasons already given—namely, less power consumption, and decreased width of kerf. In America, also, the use of large saws with inserted teeth is far more common than in Britain, the waste of wood being excessive. These saws will be described, together with others, later. The description of the dog-carriages given in the previous article applies equally well to those employed for circular saws, and need not be repeated. In **30** we illustrate a machine (Messrs. Thos. Robinson & Son, Ltd.), in which a log is seen gripped by some of the quick-acting dogs of the carriage. The latter is constructed wholly of wrought iron, so that it can sustain heavy shocks and cut at a high speed without risk of breakage. The carriage as shown is arranged to take logs up to 30 ft. in length, but there is practically no limit in this direction. The circular saw is 66 in. in diameter, and runs at 500 revolutions per minute. There are three speeds, or rates of feed, to the log, and a rapid return.



31. SAW BENCH WITH ROPE FEED

A circular steel disc of wedge section is placed immediately behind the saw, to enter the kerf after it, and force the two sawn portions apart slightly, thus relieving the saw of undue side friction, which would tend to heat the saw, greatly augmenting its work and decreasing output. There is a long vertical roller located in a sliding bearing in advance of the saw, against which the log takes a bearing when travelling. The roller is adjustable by a hand wheel, and serves as a fence.

Double Saws. As the capacity of a circular saw is limited as to the diameter it will cut, it cannot be employed to cut up big logs. But by mounting another saw above, the capacity is much increased, as the two blades, working up from below and down from above, can reach through a greater thickness. The top saw is usually of smaller diameter than the bottom one, say in the relation of 72 in. and 36 in., in the case of the larger machines. Figure **32** represents a double machine, a type similar in all other respects to **30**. The upper saw is carried on a spindle in sliding bearings on an upright, and the driving belt passes around a jockey pulley by which the slack is taken up. The teeth of the saws face in opposite directions to each other, and the direction of rotation is also opposite. The two are brought as close as possible without actually touching.

30. CIRCULAR SAW LOG MILL

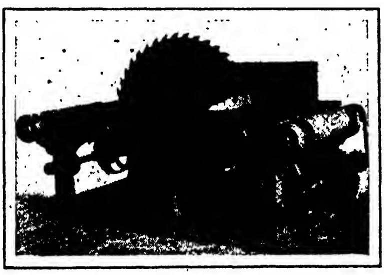
Framings. The framework of carriages is generally constructed of timber when intended for export purposes, and the American builders of these machines favour timber framings, on which the running wheels, the dogs, and the set works are fastened. The timbers are mortised and tenoned together, and well secured with bolts. The frame carrying the saw mandrel and the feed-change works is also of wood. The reverse motions are put into action by friction wheels. Other classes of feeds are the rope or cable, and the direct-acting steam (used chiefly in America), discussed in the last article.

The driving arrangements of the circular log mills depend on circumstances. The power can be derived from a special portable engine, belted to the raw mandrel, or from main shafting which serves other machines. An oil or gas engine can be located close to the mill, and belted to the pulley. The oil engines are useful for portable mills, or those which have to be re-erected from time to time in various parts of the forest.

Re-saws. We now come to a group of machines termed *re-saws*, the function of which is to cut up deals, flitches, planks, etc., which have already been sawn out from logs, into portions of various sizes. The deal frames already described are strictly re-saws, but there are also the smaller band and circular saws, which are both rapid in operation and handy in respect of the variety of work which they can be adapted to turn out. Adjustments can be made very quickly to cut a small number or hundreds of similar pieces. A feature in which these circular and band re-saws differ from log-sawing machines is that the tables do not usually travel, but the timber, being more or less even, is slid along smooth surfaces, with or without the help of rollers. The three chief methods of feeding are rope, chain, and roller. The *rope-feed* is suitable for irregularly-shaped timber, or for driving small logs. The bench [**31**] (Thos. Robinson & Son, Ltd.) embodies a cored casting, carrying three bearings for the saw spindle. The timber is drawn along on the top of the table past the saw by a rope, fitted with a drag hook at the end, as seen, and the rope is wound around the drum at the left-hand end of the bench. Four rates of speed, from 15 ft. to 60 ft. or upward per minute, can be obtained through the medium of cone pulleys, and the movement of the rope can be instantly started or stopped by throwing a clutch in or out of gear. The speed of the drum is reduced by back gears. The rope is passed up over a roller at the edge of the table, this roller enabling it to run over the edge without friction. In cutting long pieces, which overhang the ends of the bench to a considerable distance, some extraneous support is required; this is afforded by a *trolley* at each end, running on lines of rails laid down in line with the machine. The timber, therefore, rests on one trolley, and gradually leaves it, to pass over the bench past the saw and be supported by the other trolley. The fence for keeping the timber straight is fitted with a counterbalanced roller, pulled over by a weight, in a similar manner to that described in connection with **28**.

32. DOUBLE SAWS FOR LARGE LOGS

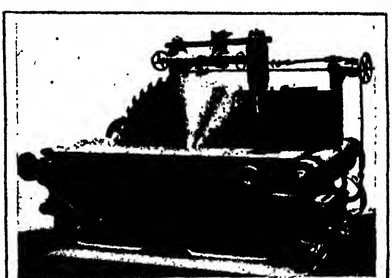
Some rope-feed benches have, instead of the small drum, a large grooved wheel placed with its spindle at right angles to the saw mandrel; it lies close up to the end of the bench, and the rope is conducted over a small pulley on to the table. The rope is subjected to less strain while running on the large pulley than it is on a small drum. When the rope has been pulled along to its drum or wheel, the return, in readiness for another feed, is effected by pulling at it with the hands, the clutch being thrown out meanwhile, so that the drum revolves freely upon its spindle.



33. HORIZONTAL ROLLER-FEED SAW BENCH

Chain-feed Benches. *Chain-feed* benches, which are employed principally for cutting up sleepers and the various short pieces of waggon framings, have a greater output than the rope-feed machines, because the action is continuous. One, or in some cases, two endless pitch-chains are driven over wheels at the ends of table, and they run in grooves past the saw. The timber is fed by the pressure of dogs dropped on to the chains between the links. As the chain or chains are always running, the timber can be pushed along as fast as it is placed in position. Rates of feed vary from 40 ft. to 120 ft. per minute. Some of these machines will split 2,500 balks in a day of ten hours, resulting in the production of 5,000 sleepers.

Roller-feed Benches. The best method of feeding, providing the work is suited thereto, is by continuously revolving *rollers*, either horizontal or vertical, the latter method predominating. A horizontal roller bench is shown in **33**, one of Messrs. Robinson's designs. The rollers, which are smooth, lie at the ends of the table, and their top surface is raised slightly above that of the table. They are driven at any one of three different speeds, and the weight of the log, or flitch, combined with the downward pressure of the revolving saw, gives sufficient friction to feed. The rollers can be reversed at a quick speed, in order to return heavy pieces after each sawing. The largest of the machines takes saws up to 5 ft. in diameter.

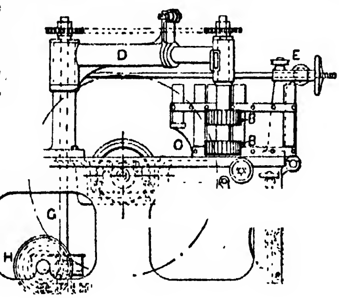


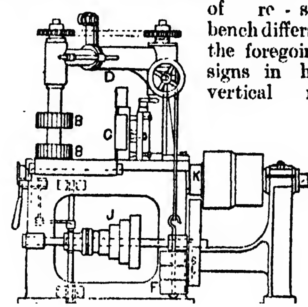
34. SAW BENCH WITH COMBINED HORIZONTAL AND VERTICAL ROLLER FEEDS

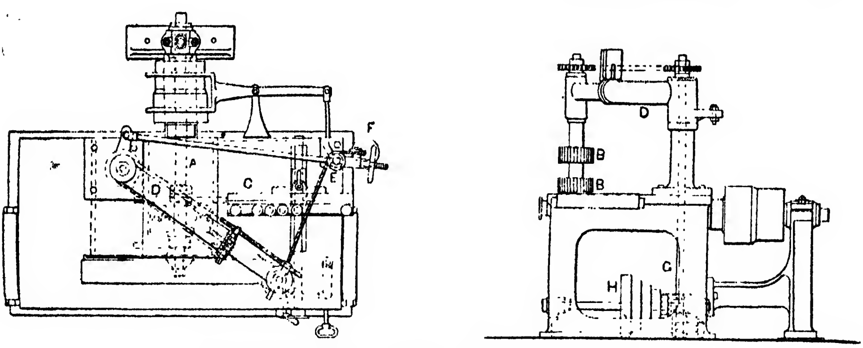
One of the most useful forms of roller-feed bench is that shown by the drawings in **35** of a bench taking 42 in. saws, and having a table measuring 6 ft. by 3 ft. The example is one by Messrs. John Sutcliffe & Son, Ltd., Halifax, and shows it in side elevation, plan, and two end elevations. The saw spindle, A, is supported in two bearings, the outer one being placed outside the driving pulley; the latter is made slightly larger than its adjacent loose pulley, on which the belt is slid to run idle and slack. The belt shipper is seen to be actuated by a pivoted lever worked from a rod passing through to the front of the bench, where the control is best effected [see the plan view]. Removable plates are fitted over the bearing and the spindle end to facilitate examination and the changing of saws. The feed rollers BB, serrated in ratchet form, are revolved against the timber, and force it along while making contact

with the fence C. A number of small plain rollers are set in the fence, to relieve the friction. Lateral adjustment, to suit the thickness of wood which it is desired to cut, is effected by a transverse screw passing through the table, and turned by a small knob seen near the right-hand end. Quick adjustment is provided for by a locking handle, which releases the fence, enabling it to be shifted to and fro instantly.

The mechanism of the feeding rollers includes a radial arm, D, pivoting upon a pillar bolted to the table, and carrying a rod in clamp bearings, which rod holds the vertical shaft bearing of the rollers, and is adjustable in the clamp bearing to accommodate different diameters of saws. Pressure against the wood is produced by a rope or chain pulling at the side of the bearing, leading over guide pulleys at E, to a weight at F. The rollers are driven in a positive manner by a pitch chain on the top of the shaft, worked from another shaft, G, which passes down through the table pillar to the floor, where a worm drive is received from a four-stepped pulley, H. belted from another pulley, J, which derives motion from a pair of pulleys, one on its shaft, and one on the saw mandrel, at K. A claw clutch, put into mesh by a handle at the front of the bench, enables the sawyer to start and stop the rollers instantly; the clutch works into teeth on the stepped pulley. At each end of the bench a smooth roller rests in bearings to take the weight of the wood as it passes over, and so to lessen the friction. If it is desired to use the machine without the roller feed, the radial arm can be swung out of the way, leaving the bench free.







35. CIRCULAR SAW BENCH WITH ROLLER FEED

Combination Feeds. Several types of benches are constructed with a combination of feeds, as rack and roller, or rope and roller, the idea being to use one for rough logs, which cannot be fed by rollers, and the other for regular pieces, like deals. Such machines are very useful to sawyers who cannot have two separate benches for the different classes of work. Messrs. Robinson make a bench [34] which incorporates the horizontal and the vertical rollers. The details will be clear from the illustration. The vertical rollers are adjustable vertically upon their shaft, to suit varying heights of timber. The reason for the adoption of two rollers is that a better grip is secured on the timber. When the horizontal rollers are in use, the radial arm is pushed round to the back of the bench.

In one type of machine the feeding is imparted by a fluted roller, which projects through an opening in the table in front of the saw, the amount of projection being variable, to suit the nature of the timber. In all these roller-feed benches, the stuff can be fed continuously, and the length of time during which the saw will be running idly is reduced to a minimum.

Canting fences, are designed for use with the roller-feed benches, to cut feather-edged boards, etc. The fence tilts bodily with its rollers, so throwing the stuff over in relation to the saw. A special class of re-sawing bench differs from the foregoing designs in having vertical rollers duplicated at the end, by means of which the deal or batten can be passed through and be divided exactly in halves by the saw, the rollers being self-centring. At the same time, the machine can be adapted to sawing boards of varying thicknesses by locking one of the rollers and using it as an ordinary fixed fence. A canting movement is fitted in certain cases, to throw the stuff over for cutting feather-edged work.

In these machines the table is represented by narrow ledges only, just sufficient to carry the width of stuff being dealt with.

Saws are duplicated on a spindle in some cases for making more than one cut along a piece of stuff, with the idea of saving time and producing repetition work. Some of the chain-feed benches are constructed with a saw flanking each side of the chain, for edging deals and boards after they have left the log frame. Small logs may also be squared on two sides simultaneously.

REFINING PETROLEUM

Petroleum Oil and its By-products. Shale Oil. Uses of Petroleum and its Products

By Sir BOVERTON REDWOOD

THE object of the operations which are collectively known as the refining of crude petroleum is to separate the liquid into a series of products best suited for various industrial uses. Crude petroleum as it comes from the well has already been shown to consist chiefly of a mixture of hydrocarbons or chemical compounds of the two elements hydrogen and carbon. These hydrocarbons exhibit a progressive range of boiling points, those at one end of the scale boiling at common temperatures, whilst those at the other end require to be heated to many hundred degrees Fahrenheit before entering into ebullition.

Fractional Distillation. It is, therefore, obvious that if we apply a gradually increasing heat to the crude petroleum we shall successively convert one constituent after another into vapour in the order of their boiling points, and if we pass this vapour through a tube surrounded by cold water we shall cause it to return to the liquid condition. The liquid so obtained may evidently be collected in as many separate portions as we wish, and we have thus the means of dividing and subdividing the crude oil into various products. The process in question is termed *fractional distillation*, and the separated liquids or distillates are called *fractions*.

Stills and Condensers. On the practical working scale the fractional distillation is carried out by the use of a still and a condenser. The still usually consists of a horizontal cylindrical vessel of iron or steel plate, with a dome, like that of a steam boiler, from which a tube or vapour-pipe passes with a slight downward inclination to the condenser. The still is set in brickwork, and is heated by a furnace. The condenser commonly consists of a coil of iron tubing, or a series of straight pipes joined by curved pipes or bends, placed in a tank filled with cold water. The outlet end of the condenser passes into a trough arranged so that the stream of liquid issuing from the condenser may be diverted into various receptacles.

Products. When ordinary crude petroleum is heated in such a still the first commercial product which flows from the condenser is petroleum spirit, or benzine, and this is allowed to flow into the tank provided for it until the temperature of the contents of the still has risen to such a point that distillation of the next commercial product—namely, the petroleum oil or kerosene, for use in lamps—begins. The stream of distillate is then diverted into the kerosene tank until the whole of this product has been obtained.

On further increase of temperature oils of higher boiling point, intermediate in character between the kerosene and the lubricating oils, distil over, and, lastly, lubricating oils of various grades issue from the condenser, these containing the solid paraffin wax if the crude oil undergoing distillation contains this substance, the residue in the still consisting of coke if the distillation is carried to *dryness*, as it is termed.

Usually the process herein described is conducted in two parts, the benzine and kerosene being separated in one still, and the distillation being completed in another still to which the residual oil is transferred. In some districts, and notably in Russia, only a small proportion of the residue which remains after taking off the benzine and kerosene is further distilled, the greater part of the residue being sold as liquid fuel. Where the distillation is carried to dryness, the operation is completed in cast-iron stills, the bottoms of which are of hemispherical form. In the distillation of the lubricating oils it is customary to inject steam into the stills, as this tends to prevent the products being injured by overheating, and facilitates the passage of vapour from the still to the condenser. On the other hand, in the distillation of the kerosene, overheating is often aimed at, the yield being thus increased by what is known as "cracking," which is the conversion of some of the heavier constituents of the crude oil into lighter ones of lower boiling point.

The benzine distillate is re-distilled with the aid of steam, so as to subdivide it into the various commercial products, including motor spirit.

Continuous System of Distillation. The process of fractional distillation which has been described is known as the *intermittent* system, because the still has to be periodically re-charged. In conducting the process of *continuous* distillation, which is the system commonly adopted in Russia, a series of stills is employed. The second of the stills in this series is heated to, and maintained at, a higher temperature than the first, the third to a higher temperature than the second, and so on throughout the series of ten or a dozen, or even more, stills. The crude oil is caused to flow slowly through the whole series, being thus subjected to a gradually increasing heat, while the temperature of the contents of each still remains practically constant. Under these conditions each still continuously yields a product of given boiling point corresponding with the temperature at which it is maintained, and the loss of time, waste of fuel, and injury to plant involved in cooling down and re-heating the stills in the intermittent system are avoided.

Benzine and Kerosene. The benzine or benzine products and kerosene are purified by agitation successively with sulphuric acid and a solution of caustic soda, followed by washing with water, and when the crude oil contains sulphur a special process is also adopted to remove this impurity from the distillates. The agitation is effected by means of compressed air, the operation being conducted in vertical cylindrical iron vessels termed agitators.

Lubricating Oils and Solid Paraffin. The lubricating oil distillates obtained from crude petroleum containing solid paraffin are artificially cooled to a low temperature, when the paraffin crystallises out and is separated from the oil by means of filter presses and hydraulic presses. The paraffin thus obtained is cast into thin cakes, which are slowly heated in an oven, when the most fusible or readily melted part liquefies and runs

away, carrying impurities with it. The residual wax is then melted up and refined by means of animal charcoal or fullers' earth, being thus rendered colourless and odourless. The separated lubricating oils of various grades are purified in the same manner as the kerosene by treatment with acid and alkali.

Vaseline. This product is obtained by concentrating the residuum of ordinary Pennsylvanian or other similar petroleum to the consistency of butter, and dissolving it in petroleum spirit, the solvent being evaporated off after repeated treatment of the solution with animal charcoal.

Characters of the Commercial Products. On redistillation, benzine obtained from the crude petroleum of the United States may be divided into gasoline and a number of other less volatile products, but gasoline itself is sometimes further subdivided into cymogene, rhigolene, and gasoline. Cymogene boils at 32° F., and can therefore be preserved only in a liquid state in a freezing mixture, or under pressure; while rhigolene has a boiling point of 65° F. These products, which have in admixture a specific gravity of ·636, are much used for surgical purposes as local anæsthetics. A highly volatile product, of specific gravity ·625, obtained from gasoline, has long been employed for the same purpose in admixture with sulphuric ether. The generic term of *petroleum ether* is applied to the product in question (not the mixture), but various other descriptions of petroleum ether of higher specific gravity and lower volatility (or higher boiling point) are made in this country. Gasoline, the specific gravity of which usually ranges from ·642 to ·648, is used to carburet air, in what are known as *air-gas machines*, for burning as an illuminant, and is also largely employed as fuel in cooking-stoves in the United States. For use in the internal combustion engines of motor-cars, preference has long been given to a petroleum spirit of ·680 specific gravity imported from the United States or manufactured in this country; but it has become difficult to obtain adequate supplies of this product, and within recent years there has been a progressive increase in the specific gravity of the spirit employed for the purpose. Moreover, a large proportion of the benzine now imported comes from the Dutch East Indies, and this product has a lower boiling point in relation to the specific gravity than that of the American spirit, so that the specific gravity has ceased to be a trustworthy guide to the volatility of the product unless the origin of the spirit is also taken into account. The American deodorised naphtha or benzoline of commerce, which has a specific gravity of about ·700, is used for detergent purposes in the process known as *dry-cleaning*, and as a source of light in sponge lamps. Petroleum spirit from Rumanian petroleum is also now an article of commerce in this country.

Refined Oil. The refined oil (kerosene) obtained from the crude petroleum of the United States is of several descriptions, but only two of these—the ordinary American lamp-oil of commerce, known under the brands of Tea Rose, Royal Daylight, etc., and water-white or high test oils, sold under the brands of White Rose, Snowflake, etc.—are imported into this country. The ordinary oil is usually of a pale straw colour, and has a specific gravity of about ·800. Its flash-point is generally not much above the legal limit of 73° F. (Abel test). The higher grade of oil, of which the average crude petroleum yields only about 15 per cent. or 16 per cent., is colourless, or nearly so, and has a specific gravity of about ·79. Its flash-point is over 100° F. (Abel test). There is also manufactured to a small extent a burning oil having a specific gravity of ·825 to ·830 and a flash-point of about 250° F. (Abel test). Of this oil, which is usually known as *mineral colza oil*, about 10 per cent. may be obtained from the crude petroleum.

Russian crude petroleum furnishes parallel products of a somewhat different character. The yield of benzine is usually much lower, and the ordinary kerosene, obtained to the extent of only from 27 per cent. to 40 per cent. of the crude oil, has the comparatively high specific gravity of ·825, and a flash-point of about 85° F. (Abel test). The most important commercial product is the residuum, which, under the name of *astatki*, is very largely employed as liquid fuel.

Kerosene is also imported into Great Britain from Rumania.

Of mineral oils for lubricating purposes an extensive series is imported from the United States and Russia under the names of spindle oil, engine oil, cylinder oil, valve oil, etc., the names indicating the general characters and uses. These oils are of various specific gravities, flash-points, and viscosities, according to the purposes for which they are intended.

Oils for gas-making and other purposes, intermediate in physical characters between the burning oils and the lubricating oils, are also imported.

Methods of Testing. Although, for commercial purposes, many tests are applied to petroleum products in order to ascertain their suitability for the uses to which they are intended to be put, the legal enactments are based solely on the determination of the risk of fire as measured by the temperature at which inflammable vapour is given off by the oil, the test being known as that of *flashing-point* or *flash-point*, and on this basis regulations are made respecting the keeping, carriage, and handling of such crude oils and products as are regarded as dangerous. The early petroleum legislation in the United Kingdom fixed the standard of flash-point at 100° F., the test being performed by heating a sample of the oil in a small open cup placed in a water bath, the arrangement resembling a carpenter's gluepot, and passing a small flame at intervals across the surface of the oil as the temperature rose above 90° F., until a pale-blue flicker or flash was observed. Owing to the unsatisfactory results furnished by this comparatively rough method of testing, the Petroleum Act of 1879 was passed with the object of substituting the "Abel test," devised by the late Sir Frederick Abel, in which a closed cup is used. The Abel testing instrument consists of a cylindrical oil vessel, fitted with a thermometer and provided with a cover, in which there are three openings. These openings are covered and uncovered by means of a slide working in guides, and having corresponding perforations. As the slide is drawn back to open the cup, it automatically tilts a small test lamp, so that the flame of the latter just enters the oil vessel. The oil cup is placed in an air-jacketed space in an outer vessel containing water previously heated, and, in order to ensure uniform results, the test has to be performed in accordance with specific directions relating to the filling of the oil cup, the initial temperature of the water bath, the size of the test flame, and the time occupied in applying this flame. The first application of the flame is made when the oil attains a temperature of 66° F., and the standard flashing-point is fixed at 73° F., this temperature corresponding to the old standard of 100° F. in the open cup. A modification of this apparatus, in which the slide

is moved by clockwork, is used for testing petroleum under the Indian Petroleum Act, the minimum flashing-point for safe oil being fixed at 76° F., with a correction for the effect of variations in atmospheric pressure. In India the application of the test flame is directed to be begun at a relatively earlier stage of the test than in colder countries, with the object of getting rid of the vapour which is liable to be disengaged from the oil in filling the cup in a tropical climate, as this may cause a flash to occur prematurely.

Testing Lubricating Oils. For testing the flash-point of lubricating oils, another modification of the Abel apparatus, known as the Pensky-Martens tester, is largely used. The oil-cup of this instrument is fitted with a stirrer to ensure uniformity in the temperature of the contents of the cup, and the application of the test flame (furnished by coal-gas issuing from a small jet) is effected by means of a rotating vertical rod. The oil-cup is heated to the requisite temperature in a cast-iron air bath surrounded by a brass jacket.

The viscosity of lubricating oils is also tested, for this affords a measure of the relative lubricating values of the oils. The instruments employed in making this test are termed *viscometers*, and their action is usually based upon the principle of determining the time occupied in the outflow of a specified quantity of the oil through a jet or small orifice at a given temperature. The standard instrument in this country is the Redwood viscometer, while on the European continent a somewhat similar form of apparatus, known as the Engler viscometer, is largely used.

The commercial value of paraffin wax is largely governed by the so-called *melting point* (which is really the setting point or solidifying point) of the material. This is determined by melting a small quantity in a test tube and stirring it with a sensitive thermometer while the tube and its contents are allowed to cool slowly in the air until a point is reached at which the cooling is arrested by the heat given out by the solidifying paraffin, and the mercurial column remains stationary for a short time. The temperature recorded by the thermometer when this occurs is the melting point.

Transport. Refined oil (kerosene) is chiefly transported in bulk in tank steamships, tank barges, tank railway waggons, similar to those already referred to as being employed in the carriage of crude petroleum, and tank road waggons, the aim of modern practice being to cheapen the cost of transport by keeping the oil in bulk from the time it leaves the refinery until it reaches the lamp in which it is burned. The use of the 40-gallon wooden barrels in which this product was at one time so largely distributed has, accordingly, been almost entirely superseded, but "cases," which are wooden boxes, each holding two tin cans of 4-gal. capacity, are still largely employed for sending the oil into sparsely populated countries, especially in the tropics.

At the present time the Atlantic petroleum steamship fleet is a large one, and some of the vessels are of great capacity. The engines and boilers are sometimes placed amidships and sometimes at the after end. The tanks are formed by the skin of the ship, a decking, and a series of transverse bulkheads, with a central fore-and-aft bulkhead, and they are isolated from the stokehold and engine-room by a double bulkhead or coffer-dam, two of these being required when the engines are amidships, and the screw-shaft being then carried through an oil-tight tunnel. The most important fundamental principle of construction lies in the provision of expansion trunks, extending upwards from the top of the tanks, by means of which the contraction and expansion of the oil under changes of temperature are allowed for, and the tanks always remain full. If it were not for this arrangement the tanks would be liable to overflow or to become partially empty, when the oil would be liable to be set in oscillation and the safety of the ship would be imperilled. The oil is delivered into these steamships by pipe-lines, and is discharged at the rate of hundreds of tons per hour by the vessel's powerful pumps.

Lubricating oils are now very largely shipped from the United States in bulk, and wholly so from Russia. The gas-oil used by gas companies in the manufacture of carburetted water-gas, and in the enriching of coal-gas, is also shipped in bulk.

Paraffin scale for candle-making is transported in barrels, the material being frequently run into the packages in a melted state; and paraffin wax is packed in cases.

Under the bylaws of the Thames Conservancy, petroleum spirit, now almost entirely imported in bulk, is landed at Thames Haven, and is brought up the river in licensed tank barges.

Scottish and Other Oil Shales. The bituminous shales occurring in Scotland (Linlithgow and Midlothian), France (Autun), New South Wales, New Zealand, Nova Scotia, Servia, and elsewhere, yield on destructive distillation, besides ammonia, a series of commercial products, including burning oil, lubricating oils, and solid paraffin, resembling those obtained from crude petroleum. The Scottish shales usually give from 18 gal. to 30 gal. of crude oil to the ton, and in some cases as much as 60 lb. to 70 lb. of sulphate of ammonia. A rich description of shale is mined in New South Wales, which furnishes over 100 gal. of oil to the ton, and some of the New Zealand shale is remarkable for the very large proportion of solid paraffin obtainable from the products of distillation.

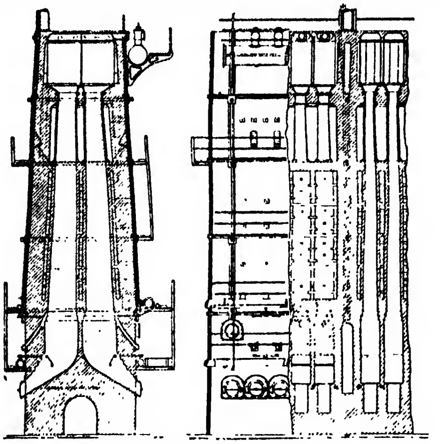
Scottish Shale Oil Industry. The industry has suffered severely from the competition of imported petroleum products, but adversity has been met in a manner deserving of the highest praise, remarkable improvements in plant having been made, and economies effected in working costs. In this connection it should be pointed out that in distilling shale there is an additional source of profit in the ammonia obtained with the oil, and that of the most valuable of the oil products – namely, the solid paraffin—shale oil usually gives a comparatively large yield.

Oil shale is mined similarly to coal, is screened at the mine, and on reaching the works is broken by machinery into flat pieces about six inches square.

Shale Retorts. Horizontal retorts, similar to those used in coal-gas manufacture, were at first adopted for the distillation of the shale, but at an early date these were replaced by vertical retorts, and steam was injected into the retorts to carry off the oil vapours. Distillation under reduced pressure was subsequently introduced, and the spent shale was utilised as fuel for heating the retorts. The use of steam increased the yield of oil by 20 per cent., and by subjecting the shale to a higher temperature in the presence of steam after the oil had been driven off at a moderate heat, a much larger proportion of the nitrogen was obtained in the form of ammonia.

Various improvements in shale retorts were made from time to time by Young, Henderson, Beilby, Fyfe, and others, with the objects of diminishing the cost of working and increasing the yield of oil

and ammonia. The retorts at present in use, of which one type is shown in 2, hold about 30 cwt. and are about 28 ft. in height; they consist of an upper portion of cast iron, surmounted by a hopper,



2. SHALE OIL RETORTS

and a lower portion of firebrick. They are set in benches in a combustion chamber, and are heated through the agency of a gas-producer. The upper part is heated to dull redness, and the lower to a bright, red heat.

Retorting. The process of distillation is a continuous one, the spent shale being gradually withdrawn from the base of the retort, and a corresponding quantity of fresh shale entering from the hopper at the top. About twenty-four hours is occupied in the passage of the shale through the retort.

The vapours issuing from the distilling charge, amounting to about 3,000 cubic ft. per ton of shale, pass from the top of the retort into a vertical tube condenser, where the oil and ammoniacal liquor are separated. The uncondensed gas may be used for lighting or heating, or the very volatile liquid hydrocarbons which it contains may be obtained by passing it through a scrubber, and the residual gas, which then has no illuminating power, is utilised as fuel.

The ammoniacal liquor from the condenser is distilled, and the liberated ammonia is brought into contact with sulphuric acid, with which it combines to form commercial sulphate of ammonia.

Shale Oil Refining. The crude shale oil, which is of a dark green colour, is subjected to a continuous process of fractional distillation substantially similar to that already described as applied to crude petroleum, and is thus separated into light and heavy oils and paraffin wax, steam being passed into the stills in order to facilitate the operation and prevent injury to the products by overheating. The light oil furnishes a small proportion of naphtha on redistillation, after treatment with acid and alkali, the remainder of the light oil consisting of the burning oil, or paraffin oil, used in lamps. The heavy oil is cooled, so as to cause the solid hydrocarbons to crystallise out, and is then passed through filter-presses, which separate the paraffin from the oil.

Paraffin Refining. The crude paraffin was formerly refined by dissolving it in the naphtha obtained from the light oil distillate, allowing it to crystallise out in shallow trays, and pressing the cakes thus obtained. This method of treatment has, however, been superseded by the "sweating" process, in which the paraffin is pumped, in a melted state, into shallow trays, supported above transverse heating-pipes in a closed chamber or stove. Each tray is fitted with a perforated strainer, of about 16 apertures to the inch, which is covered to the depth of about half an inch with cold water, the melted paraffin floating on this layer of water above the strainer. When the paraffin has solidified, the water is drawn off, and the cake of paraffin rests on the strainer. Steam is then passed through the heating-pipes, and the temperature of the stove is slowly and cautiously raised to the point at which sweating takes place. The effect of the heat so applied is to cause the softer and more fusible portion of the paraffin to melt and drain through the strainer, carrying with it the impurities, and this portion is drawn off. The hard paraffin remaining on the strainer is then melted by further raising the temperature of the stove, drawn off from the tray, decolorised by agitation for some time with animal charcoal and cast into cakes for sale to the candle makers.

Yield of Products. The heavy oil from which the paraffin has been separated in the filter presses yields, by further refining, a series of lubricating oils of various specific gravities, flash-points, and viscosities. The proportions of the various commercial products yielded by Scottish shale vary with the nature of the shale and the process of manufacture, but may be taken as ordinarily being about 3 per cent. to 6 per cent. of naphtha (including gasoline), 39 per cent. of burning oil (including gas oil), 18 per cent, of lubricating oils, and 10 per cent. of paraffin (refined and semi-refined), the loss being thus no less than 30 per cent. The loss is very large compared with that sustained in the refining of crude petroleum, and indicates the disadvantage under which the shale-oil refiner works. Before he is in the same position as the petroleum refiner he has to mine and break the shale and subject it to destructive distillation, and his crude oil is far more difficult to refine than the raw material with which the petroleum refiner usually has to deal. Against the extra expenditure which this entails the profit on the sulphate of ammonia is to be set, and it is this, coupled with the large yield of the valuable product, paraffin, which has enabled the shale-oil industry effectively to meet the competition of petroleum.

French Shale Oil Industry. In France the distillation of shale was begun as far back as 1830, and the French industry is, therefore, much older than the Scottish, though it has made less progress, and is of smaller commercial importance. The chief centres of the industry are at Autun, and Buxière-les-Mines. The shale yields only about 17½ gal. of oil to the ton, and 5 per cent. to 7 per cent. of sulphate of ammonia. The oil is fractionated and refined in the same manner as Scottish shale oil, but is less easily converted into commercial products of satisfactory quality. It yields about 3·5 per cent. of naphtha, 19 per cent. of burning oil, 23 per cent. of gas oil, 8 per cent. of pale oil, 17 per cent. to 18 per cent. of lubricating oils, and 2·7 per cent. of refined paraffin. The industry has declined since the removal of the heavy import duties on crude petroleum, which formerly protected it.

Australian and New Zealand Shale Oil. In New South Wales, a so-called "kerosene shale," resembling cannel coal, has been mined and distilled since 1865. Some of this mineral yields over 100 gal. of oil to the ton. The retorting has latterly been carried on near Torbane, west of the Blue Mountains, and about 130 miles from Sydney,

the crude oil being transported by rail in tank waggons to a refinery at Hartley Vale. Recently an English company has been formed to develop the industry on a large scale, and plant for retorting and refining, capable of dealing with a large output of shale, is in course of erection.

Bituminous shales occur in the upper portions of the coal measures of New Zealand, and that which is found at Orepuki yields a crude oil containing a remarkably large proportion of solid hydrocarbons.

The Brown Coal-tar Industry. In Prussian Saxony, the destructive distillation of lignite, and conversion of the tar obtained into commercial products resembling those yielded by shale oil, constitutes an industry of local importance. The tar is fractionally distilled under reduced pressure, with the object of preventing the decomposition which would otherwise occur, and in this manner from 8 per cent. to 30 per cent. of light oil, 15 per cent. to 30 per cent. of lubricating oils, and 1·5 per cent. to 12 per cent. of paraffin, are made from it. In other respects the process adopted resembles that already described as applied in the refining of shale oil.

Kimmeridge Shale. The extensive deposits of shale in Dorsetshire admit of being mined at a low cost, and give a satisfactory yield of crude oil, but the refining of this oil presents exceptional difficulties which have hitherto stood in the way of its utilisation.

Uses of Petroleum. Crude petroleum has from the earliest times been employed as a curative agent, especially in cutaneous affections of men and animals, in the treatment of wounds, and for the relief of strains and rheumatism. For pharmaceutical purposes crude petroleum is no longer in general use by civilised communities, but the well-known product vaseline is very largely employed, both alone, and as a means of applying medicinal substances, where local action, rather than absorption, is desired, its physical and chemical characters rendering it superior to an animal fat for such a purpose.

Vaseline is also largely used as a protective coating for surfaces liable to injury from damp and exposure to the air; and it is an important ingredient of the smokeless explosive, cordite.

In surgery the more volatile products of petroleum have been found valuable as anæsthetics, especially in producing local insensibility by the cold resulting from rapid evaporation.

Petroleum Lighting and Heating. As a source of light and heat, petroleum and natural gas have been favourably known for ages, and at the beginning of the second half of the past century the petroleum or paraffin lamp and the paraffin candle became recognised as among the necessaries of civilised life. Indeed, it may be said that no modern article of commerce has done as much as refined petroleum to promote comfort and extend man's capacity for leading a fruitful life, for it has encouraged domesticity and has largely increased the number of hours available for study. Recognising this, some have even gone as far as to say that the progress of a nation in civilisation may be measured by the consumption of petroleum per head of population.

The illuminating agent supplied by the gas companies is often largely composed of carburetted water-gas, in the manufacture of which great quantities of petroleum are used. In some of the principal cities of the United States the latter gas has, in fact, entirely replaced coal-gas. Volatile petroleum products are also used in enriching coal-gas, so as to bring its illuminating power up to the required standard.

Petroleum - driven Vehicles. It is scarcely necessary to mention the highly important part which petroleum spirit is now playing in revolutionising the means of locomotion through the medium of public service vehicles (motor omnibuses) in the great cities, and private self-propelled carriages throughout the country.

The advent of the private motor-car is directing renewed attention to the splendid high-roads of this country, and is reviving the ancient glories of wayside hostelries, with great advantage to the mental and physical condition of those who are fortunate enough to be able to employ, wisely, temperately, and judiciously, this means of travelling in place of the railway.

It is well known that the source of power in that modern addition to the belligerent marine, the submarine, is petroleum spirit, these vessels being propelled by internal-combustion motors whilst on the surface of the water, and receiving their stores of the electricity which drives them beneath the surface from the same source.

As liquid fuel for use in steam raising for power purposes, both on land and at sea, as well as in metallurgical and other work, petroleum has now taken a most important place as a heating agent of far higher efficiency than even the best steam coal.

Lubricating Oils. The lubricating properties of petroleum were recognised at a very early date, and one of the first applications of the more viscous descriptions of this product found on or near the surface of the ground was in the greasing of the wooden axles of primitive carts. The manufacture of lubricating oils from petroleum has long since been brought to a high degree of excellence, and such oils have now very largely replaced the animal and vegetable oils and fats previously employed for the purpose.

There is a large consumption of the softer and more fusible kinds of paraffin for rendering wooden matches readily inflammable. Paraffin also is or has been used in waterproofing match-heads; in strengthening and waterproofing woollen fabrics; as a "resist" in dyeing, the parts of the fabric coated with it rejecting the dye; for lining brewers' vats and beer barrels; for preserving stone, wood, eggs, meat, fruit, and flowers; for glazing, protecting, and waterproofing paper; as an adjunct to starch for glazing linen; as an auxiliary to soap for laundry work; as an electrical-insulator; as a substitute for fat for absorbing perfume from flower petals; and as an easily-moulded material in making ship models.

Petroleum in Soap Manufacture. The detergent properties of petroleum account for its extensive introduction into household soaps. Petroleum is also the active ingredient of certain insecticides. Petroleum spirit is largely employed in the process known as dry-cleaning; in the extraction of grease from leather; as a solvent for various purposes, and especially, in a carefully prepared form, as a substitute for oil of turpentine for use in making paints and varnishes.

Among other uses of petroleum may be mentioned those of ore-concentration, and the removal of fusel oil from crude molasses spirit.

In the form of "westrumite," and other preparations, petroleum has been successfully employed as a dressing for road surfaces to prevent disintegration and the raising of dust, its slower rate of evaporation rendering its action more lasting than that of water.

Many patents have been granted for the solidification of petroleum, chiefly with a view to the use of the product as a fuel, either alone, or in admixture with coal-dust or other combustible substances, in the form of briquettes. Among the solidifying agents which have been specified for this use are resin soap, extract of quillaia bark, lichen extract, fish glue, casein, and glue (with formalin as a hardening agent).

A product known as soluble petroleum is prepared by partially saponifying resin previously dissolved in the oil, or by blowing air through a mixture of resin oil and caustic soda solution, and adding to the jelly-like mass thus obtained an aqueous solution of a fatty oil soap and mineral lubricating oil. The product is intended to be employed, in admixture with water, as a lubricant, especially for tools used in boring and cutting metals, and is stated to have given excellent results.

Petroleum as an Illuminating Agent. Petroleum or paraffin lamps are usually fitted either with a single or duplex flat-wick burner or with an Argand burner, the former being more largely used in Great Britain and America, while the Argand, or annular wick type, is more popular on the Continent. The latter type of lamp is provided with a central air-supply channel, sometimes extending down through the oil-container to the base, and a disc or button is usually fixed at a short distance above the top of the wick-tube, so that the upward current of air induced by the heated chimney is deflected outwards and caused to impinge on the inner surface of the flame. Air is also supplied separately to the outer surface. Burners of the duplex type are usually fitted with an extinguisher, which is sometimes arranged to come into action automatically in the event of the lamp being overturned.

In one form of lamp the petroleum is vaporised and the vapour is conducted into an inverted Argand burner; in another a mixture of petroleum vapour and air, burning with a non-luminous flame, is employed to heat a Welsbach incandescent mantle.

A given amount of light was formerly obtainable from mineral oil at a much lower cost than from gas, but the general use of the incandescent mantle has so largely added to the efficiency of the latter illuminating agent that the comparative positions in respect of cost have been reversed, unless a mantle be also used with oil.

Petroleum Lamps. The subject of accidents with mineral oil lamps has in past years attracted considerable attention, and it has been contended that the minimum legal flash-point of 73° F. should be raised to 100° F. in the interest of public safety.

Formerly all lamp accidents were described in the newspapers as explosions, but investigation has shown that at least 75 per cent. or 80 per cent. of them have been due to the overturning or dropping of the lamp or to its fracture from some other cause. In fact, with a properly constructed lamp, and with ordinary care and intelligence in its use, an explosion ought never to occur.

In choosing a table lamp the purchaser should note whether it has sufficient stability, or, in other words, whether it is easily upset or not. If the lamp has the usual pedestal its attachment to the oil container should be substantial. The oil container should be of sufficient strength to withstand a fall from the height of a table on to a bare wooden floor without being broken or allowing the oil to escape, and, notwithstanding the merits of glass, it is safer to have a well-made container of metal. The burner should be securely attached to the oil container, and there should be no opening in it by which flame can communicate with the interior of the oil container. The burner should admit of being taken to pieces for cleaning, and it should be fitted with a good, substantial chimney gallery.

The Use of a Lamp. In the care and use of the lamp, the following should be borne in mind:

1. The wick should quite fill the wick-tube without having to be squeezed into it.
2. Before using, the wick should be dried at the fire, and then immediately soaked with oil.
3. Wicks should be in lengths of not more than 10 in., and should always reach the bottom of the oil container.
4. It is well to change the wick after two months' use.
5. See that the chimney of the lamp fits properly, and is held sufficiently tight so as not to fall off when the lamp is used.
6. When a new wick or chimney is required, it is always advisable to take the burner to the shop so that it may be properly fitted.
7. The burner should be taken to pieces and thoroughly cleansed at least once a month, and all burnt pieces of wick, dead flies, etc., should be carefully removed.
8. Never refill the lamp when it is alight or near a fire or other light.
9. After filling, see that the burner is properly fixed on, and if there is a side filling-hole, be careful to screw in the plug.
10. Before lighting, remove the burnt crust of the wick.
11. Be careful not to spill oil in filling, and if any is spilt on the lamp, wipe it off.
12. Before lighting, see that the slit in the cone of the burner is exactly over the wick-tube, so that the flame will not touch the metal.
13. When first lit, the wick should be partially turned down, and then gradually raised, but not so as to smoke. When the edge of the flame is orange coloured the lamp is not burning properly, and the burner should be examined.
14. Do not continue to burn the oil until it is completely exhausted. It is best to keep the lamp well filled.
15. Lamps which have no extinguisher should be put out thus: The wick should be turned down until there is only a small flickering flame, care being taken not to turn down so far that the wick falls into the oil container. The small flame may be extinguished by placing a piece of flat tin or card on the top of the chimney or by blowing across the top of the chimney. Never blow down the chimney.
16. Never use a lamp which is broken or in any way out of order, or a chimney which is cracked. If any part comes loose, or is out of shape or defective, it should be taken to a lamp shop to be repaired.
17. Always place the lamp in a secure place, and on a level surface, and never on a rickety table, or in any position where it could be easily upset. Hanging lamps should not be put on insecure nails in the wall.
18. Table lamps should not be carried about more than is necessary, and nothing else should be carried at the same time. Heavy lamps should be carried in both hands. The greater number of lamp accidents have been caused by dropping a lamp while it was being carried.
19. Lamps should not be turned down except for the purpose of putting them out. If turned low, the oil is liable to be unduly heated.
20. Should a person's clothes become ignited, the flames should be smothered with a hearth-rug, blanket, woollen tablecloth, or wet towel.
21. Never pour oil on a fire.

Outdoor Lighting. Various special kinds of lamps are used in the open air. For use on ships and on the rolling-stock of railways it is necessary that the lamps shall be constructed so that the air supply is not affected by the force of the wind, and that water cannot gain entrance. In the lighting of large areas during building and engineering operations, extensive use is made of lamps of the Lucigen and Wells type, in which the oil is forced up from a closed receiver by compressed air and sprayed through a heated burner, a light of 2,000 to 2,500 candle-power being given. In the Kitson lamp for street lighting compressed air is also used to raise the oil to the burner, where it is vaporised, and by means of the flame thus obtained a large mantle is heated to incandescence. A light of 1,000-candle power is thus produced at the very low cost of 1d. per 1,000 candle-hours. This represents the highest economy hitherto obtained in the use of mineral oil, and compares with 2¼d. for the incandescent table lamp, or 7¼d. for the duplex lamp. The same amount of light obtained from coal-gas on the pressure incandescence system (with

which the Kitson system of oil burning is fairly comparable) probably costs, on the average, about 1¾d.; with the ordinary incandescent mantle as used in dwellings, 2¼d. (the same as oil); or with a fish-tail burner, about 1s. 6d. The comparative cost of incandescence electric light may be put at 1s. 2d.

Air-gas. To some extent in this country, and far more largely in America, air saturated with the vapour of petroleum spirit is employed as an illuminating agent under the name of *air-gas*, and various mechanical devices are employed to effect uniform saturation under varying conditions. The air-gas may be used with ordinary gas-burners, or, after admixture with a further quantity of air, may be burned under a mantle. A portable lamp has been introduced in which the spirit is absorbed by a porous material and gradually vaporised, the heavy vapour flowing by gravitation to the burner and drawing in the air required to produce a non-luminous flame for heating a mantle.

Oil-gas. In order to produce a permanent gas of high illuminating power (50 candles) capable of bearing compression to 10 atmospheres, for use in lighting railway trains, buoys, and lighthouses, a suitable description of petroleum is slowly introduced into a retort maintained at a cherry-red heat.

Carburetted Water-gas. A similar description of oil is also very largely used by the principal gas companies in the manufacture of carburetted water-gas, and as a substitute for cannel coal in enriching coal-gas. In the Lowe system, used in English gasworks, water-gas is formed by blowing steam through incandescent coke or anthracite in a generator. This gas is passed through a superheater, where the oil is added, and the mixture of oil-vapour and water-gas is then taken through another superheater of large size in which the hydrocarbons are converted into permanent gas.

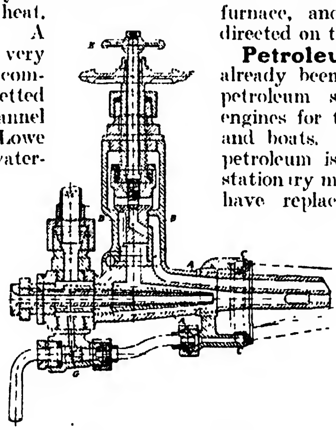
Natural Gas. Certain portions of the petroliferous territories of the United States yields natural gas of an estimated aggregate annual value of about 36,000,000 dollars, and this gas is used for lighting and heating, as well as in the manufacture of lamp-black. The gas may usually be burned with an Argand or fish-tail burner, but the best results are obtained with a mantle. For some time, natural gas was used to light the railway and town at Heathfield, in Sussex.

Liquid Fuel. Crude petroleum is largely used in the oil-fields, for steam raising, and in refineries, as a means of heating the stills; but the presence of very volatile constituents is a source of risk in storage and handling. Accordingly, either petroleum residuum, which remains in the stills after the separation of the kerosene from such crude oil as that of the Russian oil-fields, or a suitable distillate, with a specified minimum flash-point, is employed on steamships and locomotives, as well as in most industrial establishments where liquid fuel has taken the place of coal. In the British mercantile marine the minimum flash-point is 150° F., but for use in the Navy, liquid fuel is required to have a flash-point of 200° F. It is also needful that the oil should bear exposure to a low temperature, say 32° F., without solidifying.

On the Caspian Sea, and on the railways of Southern Russia, petroleum residuum (ostatki) is the sole fuel; and in California the consumption of liquid fuel has reached very large dimensions. It is common knowledge that the British Admiralty have adopted oil fuel as an adjunct to coal in the modern battleships and armoured cruisers.

Oil fuel is also not only largely used in the furnaces of stationary steam boilers, but is giving highly satisfactory results in metallurgical work, glass melting, etc.

The oil is usually burned by spraying or atomising it by means of steam, but in some cases is broken up into small particles by forcing it under high pressure through a small orifice. The Holden burner, employed in this country on the locomotives of the Great Eastern Railway, is shown in 3. The oil is admitted to the interior of the coned body AA through a regulating valve, BB. The annular steam jet D is provided with a central air-passage. CC is an annular chamber to which steam is admitted, and from which it escapes in jets through six small orifices. E and F are wheels by means of which the valves controlling the supply of fuel may be opened or closed. The cock G regulates the supply of steam to CC. The burner is fixed in the front of the furnace, and the intensely hot flame is directed on to a sloping bridge of firebrick.



3. HOLDEN BURNER FOR LIQUID FUEL

Petroleum Engines. Reference has already been made to the extensive use of petroleum spirit in internal-combustion engines for the propulsion of road vehicles and boats. A less volatile description of petroleum is also very largely employed in stationary motors, which in many instances have replaced steam engines and gas engines. In steam engines of moderate dimensions only 12 per cent. of the heat-value of the fuel burned in the boiler furnace appears in the engine as indicated work, whereas, in the internal-combustion engine, the proportion of heat rendered effective is, in many cases, more than double that percentage, and in one type of engine is as high as 37 per cent. The superior economy of the oil engine is therefore very marked. Preference is generally given to those engines in which one explosion occurs for each two revolutions of the crank-shaft. The first forward stroke of the piston draws in the explosive charge of oil or oil-vapour and air, and the return stroke compresses it. During the next forward stroke, the explosion drives the piston, and on the return stroke the products of combustion are discharged from the cylinder. The Priestman, Hornsby-Akroyd, Trusty, Tangye, and Diesel engines may be taken as typical of the principal forms of oil-motors. The Priestman engine is fitted with a spray-producer, as well as a vaporiser, and the charge is ignited by means of an electric spark. In the Hornsby-Akroyd engine, the explosion is effected by injecting the oil into a red-hot chamber, into which heated air is forced by the piston. In the Trusty engine, the oil is vaporised and the charge is fired by means of an igniting-tube maintained at a red heat. The Tangye engine also has a vaporiser and an ignition-tube. In the Diesel engine, the air admitted to the cylinder is heated, by very high compression, to such a temperature as to cause the immediate combustion of the injected charge of oil.

PETROLEUM concluded; followed by PAPER-MAKING

SILK HATS & CAP-MAKING

The Manufacture of Silk Hats. Body-making. Finishing. Shaping. The Cutting and Making of Various Shapes of Caps. Straw Hats

SILK HATS

The silk hat was first manufactured in France, and its introduction into England was at first conducted with great secrecy, especial care being taken to prevent anyone seeing the process, except those whom they had undertaken to teach "the art and mystery of silk-hat making." However, at the present time the journeymen silk-hatters of this country are as skilful as any of their foreign rivals, and the English-made hat holds its own in the markets of the world.

The variety of shapes in the crown will not be dealt with, as they alter and change so often, but the various curls and shapes of the brim will occupy a prominent place.

The first article to be made is "proof," which is composed of best orange shellac (2 parts), button shellac (1 part), let down by ammonia (½ lb., to every 8 lb. of shellac).

The Foundation of the Hat. The foundation, or body, of the hat is made from calico of different strengths dipped in the "proof" and stretched on frames. First of all we take the brim, which, being the strongest, takes the longest to dry. After the "proof" has been thoroughly cooled, take a frame about 5 ft. by 3 ft. 6 in. along the woodwork of which are a number of nails with large heads and the points protruding on the reverse side about 1½ in., with 5 in. between each nail. Then put the calico, No. 10 or D, in the proof and thoroughly saturate it, taking care in every instance that all parts have absorbed some.

1. FITTING THE BRIM

It is not absolutely necessary that this should be so heavily "charged" with proof, so draw it through the hand. Stretch it on the frame and prepare a stronger calico "twill." This must be charged with proof more than the previous one; in fact, it should be left as full as possible without running. Stretch it on the top of the fold already on the frame, taking care to squeeze both together with finger and thumb at every nail. Then rub with the flat hand, so that the proof of one will adhere to the fold of the other, taking care to begin at the centre and work outwards. The reason for this is to prevent any air between the two "plys," which would prevent their adhesion. As this is an important factor in the manufacture of a good sound brim, special care should be exercised. These two plys are followed by other two, put on in the same manner, the frame to be turned top to bottom after each "ply" is put on to prevent the proof from running to the bottom of the frame if kept in one position too long. Now we are ready for the drying process. Heat plays an important part in the making of the body, yet, while it should be dried quickly, it should not be scorched, for a scorched body never wears well. Therefore the best plan is to dry in a hot stove, but away from the fire that heats it. The crown is then dipped in a similar way, but only one ply is put on the frame.

The Block. The block is made from wood and shaped according to the fashion; some "bell" more than others, whilst some are called taper or straight crowns. The block is made in five pieces, the two largest being for front and back of hat, whilst one is placed in position for each side and the whole is fitted tightly in the hat by a centre piece, graduating from tip to head part.

Take a strip of calico about 8 in. deep and measure twice across the length of the block and once across the width; cut, and fasten the ends together by laying one about ¼ in. or $\frac{3}{16}$ in. over the other and running a warm iron over them. Do not have the iron very hot or it will harden the seam. Place the front and back pieces of the block inside the foundation, allowing ⅜ in. over tip; put in the two side pieces. It will be seen that the "foundation" appears too small, but a gradual warming will allow both the sides and centre piece to be put in. Round two sides of the centre piece put a piece of brim stuff to make the hat a little larger. This "packing" is to allow for a shell which is used at a later stage.

Stretching the Tip. For the next calico required it is necessary to dip a piece in spirit proof, which is best orange shellac dissolved in wood naphtha and called varnish. Having dipped the calico in the varnish and dried

it, cut it into strips of about ½ in. and place ¼ in. on the side crown from the tip, fasten with a warm iron and then iron the other ¼ in. on the tip of the block. Cut level all round. Take another piece of foundation and fasten on the edge of the tip, stretching by warming it, then cut round with scissors. It is necessary to *stretch* the tip, for, if allowed to be fastened slack, it will sink, and to prevent that the tip is stretched to its utmost capacity by warming it and then fastening it to the edges left over from the foundation.

A large mug or tin containing waterproof placed on the back of the bench is necessary, also a brush after the same pattern as a large paint-brush. With the brush apply a coat of proof to the tip and stretch a piece of plain calico across as in the manner described before, and again "proof" it, to make it adhere to the previous portion of the tip and form one solid substance. Take another piece of the calico, which has been dipped in spirit, about 1¼ in. wide, and iron it round the tip in the same manner as the previous one, placing about ¾ in. on the side crown and the rest on the tip.

Fixing the Brim. Take a brim, size 13 in. by 12 in., place it flat on the bench, and arrange the head part of the block in the centre and mark with a knife—or anything with a point—round by the block. Do not cut, but simply mark. With a pair of scissors cut out the centre, allowing about ⅓ in. inside the mark. A wooden frame, called a sunk frame, because the wood is hollowed out to allow the block to fit inside, is now required, the right depth being got by placing pieces of wood underneath the block and allowing ⅛ in. for the thickness of the brim. With a hot iron thoroughly soften the portion inside the mark already made, and then smartly pull over the tip of the block as far as possible. With an iron dummy press it as close to the frame as it can be got, making sure to have some portion of the brim up the side crown of the hat, which must be ironed together a little portion at a time, and followed immediately by the dummy being pressed on the portion ironed. Sides should be done first, then back and front [1]. With a knife cut or pare away a portion of the brim which now adheres to the side crown, taking care not to cut the other portion of the brim, but "paring" it gradually thinner towards the top so that it will not appear thick and bulky.

Take the centre of brim, already cut out, and split the four folds apart; cut two pieces, 2 in. by 1 in., from one of them and iron one on front and the other on the back, ⅝ in. on brim and ⅜ in. on side crown. Cover that piece with a larger one ironed on in the same manner. Iron a spirit "robbin" round the band of the hat, the same width as the previous one, to fasten the brim and side crown more firmly. See the hat is the exact depth; take it out of frame, and cut away the corners of the brim.

With the brush apply a coat of proof to the side crown, taking care not to miss any portion of it; then take a piece of fine muslin about 8 in. wide, beginning at the centre of side with the body seam on the right hand, and pull it round whilst the proof is wet so that the calico will adhere to it. When covered, cut off, take up the end first laid and lay the left side of seam over right; with scissors cut the calico over the tip with the exception of ¼ in., which must be ironed over. The remaining portion of the calico must be put on the tip—after it has been proofed—in the same manner as the previous one; then carefully cut off all corners and apply another coat of proof to all parts of the body, the brim included, and place in stove to dry. Again "proof" it whilst warm; let it cool and then pull block out. Another coat of proof must now be applied, and allowed to dry without the block being in the body.

The Ironing Process. It is now ready for the ironing or smoothing process, for up to the present it presents a rough appearance. First cut away closely with a knife the foundation from underneath the brim; place inside a shell or felt body (self colour), making sure that it fits the tip closely, and put in the back and front pieces of the block. Next fit the side and centre pieces, neither of which will go into the bottom at first, but after an application of gum, powdered in a rag, and a slight application of vegetable wax, the front part can be ironed over until quite smooth with a clean hot iron, followed immediately with a cool iron dummy to set the heated part. Knock the side pieces a little further down and repeat the operation to the back of the body, when the block will easily go in with the exception of the packing pieces, which are not needed now that the shell is in the body. The remaining portions of the body are now ironed, including tip, making sure that all the seams are pressed down, until it has a smooth, level surface; then let it cool, tip downwards.

Next get a brim frame which differs from the one previously mentioned, as it has no portion cut away for block, but has two pegs fitted in on which is placed a brow the size of the hat, and a piece of felt covering the whole frame. Iron the underneath of the brim on a plate fixed in the bench and shaped to the oval of the hat; then immediately place it on the frame, iron it well, and again repeat the operation on the underneath, following it with the cool iron dummy, both on the underneath and also on the top side of brim when on the frame. Iron first one side then the other, followed in order by back and front, making four distinct ironings for the brim. When well ironed it is ready to be varnished before being handed over to the finisher, whose work it is to place the silk on the body.

Finishing. The tools required for the finishing process are these: Irons (1 pair), dummies, 1 concave iron, 1 flat iron, 1 concave wood, 1 flat wood, wire cards (1 tip, 1 side), brushes (1 hard, 1 soft), velures (1 rough, 1 velvet), scissors (1 seam, 1 crooked, 1 ordinary), sponge, stirrup, woollen patch, half block, tip block, brim frame.

Finishing is the art of sticking and retaining the bright colour of the plush. The body, after it has left the bodymaker, receives two thin coats of varnish. The plush is stuck to the body

by means of cold water sponged on the plush, then a warm iron being lightly passed over, and thus a steam is created. This steam enables the plush to stick to the body. The finisher fits the cover on the body the reverse side up; then he measures and marks with chalk the exact line where the seam must be cut. The selvedge side will be on the right-hand side. Mark ½ in. from selvedge, then pass left-hand side over, and mark to correspond. Take cover off and apply a coat of proof on back of plush 1 in. wide over where the seam has to be cut. This stiffens the plush, and will stop it from threading.

2. CURLING THE BRIM

When the proof is dry, take cover in left hand and brush back the nap on the top of the seam; place cover on bench, and apply water on the plush; pass iron over and card back the nap. When well carded, back iron till dry. Then cut with scissors down chalk line and cut selvedge side. Take the plush for brim, damp on the back side, and pull out with fingers wider and shorter. This takes the stiffness out of the plush, and enables it to fall into the band of the hat easier. When dry, pass round outer edge of brim, and stick with cool iron.

Now get brim frame on patch or felt, as used in brimming body, and pull into position the plush with stirrup, care being taken to pull out all the pleats. Then sponge, brush the nap straight, and pass iron over. The brim is usually pulled in at four separate times, first front and back, then sides; when stuck, cut with crooked scissors, care being taken to cut the brim plush ½ in. up the side crown. Now place body on tip block and fit the cover; pass sponge over, and stick top of seam first; when seam has been securely fixed pass tip card over the stitching.

3. HALF-BLOCKING

Sticking the Cover. Stick the tip in position, care being exercised to have all the stitching on tip; do not allow it to drop on the side crown. The nap will then be across the tip from left to right. This must now be carded round to the centre. Damp the plush with sponge, pass warm iron over, and card the nap round while the steam is rising. Again apply water, iron, and card, and the nap will now be in position round the tip.

Place hat on half block (which must be covered with three or four layers of felt), stick the back of hat first, working towards the seam. See that the right-hand side of seam is well stuck.

Bring the seam together, and stick about 1 in. at a time. Brush the nap back to its right position over the seam, and stick remainder of hat; brush well, apply a coat of cold water, and card the nap straight. Water the tip, and bring nap well round to the centre. When dry, brush the glaze, and the plush will now have a dull appearance. For half-blocking, use a warm iron and go round the hat twice; the first time will bring the colour back, and the second time get the hat round [3]. When half blocked place a paper cap on side crown. To cover the underside with merino, apply a coat of varnish, and brush the merino on while wet. Cut merino ½ in. from band, and stick it down side crown; run iron on the top side on brim frame, and the hat is finished.

There are four points to be remembered: (1) when the hat has been warmed with iron, dummy till cold; (2) plush to be well stuck on body; (3) seam and stitching to be pressed well down; (4) the bright colour.

Shaping. The hat is now ready for the shaper, whose duty it is to make a curl and set the hat to its proper shape. This branch has been justly called the "artistic branch," for the appearance of the hat depends to a great extent upon the shaper. A variety of curls and sets are dealt with by the shaper, which, more or less, lends to the attractiveness of the hat. Space, however, forbids us to deal with more than the principal shapes, for the others are but a distinguishing feature, while the workmanship is on similar lines, except in detail as to the size, etc., of curl or set. We will deal with a ½-in. roll, which is the common size of a curl.

First place the hat tip to plank, with the front facing you; then get the centre by placing finger and marking plush on top side of brim; turn the hat round, and perform the same operation with the back. Then place the hat brim to plank, with the centre marks exactly level from left to right. Warm the brim with the iron until it is just bendable, run flat plough over the warm part; then, with a piece of plush between thumb and first finger of left hand, pinch the edge of brim upwards, beginning about ½ in. from the mark on right hand, and finishing about the same distance from the left-hand mark.

The machine or roll brass is now used by running it along the brim and gradually turning it over to the required size [2]. Great care must be exercised in order to ensure a very even and symmetrical curl, and the brass curler must be kept flat along the plank, so that the curl can fit perfectly in the groove. An even and perfect curl is largest in the centre, tapering smaller at the shoulders. It is easy to understand that if the same pressure is exerted all along the brim, the result will be a curl one size from beginning to end; but that is not what is required. Therefore, a gradual pressure and release of same, whilst the brass is in motion, obviates

that, and makes the shoulders or ends considerably smaller than the centre. Having made the curl the required size, the brass or machine must be removed, and under the curl is placed a "rope" or "roll pad," whilst the brim is warm and pressed on the "rope" with a grooved plough. This "rope" or pad is made from calico or tissue paper, the former preferred, as it lasts considerably longer. The curl is now really shaped, but to prevent its losing its rotundity it must be ironed along the top edge, which will produce a shiny surface on the merino. After sufficient ironing, the grooved plough again comes into use in pressing and keeping it to the shape of the ropes. When the rope is removed, a perfectly formed curl is the result, but to ease the setting of the hat it is necessary and expedient to *round* the brim. To do this successfully it is imperative that great care should be exercised.

Get a piece of swansdown, about 12 in. by 9 in., and place it on the merino (with tip of crown to plank); then take a sponge and damp about 1 in. wide from the curl; rub over with the iron a few times, when the steam will have sufficiently warmed the brim to make it pliable. With first finger well under curl and thumb on the merino side of brim, pull round, beginning at the farthest point from you. As in curling, so in rounding, the greatest rounding should be in centre, tapering to each end. This will leave the front and back of brim perfectly flat, and, after curling both sides, the *fronts* can be put in. Place hat on tip, with the curls parallel to you, then gently rub the iron along the inch or so of brim that has not yet been touched, until it is bendable; pinch it as in curling, joining the two curls together, get the *front groove*, and work it along until the front is level. Care must be taken to see that the ends of the curls are evenly joined together by the front, and after front and back have been put in the hat is curled, but not quite finished, for you will observe that the edges of the curls are rough.

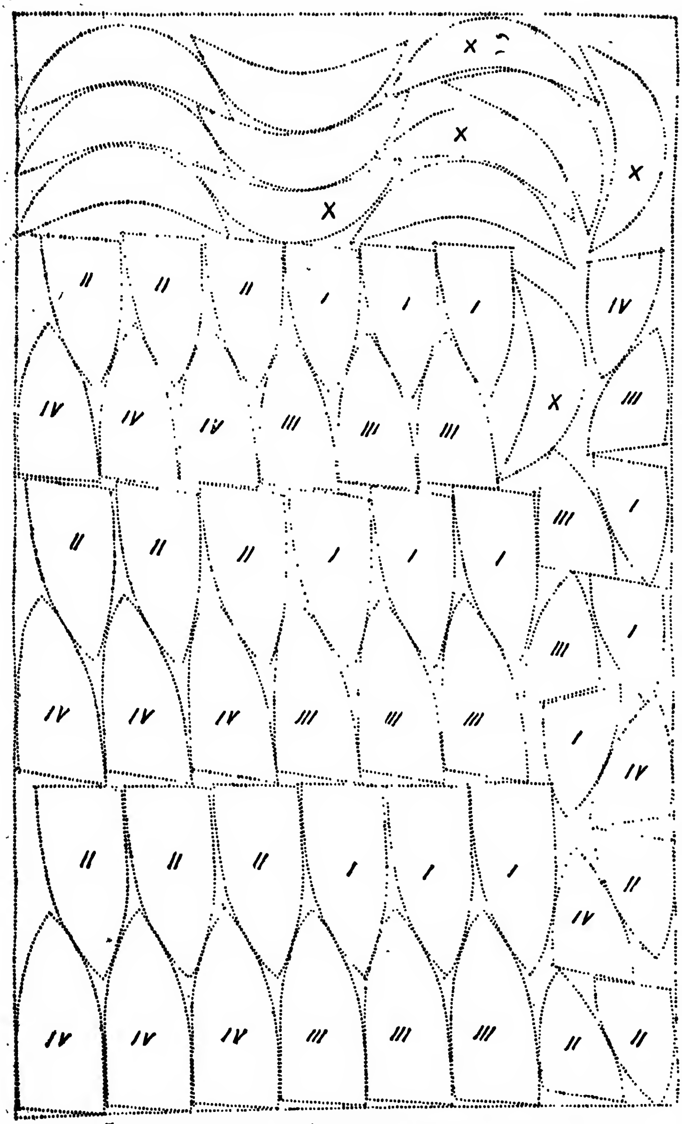
Paring the Curl. To put a perfect finish on the curl it must be pared or chipped. First get a knife—one made from an old razor is best as it lasts longer—which must be shaped and cut out at the front and back, leaving it very small and level. With a paring machine the sides must be cut to make the edges smooth and both curls equal in size. It will be seen that the plush and merino make the curl look ragged and very untidy, but the knife run under or along the edge of the curl will remove the former, whilst the latter may be cleared away by the use of scissors. A piece of fine sandpaper run along the edge of the curl will mend it in appearance. The hat is now placed on a "horse," an arrangement made of wood hollowed out at the top to allow the hat to fit steady, with a "duffer" in it. A duffer is placed in the hat to prevent the heat of the fire from *drawing* the crown of the hat out of shape. It is made from paper or felt and fits close to the head part of the hat. When the hat is warm enough to be bendable, it is ready to be set. Care must be taken not to have it too warm, or it will cockle the brim, making it very uneven.

The shaper places the tip on the plank and begins to make the hat the shape required. When the sides are set to the desired width it will be seen that the back and front look hollow and unlevel, especially in the band which is near the head part. To put it level a cloth has to be placed across the front, water it with a sponge, and then iron it until it is again workable; turn it over, and with a flat plough work the top side of the brim whilst the underneath is placed on a "cheese" or "half frame." It must then be worked with thumb and finger until it is straight, the shoulders are level, and the curl is in perfect symmetry with the brim. It is now ready for the trimmer.

Trimming. The *trimmer* receives the hat after being shaped, along with the following trimmings: Band and binding, tip paper, side paper, silk tip, silk side, leather, tassel, and sticker. First find the centre of brim at back of hat, then measure binding round the edge, and, after cutting it to the size, sew the ends very neatly before sewing it on the brim, the seam to be at back of hat. The binding will then be on the top side of brim with the stitches going through. It must be rubbed on the underneath with a bobbin, to prevent the stitches showing through the binding. Now turn the binding over curl, and sew, or "whip" it to the merino underneath. Then tie the band round the crown of hat, placing bow on left side.

4. LASHING THE LEATHER

Take the tip paper, which is very stiff, place it on the tip on hat, and make an impression round the edge with thumb and finger, which, after cutting, gives the size required, and is ready for the silk tip to be stitched on. The silk side is now sewn round the edge of the tip and the ends "run up" together, the whole forming the lining, but before putting it in the hat the side paper is fixed and made firm with a little paste; this prevents the colour of the body from showing through the silk side. After fixing the lining in, sew it round the top of the paper, which causes it to "bell," through its being cut on the bias, or cross. The leather is to be measured round the inside of the hat and the ends cut so that they will just meet, both being cut on the slant, so that a little more will be cut off the bottom than top. Place the edges of leather together, and with a sticker (a gummed piece of paper) fasten them; also make the tassel into a "bow" and stitch it to the back of the leather. Now place leather in hat, putting the seams of binding and leather in the centre of the back of hat. Get a thin cord (top cord) and fasten it on top of leather with the stitches used for sewing the leather to merino [4]. It prevents the top of the leather from showing



5. CAP-MAKING: ARRANGING MATERIAL ON CLOTH

through the stitches and gives it a more finished appearance.

The hat is now ready to be returned to the shaper, who, with his brim iron, irons the brim and brushes it until the plush presents a smooth and finished appearance. Run down the band with a band peg or thin piece of wood, strip the paper cap, iron the crown, and follow with a velvet velure. Put on the white cap, and the hat is completed.

CAP-MAKING

To-day, cap-making gives employment to thousands of hands, has special factories and machinery, and large sums of money are invested in the industry. But there is no reason why caps should not be made by any person who has a knowledge of producing other articles of wearing apparel.

As a home industry, however, cap-making has largely died out. It has been killed by machinery, skilled factory organisation, and subdivision of labour. All these things tended to make the cloth cap wonderfully cheap, but since the introduction of a much higher class for motoring purposes, and of a greater degree of artistic design in those now worn, prices have risen to so great an extent that a really well-made cloth cap is rated at a price practically equal to that of the best kind of bowler or the cheaper make of silk hat. Still, there appears no reason why cap-making should not be developed as a home industry. It is comparatively simple work.

The ordinary kind of cap is produced from eight three-cornered pieces which, when laid out flat, would form the segments of a circle.

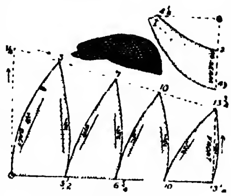
In the factories these pieces are cut from cardboard discs representing the different sizes. Thus, the circumference of the disc for size $6\frac{7}{8}$ would be about 25 in. The actual circumference for a size of $6\frac{7}{8}$ is 22 in., but the extra inches are allowed for the seams. By careful cutting a yard of cloth 54 in. wide would make a dozen golf caps of average sizes.

Getting the "Lay." The usual practice of the cap manufacturer is to purchase a number of pieces of tweed made in the large home-spun check patterns which are now the favourite designs. When these are delivered at his factory the first process is to get what is called "the lay"; that is, to arrange the cloth so that the caps can be made with the least possible waste of material, due regard being paid to the necessity of matching the pattern when the pieces come to be put together.

When this has been done, a pattern is cut out of several thicknesses of cloth by means of a band knife, which will cut through a hundred layers of the material as easily as one. The parts are then ready for the machinists, who stitch the several pieces together, after which the partly made-up cap is passed on to the finishers, who put in the linings—which are cut by the same process—cover the peaks, put strapping on the seams, and complete the work.

In the making of the caps there are four distinct processes: cutting, machining or sewing,

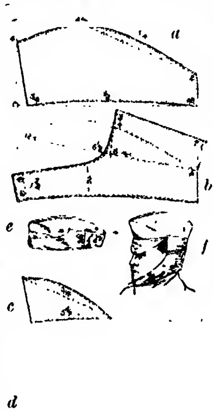
pressing and finishing. The workers become exceptionally expert in their own particular departments. The cutter can lay out his cloth so that there is no waste, the machinist can join the pieces together with marvellous quickness on the electric power sewing machine, the pressers open the seams and mould the shape on blocks, and the finishers can complete the article with wonderful rapidity. With the exception of the cutters, the hands are women workers, and one expert cutter can easily keep fifty or sixty machinists busy.



6. CLOTH CAP

The term "finishing" includes the process of sewing in the linings and other hand work, and sometimes the finisher does the pressing and blocking. When the cap leaves the hands of the machinist it looks like a cloth bag, but by careful manipulation upon a wooden block, and by the aid of a heavy iron like a tailor's goose, the seams are pressed down and the cloth shaped ready to wear. On an average a cap passes through nine processes and through the hands of as many workers before it is complete.

The rapid growth of the trade would, of course, have been impossible without the sewing machine and the band knife, but especially the first named. A cap factory, in its way, shows some of the best points of modern industrial organisation. The different processes dovetail into each other, and there is no waste of time or energy. The result is that a good, useful cap can be made to sell at a shilling, which fifteen or twenty years ago would have cost five times as much. The employes earn a fair living wage on account of the large quantity they can produce with the aid of machinery, skilful organisation, and careful subdivision of labour. The reason that the cap trade has settled down in London and Leeds is that it is an adjunct to the ready-made clothing trade. The class of labour required is very similar, and in both London and Leeds there is an unlimited supply of skilled machinists. When work is slack in the clothing factories they can work in the cap factories, and vice versâ.



7. THE 'GLENGARRY' CAP

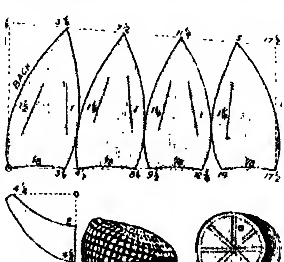
Sizes. It is worthy of note that north of the Humber the caps in demand are of a larger size than in any other parts of the country. The average size throughout Lancashire and Yorkshire and the Northern counties is 6⅞; in the South it is 6¾. The sizes of the caps start at 5 and go up to 7½. After that they are called "out sizes"; 7¼ is considered large, 7⅜ is seldom asked for, whilst 7½ is thought abnormal. A man with a head above that size would have to have his caps specially made. The first size (5) fits a head of 18 in. in circumference, and each additional size means an average increase of $\frac{5}{16}$ in. The medium size (6¾) fits a head circumference of 21 in. A size is obtained by taking the length and breadth of the head, adding them together, and dividing by two. The golf cap is the favourite style for men's wear, but a great variety of shapes are produced, and the different patterns of a large manufacturer will number a couple of hundred.

The variety is caused by the different fashions in women's and children's caps, and a great demand has sprung up recently for women's golf and motoring caps. The characteristic features are, however, retained in the various styles, the chief differences being in respect to size, shape of peak, and other details.

The accompanying diagrams show the method of cutting two of the standard shapes, and also the service cap known as the "Glengarry." Size 7 is taken as a model, and as the figures correspond to those of the ordinary inch tape, modifications both as regards size and style can easily be introduced.

The Golf Cap. The golf cap is cut in ten pieces, eight of which are sections of the upper part of the cap, and the remaining two form the peak.

The accompanying diagram [8] is a reduced model of one of the best shapes of a leading maker. The size can be varied by adding a little to, or taking a little from, the various seams; the inside portion of the peak is cut of the same shape, but rather smaller than the lower diagram. The various parts should be taken from the cloth in much the same way as they are arranged on the diagram, and should be cut exactly on the line, as provision is made for ¼ in. seams at all parts.



8. GOLF CAP

Now baste the various parts together and sew the seams by machine, making the seams ¼ in. wide, and in doing this, care must be taken to get a neat finish at the point where all the sections meet. In order to do this, the best plan is to make up the two sides first, and then seam these together from front to back. Prior to this, however, it will be advantageous to press the seams. Cap-makers have proper blocks for this, the shape varying with each style of cap; much may be done by turning a sleeve-board on its side and using the rounded end. The seams being sewn and pressed open, the peak is made up and stitched, and in order to ensure its being put on in the centre, fold the peak over and make a notch, putting this to the centre seam in front. The peak is lined through with heavy canvas.

The edge of the cap is now turned in, and it is ready for the lining, which is done in

various ways: (1) A lining of silk the same shape as the outside, which is felled round the edges. (2) A leather headband round the bottom, and a silk head lining in the crown after the style of a hat. (3) A leather band and the seams covered with galloon after the manner shown in the sketch, the galloon being stitched on so as to cover the seams and make a neat and light finish.

The top of the cap where all the seams meet is usually covered with a small button made of the same material.

The front is provided with a hook and loop or a glove fastener to make it pouch over in front, and sometimes ventilators are put in the crown, after the style shown in the sketch.

There is room for a good deal of skill in the finish of caps, and this has more to do with the pressing than any other part; the superior shape imparted to those made by high-class firms is due to the extra facilities they have in the way of blocks and so on for the pressing purposes.

We also give another style of cloth cap, with a flatter front and not so full a crown [6]. This is a style of cap very popular in the North of England. Thousands of these are made up in Leeds, where they are produced very cheaply in the way previously described. The lay here given [5] was photographically reduced from one in use at one of the largest factories. It will be seen that no material is wasted, and in order to avoid confusion the various parts are marked in numbers. These lays are prepared in buckram and are perforated; they are then placed on the cloth from which the caps are to be cut, and a pad containing powdered chalk is passed over it, and the outline is marked.

The Glengarry Cap. By way of making this article complete we give diagrams showing how to cut a Glengarry cap with part to turn down over the ears and fasten under the chin [7]. This diagram has no provision made for seams, and the size head it will fit is 7. Figures *a* and *b* represent the side, *c* the peak, and *d* the crown. Two each of these parts are required for the cap, together with peak, lining, and lining for *b*. The peak is cut on the crease. The process of making is much the same as already described, though the peak would be finished in softer style.

We give illustrations of this cap folded up, and also in wear with the ear laps brought down and fastened under the chin [7*e* and 7*f*].

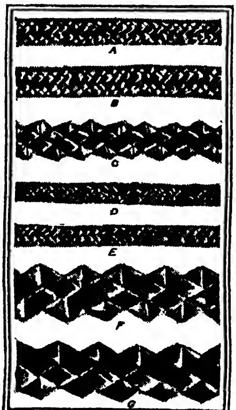
The following table gives the ordinary range of sizes, together with the head measurements to which these sizes correspond:

18½	18⅞	19¼	19⅝	20	20⅜	20⅞	21¼	21⅝	22	22⅜	22¾	23⅛	23⅝	24	24⅜
5⅞	6	6⅛	6¼	6⅜	6½	6⅝	6¾	6⅞	7	7⅛	7¼	7⅜	7½	7⅝	7¾

STRAW HATS

The making of straw hats, especially for women's wear, is one which can be easily carried on at home, as no expensive appliances are needed.

Straw hats are roughly divided into two classes, "block" and "shape" styles. The first have hard crowns and brims, and the shaped styles are usually soft and flexible. The "shape" styles are, as a rule, confined to the various sailor types, and to make them a block is necessary. The straw plait is sewn into a circular mat, and then placed over the block, and by means of a hot iron it is manipulated into the same shape as the block. This forms the crown, and the rim is blocked and pressed in the same fashion. The rim and crown are then sewn together, and the hat is ready to be trimmed and lined.



9. STRAW PLAITS
a. Pedal white *b*. Canton white *c*. Fine rustic white *d*. Tuscan white *e*. Fine pedal white *f*. Coarse rustic white *g*. Coarse rustic black and white

As stated, blocked hats are for the most part factory made, but the shaped styles for women's wear can be easily made at home. The first thing necessary is to get the skeleton, which is made of wire. This can be bought ready-made, or it can be fashioned to suit the individual taste. A plain hat of the sailor pattern can be made with three circles joined together by oblong pieces, all of wire. Upon this skeleton the straw plait is sewn, and when the hat is complete the wires can be removed, or if it is desired they can remain in the hat to enable it to keep its shape. There is a great variety of colours and styles, from the fine and narrow English and French plaits, and what are described as the rustic Japanese, which are the largest and coarsest kinds [9]. It will easily be seen that a hat can be made of a broad plait much more quickly than from a narrow one, and for that reason the broad plaits are much more in favour. The plaits are sold in bundles 12 yd. long, which is sufficient to make a large hat. The price per piece, or bundle, is from 6d. to 6s., according to style and quality. The wire skeleton costs only a few pence [see also MILLINERY, page 5217].

For men's and boys' straw hats the principal shapes are the "Boater," which has a flat top, and a flat brim of varying degrees of width, and is made from both the fine and coarse kinds of plait; the "Trilby," or Alpine style, with indented crown, for which the fine Tuscan or pedal straw is used, and the "Panama" shape, for which the finest plaits are also required. The real Panama is not made from straw, but from a long grass grown in tropical and subtropical countries, and the hat itself is plaited from the grass fibres, considerable time being occupied in the process.

The scale of sizes given for cloth caps will be equally serviceable for the ordinary shapes of straw hats.

TIN AND ZINC

The Sources, Properties, Recovery, and Industrial Uses of Tin and Zinc. Tin-plates. The Processes of Tinning and Galvanising

Continued from page 5993

TIN

Tin, the symbol of which is Sn, and the atomic weight 117·35, was one of the metals familiar to and used by primitive man. Bronze is an alloy of tin and copper, and bronzes have been recovered from the ruins of ancient Nineveh and other sites which were peopled back in the dawn of recorded history.

Properties of Tin. The colour of metallic tin is silver white, with a lustre that increases with the temperature at which it has been poured. The crystalline structure of tin is the cause of the "cry" of tin—that is, when a piece of tin is bent, the crystals grind against each other, and occasion the peculiar sound so designated. Commercial tin has a specific gravity of 7·5, purer tin being slightly lower. At low temperatures tin is very ductile—its point of maximum ductility being at about the boiling point of water—and can be beaten and rolled into foil, but at 200° C. it is extremely friable and can be powdered. Though ductile, it has little tenacity. Its exact melting point is uncertain, but is about 228° C., its boiling point is between 1,600° and 1,800° C., and at this temperature it burns in the air, thereby forming stannic oxide. Its thermal conductivity is about 150 (silver = 1,000), and its electrical conductivity at 21° C. is slightly over 11 (silver = 100).

Occurrence of Tin. The localities favoured by deposits of tin are not numerous. The mineral never occurs in the native state and only in a few chemical combinations. The most common ore is *cassiterite* or *tinstone*, a dioxide of tin (SnO_2). The tinstone found in Cornwall contains also sulphide of copper, wolfram, pyrites and other minerals. It is in the form of veins usually in plutonic or metamorphic rocks. Alluvial tin, washed from these rocks by denudation, is known as "stream tin," and possesses a high degree of purity. The British deposits of "stream tin" are nearly exhausted. The world's chief sources of tin are Cornwall, in England, and the Malay Peninsula. Less valuable deposits occur in Spain, Bohemia, Sweden, Australia, Africa, and Bolivia. The North American continent, so rich in other minerals, seems to have been very sparingly dowered with deposits of tin.

Alluvial Tin. As with gold, the first tin-workers confined their attention to alluvial deposits, which have been formed by the disintegration of portions of the stanniferous granite masses—the disintegrated portions being carried away after denudation and deposited in the lower valleys and river beds. The alluvial deposits in the Malay Peninsula are worked chiefly by the open-cast method, although in some cases hydraulic mining [see page 2959] is practised, and in exceptional instances shaft work is undertaken. They show up to 60 lb. of "black tin" or tinstone—which contains from 65 per cent. to 75 per cent. metallic tin—per cubic yard of gravel. The tin *wash*, as it is termed, is found from 2 ft. to 30 ft. under beds of clay and sand, and varies in thickness from a few inches up to 15 ft. or 16 ft. The "wash" consists of gravel worn smooth in its descent from the parent masses, and carries tin ore up to 30 per cent. of its weight. The Malay tin-miners are Chinese, and their tools and methods are primitive. The wash, as the name implies, carries much water, and after the overburden has been removed, the men work in swamps, which are drained in primitive fashion by Chinese wooden chain pumps and water-wheels.

The wash may be left in heaps to dry in the sun, in which case the clay becomes hard and may be removed, leaving gravel only. The method of concentrating the gravel ore is by putting it into a trough some 30 ft. long, with an inclined bottom; water is allowed to run over it, and the mass is agitated by men wielding long hoes. The sand is washed away by the running water, and the concentrate mineral—which is two-thirds tin—is sent to the cupola furnace to be smelted. The furnace used is small—about 5 ft. high—and is made of clay strengthened with stakes and girt with iron rings. Charcoal and tin ore are put into the centre of the furnace, which has an aperture in the rear for the supply of a blast, produced by hand bellows, and for raking. The smelted metal runs from a hole in the bottom into a depression made in the ground and is ladled into moulds in the sand, which give it the form in which it reaches the market.

The alluvial deposits of New South Wales are found under sand dunes [see page 1499] from 200 ft. to 300 ft. wide, and from 10 ft. to 20 ft. high, which have been formed parallel to the sea coast and run several miles inland.

These dunes are made up of a thick top layer of white beach sand, from 10 ft. to 15 ft. thick, under which are 2 ft. or 3 ft. of black sand, and finally about 1 ft. of gold and tin bearing sand on the top of red-brown sandstone rocks. The washing of this sand enables the recovery of the metallic tin, which is frequently associated with heavy proportions of gold and of good quantities of platinum, iridium, and other rare metals.

Tin Ore. *Cassiterite* (SnO_2), the oxide of tin, the form in which tin ore most frequently occurs, has a hardness between 6 and 7 according to Mohs' scale, a specific gravity of 6·8 to 7, and a chemical composition of 78·6 per cent. of tin and 21·4 per cent. of oxygen. These constituents vary in their proportions according as iron, manganese, copper, and other minerals enter into the composition of the vein. In appearance tin ore is dark red-brown or slate coloured.

Success in tin-mining depends more than in the case of most other base metals upon the skill which guides the mechanical preparation of the ore after mining. The ore is picked and sorted by hand, the non-stanniferous pieces being discarded and the true ore being put to one side. The latter is then passed through the stamp batteries. The stamp generally used in Cornwall weighs about 7 cwt., and makes about 60 drops of 10 in. per minute, crushing about 1 ton of ore every 24 hours. Greater efficiency could be attained by the use of more modern stamps, which would multiply output three or four times. The ore under the stamp is pulverised to a fineness that will pass through screens with about 144 holes to each square inch. The result is so much sand, and the problem now is to separate that part

of the sand which is really black tin from the worthless residue. To effect this separation, the greater weight of the black tin—which is rather more than double that of the sand—is made to assist. The crushed ore, carried by water, flows into tanks, known as *buddles*, which vary in form, but are similar in principle to those illustrated on page 5142. The heavy metallic particles sink to the bottom near the point where the mixture enters the tanks. The bottom of many of these buddles takes the form of an inclined plane, with ridges right across its face, and on these ridges the heavy stanniferous sand settles. Again, the bottom may be made to move either by an agitating or by a rotary motion, and the results of these modifications are better than those attained by the original type.

The recovered black tin still contains many impurities. It is now passed through *tossing tubs*, or *chimming tubs*, which work on the same principle as the buddles, and the further purified tin sand is known as *whits*. This is now calcined in order to decompose the arsenical pyrites. Again the *buddles* and *tossing tubs* are called into service as often as may be required to remove the impurities, and the result is a cleaned and concentrated tin sand which is the marketable commodity known as *black tin*, containing about 66 per cent. of metallic tin.

Smelting Tin. The furnace used for smelting is of the reverberatory type [see page 4126], with a bed about 18 ft. by 9 ft., and has a fireplace and a stack at opposite ends. The tapping hole is at the back, and is kept closed during the smelting. An ore charge weighs from 20 cwt. to 25 cwt., and after being incorporated with about one-fifth of its weight of anthracite powder it is spread evenly over the furnace bottom. If necessary, fluor-spar or lime may be added as a flux. The door is closed and "luted" up—that is, plastered up with clay—and the heat raised for five or six hours, after which the door is opened, the heated mass is "rabbled," or stirred up, and some powdered anthracite is spread over the surface. After being heated again for about an hour, and a further stirring, the furnace is tapped. The slag left is chiefly ferrous silicate, but contains some tin, and it is usually heated afterwards to remove this.

Refining Tin. The processes we have described carry us to the point of refining. The refining proper is preceded by a preliminary liquation in a reverberatory furnace, which takes a charge of about 18 tons. The temperature is carefully watched, and as it rises to the point of melting, the purer tin is run off into a special pot or "kettle" heated by a separate fire. The impurities—iron, copper, sulphur, and other constituents—remain as *hard head*, a white, brittle mass which contains about 20 per cent. of metallic tin. The purer tin, which has run off, is retained in a molten state in its own kettle, and logs of green wood are plunged beneath its surface. Under the heat the wood gives off gas, which causes agitation of the molten metal, and the formation of a scum containing the impurities. The same result is sometimes attained by pouring the metal from a height of 17 ft. or 18 ft. into the kettle, this process also producing the scum and removing the impurities. The operations we have described give the commercial products known as *common tin*, or *refined tin* according to quality. For the latter, purer ores are used, and the refining is prolonged. *Block tin* is a lower quality than refined tin.

Alloys of Tin. Apart from its use as a coating on baser and cheaper metals, the chief industrial use of tin is in alloying with other metals. Although it is a soft metal, in combination with other soft metals it forms a hard alloy. Lead alloyed with tin has a higher malleability and ductility than pure tin, but a lower toughness. All soft solders have tin as a constituent [see Soldering]. In addition to soft solder, the tin-lead alloys include pewter and tinfoil [see also page 5987]. Pewter was formerly used extensively in the manufacture of domestic utensils, but the solubility of the lead made lead poisoning frequent if the proportion of lead were high. The maximum proportion of lead which should be used in tin-lead alloys for culinary utensils is from 10 per cent. to 15 per cent. The acids of fruit have no appreciable effect upon such an alloy, but if the lead be in excess of this it dissolves and enters into solution in the food.

Alloys of tin and lead are used in a molten state for tempering steel tools. The finer the tools the higher is the proportion of tin. Thus, for razors, penknives, and surgical instruments the proportion is about two parts of lead to one part of tin; while for small saws, the amount of tin is only one-twelfth that of the lead.

Tin-copper Alloys. The tin-copper alloys include bronze, gun-metal, and bell-metal. Ancient bronze was a dual alloy, containing only copper and tin, but the French bronzes of to-day are made of triple or quadruple alloys, usually the latter, consisting of copper, tin, lead, and zinc, and sometimes in addition with small proportions of arsenic, antimony, nickel, and sulphur. The colour of a tin-copper alloy varies from red to white, as the proportion of tin rises. From 90 per cent. copper to 70 per cent. copper, the colour ranges from red to orange yellow, pure yellow, light yellow, and white. Bronze increases in hardness as the proportion of copper rises to 35 per cent. of the alloy. From this proportion to an alloy with 73 per cent. of copper the brittleness is high, but as the copper exceeds the latter value, the tenacity increases. Gun-metal has 90 per cent. copper and 10 per cent. tin, this proportion being the mixture of maximum hardness.

Tin-antimony Alloys. Tin alloyed with antimony gives bearings metal and Britannia metal. Such alloys are harder and less malleable than pure tin, but are equally white. Increase in the proportion of antimony increases the brittleness. Tin-antimony alloys should be cast at as low a temperature as possible, so that the excess of antimony may not separate from the eutectic alloy. Ordinary Britannia metal usually contains not more than about 10 per cent. of antimony, the remainder being tin. Sometimes a small proportion of the tin is replaced by copper, and occasionally zinc or bismuth is also employed. A small proportion of bismuth increases the fusibility. The points of merit about Britannia metal are that alloys of tin and antimony yield good sharp castings, are tougher than tin, and take a better polish than tin-lead alloys. The manufacture of Britannia metal hollow-ware, such as teapots and coffee-pots, used to be a much larger Sheffield industry than it is. Nickel-silver has displaced it considerably. Most of the Britannia metal-ware now made in Sheffield is electro-plated. It can be distinguished from nickel-silver, because when struck sharply it sounds as a dull thud, whereas nickel-silver hollow-ware similarly struck gives a clear, sonorous ring.

Antifriction Metals. Bearings metal or antifriction metal is frequently an alloy of tin and antimony, containing about 20 per cent. of the latter. It is usually, however, not a dual alloy, but contains also copper, lead, or zinc [see also page 5988]. The formulas given for antifriction metals are very numerous, but that the science of eutectic

alloys is imperfectly understood is proved by the large trade done in proprietary antifriction metals, the composition of which is not acknowledged.

Alloys of tin and zinc are harder than tin, but not so hard as zinc. Their use is limited. They are made into imitation silver leaf, and also cast into ornaments. The metals may be alloyed in all proportions.

Tin amalgam—that is, an alloy of tin and mercury—has a more restricted use than it had in the days when it was the agent adopted for silvering mirrors. Dentists use tin amalgam for filling teeth, one part of finely divided tin being triturated with four parts of mercury, and the excess of mercury being squeezed out in a chamois leather bag. The amalgam is pressed into the tooth and hardens in a few days.

Then we have alloys of tin, bismuth, and lead, used for type metal and printing blocks.

Tin-plates. Tin-plates are sheets of iron or steel, coated with tin. Sheets of Siemens steel are chiefly used for tin-plates, but charcoal-iron, which was, before the era of steel, the usual base, is still employed. Common qualities of tin-plate used to be made of puddled iron, and were known as *coke* plates, while *charcoal* plates were made from charcoal-iron. Bars of steel are made red hot, passed through chilled rolls, thereby being drawn out to about double length, folded in the middle, and again heated. Another rolling, another doubling, then another heating, rolling, and doubling takes place, until perhaps the final sheet contains as many as 32 plies. The sheets are trimmed to proper size, and the plies pulled apart, each ply then being a rough "black plate," so termed from its adhering coat of rough black oxide. This oxide must be removed before the plate can be tinned, and the operation, which is called *pickling*, is done with a warm solution of sulphuric acid in water for about fifteen or twenty minutes, followed by washing and rubbing with sand. *Annealing*, or maintaining at a high temperature for some time, then takes place. The annealing ovens are wrought-iron boxes of a size to hold the plates, and have removable upper parts, with joints that can be made tight against the ingress of air by being covered with sand. The annealing boxes are placed in a large furnace and kept at red heat for about ten hours, after which they are withdrawn, and the sheets are allowed to cool. After this, the sheets are rolled to give them smoothness, for a tin-plate can have a good surface only if the black sheet has had a smooth surface. The rolling may have made the sheets hard again, so a second annealing in cast-iron pots, and at a lower temperature, is given. Again the sheets are pickled, but in acid solution weaker than formerly, are rubbed with sand, and put into water to await the moment of entry into the tinning baths.

Plant for Tin-plates. The baths or pots used in the actual tinning process are usually five in number. The first is the grease-pot, which holds melted grease, such as tallow or palm oil, and the sheets are immersed in this until all water has evaporated from their surface, and they carry a uniform layer of grease. The second pot contains molten tin covered with a layer of grease, and the sheet is transferred from the grease and put into this, where it receives a coat of tin. The third pot is the washing-pot, also containing tin, and the sheet, with an imperfect coating taken on in the tin-pot, passes into the first compartment of the washing-pot, and acquires a uniform coating. The plate is removed and treated by a workman with a wire brush, who then puts the plate into the second compartment of the same pot, which is the final tin bath, and contains the best tin. The next pot is a grease-pot, in which the plate passes between carefully-adjusted rollers that remove excess of metal and give a better surface. The grease which adheres as it leaves this last pot is removed by rubbing with bran or sawdust, and a final surface is given by rubbing with a piece of the fleece of a sheep. The finished tin-plates are then examined for defects, and finally boxed for the market.

Varieties of Tin-plates. All the plates do not issue perfect. Defective plates are known as *wasters*, and if very bad, as *waste-waste*. In common tin-plates, *primes*—that is, sheets passed as perfect—usually amount to from 80 per cent. to 90 per cent. of the whole: but in charcoal plates the standard of quality allowed to pass inspection is much higher, and primes may be only 40 per cent. to 80 per cent. Wasters are sold as such, and there is always a market for them.

The commercial designations of tin-plate are very confusing, and the sheets are packed in boxes which are consistent neither in the number of sheets that they contain nor in weight. The table that follows gives the particulars of the various varieties and sizes. It is, indeed, time that some simpler method of packing and indicating tin-plates should be adopted. Cumbrous and awkward systems of reckoning also prevail in the manufacturing processes, but into these we cannot enter.

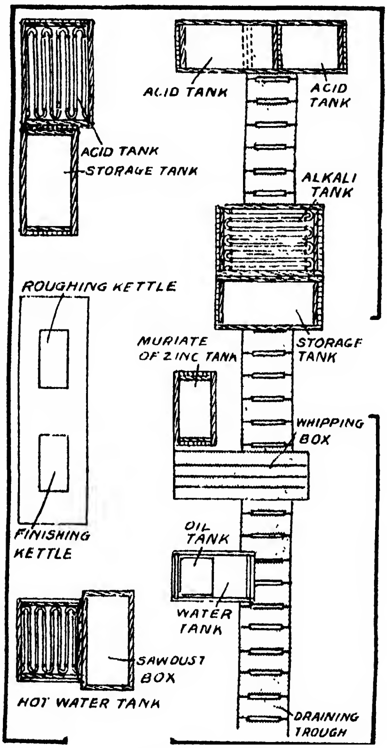
Terne Plates. Terne-plates are made in the same way as tin-plates, and differ from them only in that the coating given to the black plate is an alloy

of tin and lead. The proportions of the mixture vary, with different manufacturers, but a frequent and a satisfactory mixture contains 75 per cent. of lead and 25 per cent. of tin. Such plates are used extensively for roofing purposes, particularly in the United States, in Russia, and in mid-eastern Europe.

Uses of Tin-plates. Steam power and machinery have revolutionised the working of manufactured tin-plates. "Pieced" work, so-called—that is, articles made by the tinsmith, who cuts out and puts together pieces of the plate to make tin hollow-ware—has been superseded by the product of stamping machinery. The largest consumers of tin-plates in the world are the petroleum oil com-



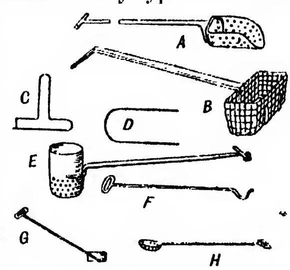
1. TINNING PLANT

panies of America and Southern Russia, who manufacture square tins in which to export much of their refined oils. The packing industries in Chicago and elsewhere are also large consumers, as well as the fruit and fish canners.

But besides the tinning of black plates, which is a localised industry, and in this country confined to South Wales, the process of tinning finds a wide scope in coating all classes of manufactured iron, steel, and metal articles, from pins to saucepans, from harness buckles to meat tins. For such work, a detailed description of the plant and processes may serve some good purpose in this article, because, while there is small likelihood that any student of these pages will desire to set up tin-plate works, it is more than probable that many may desire to install tinning plants as finishing departments of metal-working businesses.

Tinning. The operation of tinning resembles in many respects that of galvanising by the hot process. Articles are galvanised to protect them from rust. The more expensive process of tinning has the same object, but the zinc coating of the former process is not suitable for articles for culinary purposes, and in the sphere of cooking utensils and for food containers tinning finds its greatest field. Tinning also remains brighter than galvanising, although those not thoroughly familiar with the distinctive appearance of galvanising and tinning may often mistake a badly tinned article for a well galvanised article. Tinning was in vogue for coating articles of malleable iron, and of wrought iron and steel long before it was used for common cast iron. The process upon the latter material is a little more difficult, and it will demand special treatment.

Tinning Plant. A description of a tinning plant will be more lucid if we take a typical case, but it cannot be claimed for any typical case that its details are suitable for all cases. The requirements of the work must modify the details in installing a plant for a particular purpose. A good general arrangement for a tinning shop is shown in 1, and the purpose of the various fixtures will be explained as we describe the process. The small hand tools necessary are modified by the nature of the work done, but the tools shown in 2, and also used for galvanising, serve most purposes in the tinning shop.



2. HAND TOOLS FOR GALVANISING AND TINNING

Preparing the Work. The smoothness of the coating of tin depends quite as much upon the metal surface as upon the even deposition of the tin envelope. Common articles are cleaned from rust, sand, and adhering dirt, by immersion in acid—sulphuric acid, muriatic—otherwise called hydrochloric acid—or hydrofluoric acid. Where a better coating is desired, the articles are further prepared by rolling them in special barrels with gravel and water. These barrels, made of a convenient form and size for the work, are caused to rotate upon a horizontal axis, and the agitation and friction makes the articles within smooth to a degree proportionate to the time during which they are subjected to this treatment. When extra fine results are desired, the articles may receive a second rolling in coarse dry sand, and even a third rolling in scraps of leather, but common work seldom warrants the expense of this extended treatment.

Wrought iron and steel can have rust and scale removed in a pickle made of sulphuric acid diluted with water to thirty times its volume, or with muriatic acid diluted to fifteen times its volume. Hydrofluoric acid is sometimes used, and is much quicker in its action, and is less likely to injure the castings. The strength is from 1 in 20 of water to 1 in 30. The pickle should be kept warm at, say, 150° F. Stirring is necessary during the process if the articles are of such a form that the surfaces of different articles are liable to rust in the bath in contact with each other, thereby preventing the acid from getting to its work. Sheets of iron or steel are placed in wooden racks arranged to keep them apart. Every article should be examined

individually as it comes from the bath, and if not satisfactory, should be subjected to further treatment, or should have any scales removed with a pointed instrument, such as an old file. Small articles are then "rolled" in barrels, as already described. This process does not increase the adhesion of the tin coating; it merely gives a smoother surface. Over-pickling, which is apt to follow the use of sulphuric or muriatic acid, makes the work pitted, and care must be taken to avoid it.

If the articles be sandy, every particle of sand must be removed, or bad work will result. This may be done in the manner described later for preparing work to be galvanised. Washing with the aid of wire brush rubbing may be necessary to remove the sand perfectly.

Malleable castings should always be rolled with dry, sharp sand or shot, to secure a good surface. If the articles have paint or grease on their surfaces they should be immersed in a hot, strong solution of caustic soda, and then washed in clean water, finally going to the pickling tank to have the rust and scale removed.

After being cleaned by one or more of these processes, the articles are put into a tank with clean water—not into running water, which would cause oxidation—until they are wanted for the tinning kettle.

Dipping the Articles. Small work is usually strung on wires for immersion. Make the wires long enough so that there may be plenty of room to put the articles well into the tin. Take a wire laden with articles, immerse the latter for a few minutes in a tank containing a solution of muriatic acid (1 to 5) to remove any remaining traces of rust, then into muriate of zinc solution (zinc chloride) made by dissolving zinc in muriatic acid to saturation point, and finally put into the kettle of molten tin.

Common work is often done in a plant with only one tinning kettle. The diagram [1] provides for two kettles, which are almost essential. With one kettle the slag or dross which accumulates on the surface is apt to adhere to the finished articles.

Several wires filled with work are put into the kettle and allowed to remain there until the articles are as hot as the tin, which should be about 500° F. When this point is reached the work is withdrawn, care being necessary in the manner of withdrawal. With a ladle held in the right hand, clear the surface of the molten tin free from slag, so that no slag or flux may be carried away by the articles as they are withdrawn. Then withdraw a laden wire and plunge it immediately into the second kettle, which should have a temperature of about 400° F., or 450° F. for very small articles. Care should be taken that none of the surface slag or flux is taken over by the work into the second kettle. The second kettle should have a layer of tallow on the top, to the depth of ½ in. or 1 in. When the temperature of the articles in the kettle has fallen to that of the second kettle they are withdrawn, swung around sharply so as to throw off any surplus metal, and then thrown into a tank of kerosine oil. This tank has a water jacket, preferably with circulating water, to prevent the oil overheating. In this tank the tin coating sets, and when the work is withdrawn from it, which may be at any convenient time after the tin has set, it is thrown into clean sawdust, which takes up the oil. The operation of tinning is now complete, and if the proper method has been followed, and care exercised, the articles have a smooth coating, uniform in depth and colour.

Preparing Gray Cast Iron for Tinning. To get a good coating on common gray cast iron, several precautions in addition to those used for ordinary wrought iron and steel, and for malleable cast iron, are necessary. If grease or paint be present, or if there be traces of resin from resin cores used in the moulding, the articles should be washed in a strong hot aqueous solution of caustic soda, as already described for removing grease in tinning wrought iron. Castings have always some adhering sand; this should be removed with hydrofluoric acid and water, as already described. Sulphuric acid or muriatic is often used, but hydrofluoric acid is preferable, as it dissolves the sand—not dislodging it only—and does not attack the iron as the other acids do.

Of the several other processes employed to make common gray castings suitable for a deposit of tin, one successful process may be described. A special tumbling barrel, containing a mixture of muriatic acid, sal ammoniac, and water, is used. The barrel should be much stronger than an ordinary tumbling barrel. A body ⅜ in. thick, with cast-iron heads 1½ in. thick, are good sizes. The manhole cover will serve if 1 in. thick, and well supported with ribs. This strength is necessary to withstand the action of the gases generated by the chemicals used, and valves should be provided to permit the escape of these gases. Place the cleaned castings in this barrel, and let one-fourth of the inside capacity be occupied by "stars"—small castings of the shape indicated by the name and used in ordinary tumbling—and shot; then add water until the barrel is three-quarters full, and finally put in 15 lb. of muriatic acid, and 2 lb. of sal ammoniac. Close the manhole and set the barrel in revolution. Soft iron requires about 2½ hours of such rolling, and hard castings may require double this time.

Then the work is withdrawn from this barrel and placed in the storing tank (containing clean water) until it is to be put into the kettle to receive its bath. When that time comes the castings, either strung on a wire or in a wire basket, are immersed in a boiling solution of caustic soda or potash for about two minutes; this is followed by rinsing in water, then by a bath in a weak solution of muriatic acid (1 in 40), then by immersion in muriate of zinc —prepared as already described—to every gallon of which 5 lb. of sal ammoniac has been added, and finally, into the first tinning kettle at 500° F. This kettle should have a special flux on the surface prepared by boiling muriate of zinc on top of the tin and adding thereto some sal ammoniac. The consistency of this flux is an essential to good work. If it tends to become thick or hard, add more of both ingredients, and remove any hard part with a skimmer. Then the second kettle is called into operation in due course, and as already described, and the subsequent oil bath and sawdust.

Recovering Waste Tin. Many thousands of pounds sterling are wasted annually in the tin which adheres to tin-plate scrap, and many solutions of the problem of how to recover this tin have been sought. Nearly all successful processes are secret.

Any process of recovery which has depended upon an acid solvent has proved far too costly. The solvent invariably attacked the iron below the tin, became soon exhausted, and had to be frequently renewed. Success is possible only by an electrolytic process, similar to that employed in the manufacture of electrolytic copper. One such process may be described. The electrolytic bath is said to be a solution of caustic soda, or of sodium nitrate, and the scrap tin-plate, of course, forms the anode.

The tin-plate scrap, freed from grease if necessary, and compressed so as to take up as little room as possible, is suspended in wire baskets in a wooden tank. Between the various baskets copper cathode plates are suspended. Both the baskets and the cathode plates are suspended so as to be clear of the bottom of the tank, where sludge accumulates. The solution is made of 30 lb. of caustic soda in 100 quarts of water, and in use is maintained at about 150° F. by an exhaust steam coil. The solution is made to cover both baskets and the cathode plates. The electric current causes the tin to deposit on the cathode plates as a spongy mass, which is easily detachable by hand. This mass must not be recovered in the presence of air, or it would oxidise away. It is covered with powdered charcoal and coke breeze, and is melted in a closely-covered crucible.

ZINC

Zinc was one of the last of the common metals to come into extended industrial use. There is evidence that it was known to the ancients, because zinc bracelets have been found in the ruins of Eastern cities which were destroyed several centuries before the opening of our era, but the knowledge was evidently lost, because during the long Middle Ages zinc was unknown to Europe as a metal. True, brass used to be manufactured by heating copper in a mixture of calamine (the ore of zinc) and charcoal, but the metal zinc was not known to be procurable from this ore. During the third decade in the eighteenth century Henckel discovered that zinc could be obtained from calamine. But it was about a century later before what may be termed the zinc industry was established. Thus, zinc may be said to be about one hundred years old as a commercial product, and the process of galvanising, or coating iron sheets with molten zinc, to impart powers of resistance to corrosion, was first applied only seventy years ago.

The world's chief sources of zinc ore are Germany, Italy, Spain, France, Sweden, Austria, Algeria, Great Britain, New South Wales, Greece, and Belgium, this being the order of importance. The chief producers of zinc are Germany, Belgium, France, and Great Britain, in the order named. Thus, the smelting and refining of zinc ores does not belong essentially to the districts where the ores are found. Zinc ores carry high percentages of zinc, so that transport in their unreduced state is relatively inexpensive.

Zinc Ores. There are two main zinc ores—*calamine*, or carbonate of zinc ($ZnCO_3$), and *zinc blende*, or sulphide of zinc (ZnS), which the miners term "black jack," on account of its deep black colour. Minor sources are the oxide of zinc, which usually occurs in combination with oxide of manganese and zinc silicate.

Characteristics of Zinc. Zinc is a bright bluish white metal, with the atomic weight 65·4, a specific gravity of about 7·125, which rises if it be cooled rapidly, and a melting point of 415° C. In Mohs' scale of hardness its place is 2·5. Its boiling point is 920° C., but it burns in the atmosphere at a temperature of 500° C. The texture of zinc is laminar, sometimes granular. Its fracture is granular or crystalline according to the temperature to which it has been raised in casting, and is easily recognisable. When heated over 100° C. the metal becomes ductile and may be rolled into rods or sheets, or drawn into wire. After cooling subsequent to this treatment, it remains ductile. The tensile strength of zinc is between 7,000 lb. and 8,000 lb. per square inch of section; its thermal conductivity is 28·1 (silver = 100), and its electrical conductivity is 16·92 (mercury at 0° C. = 1).

The ores are formed in two distinct forms—in mineral veins and in irregular deposits. Of the former class zinc blende is the most abundant, and within the last two decades it has taken place above calamine, which was the first form of zinc ore to be treated.

Preparing Zinc Ores. Since the inception of the zinc smelting industry, the plants and processes employed have undergone modification, and we shall consider only those practised to-day in modern works. There are two main processes, termed respectively the Belgian and the Silesian. They differ in the retorts and furnaces used, and in the methods of handling the ore. Zinc ores, having been raised to the surface, are concentrated so that the cost of furnace treatment may be reduced. Concentrating merely means rejecting the valueless or objectionable portions of the ore mass, leaving the selected rich pieces to be treated. Three processes of concentrating are in practice, and specific ores may be subjected to one, to two, or to all three of these processes, which are hand separation, gravity separation, and magnetic separation. The processes employed in individual cases depend upon the class of ore under treatment.

The ore as brought from the shaft is usually broken either mechanically by jaw crushers or by hand. The latter practice is the better, although the more costly. It is usually practised when low wages rule in the district. Hence it is common in Central Europe, but infrequent in America. Mechanical breaking causes too heavy a loss by making "fines," or dross, and it is valuable zinc-carrying rock that is most easily made into fines. Hand-breaking with hammers is thus the better practice.

Having been broken, the ore is screened to remove the fines. The remainder is then sorted by hand. The best method is by a circular revolving table, or by a long belt conveyer. In either case the work moves in front of the operator at suitable speed, and he or she (for in Continental Europe the sorters are often women) removes the pieces according to instructions, putting the waste aside and retaining the blende or calamite as the case may be.

The process of gravity separation requires, first, that the ore should be crushed to such a fineness that the minerals are well separated. The crushed ore is carefully screened, which grades it into various sizes, and each size is washed and treated by itself in tanks or buddles, such as are used in other metallurgical processes, and which are described in Tin Recovery.

The magnetic separation in zinc ore concentration is practised in New South Wales and in America. It is somewhat costly, involving the use of expensive plants, but it has been found to be remunerative. Zinc and zinc compounds are non-magnetic, or, at most, only feebly magnetic. But if the associated minerals in the zinc ores are magnetic, they can easily be separated by magnetism. For instance, in Bohemia iron in the form of siderite is separated from zinc by heating the mass, then grinding it and screening it, and finally treating it in magnetic separators. In Pennsylvania also the zinc ores which carry franklinite, willemite, calcite, zinkite, and tephroite, are separated by a direct magnetic process without previous roasting.

Calcining Zinc Ores. When the ore has been concentrated in the manner described, it must be calcined, to remove the carbon dioxide and water, and also to make it more porous. Roasting decomposes carbonate of zinc into zinc oxide and carbon

dioxide, and nearly all of the latter is driven off. The roasted mass weighs only about 65 per cent. of its original weight.

The process of roasting may be carried out in the open, the ore being piled in heaps, or it may be done in reverberatory or shaft furnaces. The first method is the most costly and wasteful, and is not suitable for calamite, although it was formerly employed for "blende" ores. Some sulphide ores (such as nickel ores) are roasted in the open, as their sulphur contents supply a great proportion of the heat necessary for their calcination. Thus for zinc a furnace of some sort is almost invariably employed. A common shaft furnace of the limekiln type may serve, but it has the objection that the calcined ores are mixed with the fuel ashes. Such furnaces run to 20 ft. high, and treat up to 30 tons each 24 hours, the fuel consumption being from 3 per cent. to 6 per cent. of the ore before treatment. The shaft furnaces are sometimes grate-fired: these give a cleaner result, but are more expensive in fuel charges, these running from 6 per cent. to 9 per cent. of the raw ore. Their capacity also is only half that of the ordinary shaft furnaces.

Several varieties of the reverberatory furnace are employed, and these furnaces are the only suitable means of treating "fines." They are more expensive than shaft furnaces in both labour and fuel. Sometimes they are heated by the waste gases from reduction furnaces. In Kansas and Indiana natural gas supplies the fuel.

Calcining Zinc Blende. *Blende*, the sulphide ore of zinc, must be calcined to reduce the sulphide to an oxide, and the contained carbonates, if any, must also be converted into oxides. In practice, it is found impossible to remove the sulphur entirely, and up to about 2 per cent. may remain. The ore must be finely crushed, and may not be coarser than can pass a mesh of $\frac{1}{12}$ in. Calcination of zinc blende reduces its weight by 12 per cent. to 20 per cent. The operation is performed in shaft, reverberatory, or muffle furnaces. Preliminary roasting is frequently conducted in shaft furnaces, and the sulphur, which may have been up to 30 per cent. to 35 per cent. of the raw ore, is reduced to 7 per cent. or 8 per cent. The sulphur dioxide given off may be used for the manufacture of sulphuric acid [see page 4627].

The final roasting when shaft furnaces are used for the preliminary roasting—or the only roasting if the shaft furnace has not been used—takes place in either a reverberatory or a muffle furnace. The former is adopted when the gases given off are not to be used, and the latter when they are to be used for sulphuric acid manufacture. Muffle furnaces yield gases rich in sulphur dioxide, and calcine the ore thoroughly. The gases of reverberatory furnaces, on the other hand, give gases very low in sulphur dioxide, which cannot be profitably utilised. Before the gas can be allowed to pass into the atmosphere, however, it must be diluted or otherwise treated so as to render it innocuous.

Zinc Distillation. The next process in the treatment of zinc ore after it has been concentrated and converted into oxide is the recovery of the metal by distillation. Zinc oxide when heated to a high temperature is reducible by carbon or carbon monoxide. Practice employs a heat of 1300° C., although the precise reduction heat is below this. The metal is reduced in retorts or muffles to the form of vapour, which is liquefied by cooling to about 500° C., and is collected in clay vessels called *receivers* or *adapters*.

The Belgian retorts have a round section, the Westphalian are of oval shape with a flat base, and the Silesian are ⌂-shaped. They are usually made of fireclay and burnt clay, and it is essential that they should be of as refractory a nature as possible. The receivers or adapters in which the zinc vapour condenses are short tubes of clay which are luted to the end of the retorts. The furnaces in which the retorts are heated are shaft furnaces, and are fired externally. The retorts are ranged in tiers, and slope forward in the furnaces. The zinc oxide is charged into the retorts with from 40 per cent. to 60 per cent. of its weight of coal or coke. Sometimes the charge is pressed into blocks with tar. The actual process of distillation requires care. The furnace is fired for some days before the retorts are charged, and at first the charges which are introduced into the retorts after removing the adapters are light, but are gradually increased. A retort charge is usually about 63lb. of ore, and is reduced in twelve to twenty-four hours. The condensed zinc is raked into ladles from the adapters into iron moulds, and forms ingots weighing from 40 lb. to 44 lb. After a charge has been reduced the residue is raked from the retort, which is again charged with a fresh supply of material, and the process is repeated as before.

Refining Zinc. The zinc drawn from the adapters may be sufficiently pure for commercial purposes if the ores have been carefully selected, but it may, on the other hand, contain fair proportions of iron and lead, which can be removed by a simple process of refining. The crude zinc is melted gradually again, and kept in that state for some time. The iron rises to the surface, and may be removed as scum. The lead sinks to the bottom and the zinc may be drawn off, leaving the lead; or the underlayer of lead may be removed by an endless screw working in a cast-iron pipe. The higher the purity of the zinc the greater its value, and while pure zinc is almost impossible to obtain, care in selecting the ores and in the subsequent treatment will give something approaching chemical purity.

Zinc Alloys. The most important use of zinc is in the galvanising trade, and the processes of galvanising are discussed later. The next most important use is as a constituent of alloys. In alloying, many metals—including tin, nickel, aluminium, manganese, iron, and copper—exercise a stronger colour influence than zinc, while zinc has a stronger colour influence than lead, platinum, silver, and gold. This means that the metals which we describe as having a stronger colour influence impart their colours to those lower in the scale to an extent much higher than their proportion of the alloy. The most important binary alloys of zinc are with copper and with aluminium. Zinc-copper alloys form brass and yellow metal, and these constitute a science in themselves [see next article]. The two metals unite in all proportions, but for industrial use the proportion of copper is seldom less than 50 per cent. When zinc is in excess the alloy loses strength, and the higher the excess of zinc the weaker and harder is the alloy. Increase in the copper proportion of a zinc-copper alloy gives a deeper colour, at the same time increasing the malleability and softness. Alloys having up to 35 per cent. of zinc can be rolled and drawn only if cold; if the zinc proportion be from 35 per cent. to 40 per cent., the alloy can be worked either cold or hot. Brittleness, and therefore difficulty of working, increases as the zinc increases. The most ductile alloy contains from 15 per cent. to 20 per cent. of zinc, and sheet brass for fine work has this proportion. Brass for

cartridges has 28 per cent. of zinc. Cast brass usually contains more zinc, as it is the cheaper ingredient, from 30 per cent. to 40 per cent. being common.

Alloys of zinc and aluminium are important industrially, especially since the reign of the motor-car began. Castings containing from 25 per cent. to 33 per cent. of zinc are clean and sharp, besides being very strong and capable of being machined easily.

With lead, zinc has very little alloying power, as the two metals unite to a very small extent. Each of them can dissolve not more than 1·6 per cent. of its fellow. Bismuth and zinc are also unsuitable for alloying. It has been found that zinc can dissolve only 2·4 per cent. of bismuth, and bismuth can dissolve not more than 14·3 per cent. of zinc. Zinc amalgam—that is, an alloy of zinc and mercury—is used in the zinc anodes of galvanic batteries. In its preparation, a zinc plate is heated to about 500° F., and after being coated with a brush with a solution of chloride of zinc and ammonia, it is dipped into mercury. Anodes prepared thus give currents more constant and intense than do ordinary zinc plates.

Sheet Zinc. Zinc has been used as a roofing material for about a century. Nowadays, galvanised steel sheets have a much wider application than zinc sheets for roofing. But the life of a galvanised iron roof is seldom longer than fifteen years, even with periodical painting, while the life of a zinc roof is indefinite. Some zinc roofs are in good condition after forty years of service. The sheets of zinc used for roofing should not be soldered when they are to be subject to wide degrees of temperature, as the contraction and expansion of zinc is higher than those of other roofing metals. Nails used with zinc roofing should be of zinc, or, at least, should be galvanised. A zinc roof has the advantage of lightness, being only about one-fifth as heavy as a lead roof—zinc sheets being thinner than lead sheets—and one-tenth as heavy as tiles.

Other uses of zinc sheets include their suspension as plates in boilers to prevent corrosion of the boiler shells. The galvanic current which they induce causes the lime and organic matter to act upon the zinc instead of on the boiler, thereby protecting the latter. Thin zinc sheets, sometimes purchased as flat discs and sometimes turned off the zinc bar in spirals, are used in gold extraction by the cyanide process. Perforated sheet zinc—the perforations being round or ornamental in form—is used extensively for ventilators, and for domestic meat safes. As lining for packing-cases and coffins, as a material for hollow-ware, such as watering-cans, buckets, etc., sheet zinc has a limited but useful consumption. The printing trades use zinc extensively for process blocks.

Other Uses of Zinc. Zinc castings—except so far as zinc enters into brass as an alloy—have not an important industrial use, but many cheap ornaments are made of cast zinc, electroplated or otherwise finished.

Zinc oxide, or *zinc white*, as it is termed commercially, is prepared by burning zinc and leading the fumes into condensing chambers. It is used as a pigment, and also in medicine. *Zinc chloride* is used as a caustic in medicine, and also for weighting cotton goods, and in mercerising cotton. *Zinc sulphate* is used in dyeing, in calico printing, and in medicine.

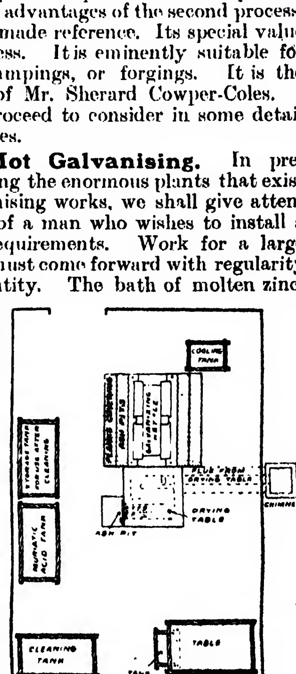
Among the cheaper metals, zinc excels in the property of resisting atmospheric action. For this reason iron and steel, and sometimes other metals, are given a thin coating of zinc, which presents a closed surface to the agents of corrosion and oxidation, and prevents these latter from penetrating to the surface beneath. The process of zinc coating is termed *galvanising*.

Processes of Galvanising. There are three different processes of galvanising—the hot process, the electrolytic process, and the dry or oxide process. The first named is the original process, and is practised by nearly every firm who do galvanising work. It has many advantages, although it has a few disadvantages; but the former have, up to the present, been held to warrant faithfulness to it. It is suitable for all classes of work—sheet, cast, and wrought iron and steel. The plant must be large enough to handle the articles to be galvanised, of course, but there is no class of work that cannot be undertaken by it. No other method is suitable for what is termed *galvanised hollow-ware*—that is, articles such as buckets, bins, water-pots, and other containers of sheet iron or steel that have to be galvanised. Such articles are made with seams which are not always watertight, but the molten zinc during the process of galvanising lodges in these seams, doing duty as a solder, and rendering the vessel free from leaks. The hot process also is capable of giving a *watered* or *spangled* effect which no competing process hitherto tried is able to produce. This surface is for some purposes better than the uniform gray surface attained by other processes. It may be noticed often, but not always, on galvanised corrugated iron and on galvanised buckets. The second process, that of electrolytic deposition, has as its recommendation that it uses much less zinc than the hot process, and may be less expensive; the coat is more uniform than that given by the hot process, and it may be utilised by firms who have not a special galvanising plant, but who have an electroplating plant.

The third, or dry process, is the most recently introduced and has not yet been widely adopted. Except that it requires a special and an expensive plant, it has all the advantages of the second process, to which we have made reference. Its special value lies in its cheapness. It is eminently suitable for small castings, stampings, or forgings. It is the patented process of Mr. Sherard Cowper-Coles.

We may now proceed to consider in some detail the several processes.

Plant for Hot Galvanising. In preference to describing the enormous plants that exist in the large galvanising works, we shall give attention to the needs of a man who wishes to install a plant for small requirements. Work for a large galvanising plant must come forward with regularity and in large quantity. The bath of molten zinc, usually containing several tons of metal, must be kept hot constantly whether work is going through it or not, because if the bath, or *kettle*, be allowed to cool—that is, to solidify—it cannot be melted again without breaking up the kettle—an enormous expense which every galvanising works manager is careful to avoid. But nothing so

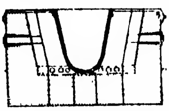


3. GALVANISING PLANT

disastrous follows the solidifying of a kettle containing two or three hundredweights of zinc, although it is better that even these should be kept in constant work.

A galvanising plant should be situated in a separate building, as the fumes from the acid used are destructive to tools and machinery. The building should be well ventilated, the water supply abundant, and the drainage perfect. In **3** we show a good arrangement for a galvanising plant, and the various parts of the plant should be as follow.

Galvanising Kettle and Tanks. The kettle is a long trough built in brickwork, having flues some way up the sides. It should be not less than 36 in. long, 20 in. deep, and 18 in. wide. This size would be of no use for large work, such as corrugated sheets, which, however, would not be handled by a small plant. The kettle should be made of best fire-box steel, not less than ½ in. thick. A good sectional view of an efficient kettle of small size is shown in **4**. The fire underneath must be of a size to keep the zinc in a molten condition.



4. GALVANISING KETTLE

The tanks for acid and cleaning liquid are merely rectangular boxes of a suitable size. If it be desired to economise, an oil barrel, sawn in halves, will make two suitable tanks. It is sometimes considered well to have the acid tanks lined with lead, but this is by no means necessary, and the expense may well be saved.

Sundry Tools. The hand tools used by galvanisers consists of tongs of a shape suitable for the work to be undertaken, of baskets of woven wire or perforated iron, and sundry wire tools, bent to different shapes. In **2** are shown some tools generally used, and the description attached explains their purposes sufficiently.

Firing the Kettle. Some precaution is necessary in firing a kettle for the first time. The fire should not be allowed to raise too great a heat before the zinc, or *spelter*, as ingot zinc is called, has begun to melt, or the shell of the kettle will suffer. The blocks of spelter should be made to lie right on the sides of the kettle, so that as the blocks next the kettle melt the other blocks will be forced into the same positions. The bath may be kept at a uniform temperature by the use of a pyrometer, and some device is usually adopted to prevent the stem of the pyrometer from contact with the molten zinc, although making the same record as if it were in direct contact. A device sometimes adopted is to have the pyrometer stem in a steel tube, closed at its lower end and filled with lead, in the middle of which the stem rests.

Removing Scale. Most work to be galvanised must have scale and rust removed before it is sufficiently clean to result in good work. This process is known as *pickling*. It is accomplished by immersing the work in a solution of 1 part of muriatic acid (otherwise known as hydrochloric acid or spirit of salt) in 20 parts of water. It may be necessary to assist the removal of the scale with a tool such as a wire brush or file. A weaker acid solution should be used for work with an unequal scale, otherwise *over-pickling* may take place, and this seriously prevents the adhesion of a good deposit of zinc. Sandy castings are cleaned by pouring over them a solution containing one part of sulphuric acid to six parts of water. They should be placed on a table or tray, and have the solution poured over them about every hour until the sand can be entirely removed by washing with water.

The Acid Bath. The work is immersed in muriatic acid before going into the zinc kettle. This acid serves as a flux, and also cleans the surfaces finally. If the work has some adhering rust, it should be kept in this bath long enough to remove the rust. The acid used is sometimes full strength, but a better bath is equal parts by volume of muriatic acid and water, with 1 lb. of sal ammoniac added to each gallon of liquid.

From the acid bath the work is taken to be dried, and many methods of drying are adopted. In a small plant, the drying table may be heated from the fire that supplies the kettle, but in big plants separate fires are used for drying the work. The muriatic acid should be apparent on the dried work as a white adhering powder. After drying, the articles should be put into the zinc kettle before they become cold.

The Molten Bath. The molten zinc should be at a temperature suitable for the work being put through, and a pyrometer is the only means of getting exact results. Different classes of work require different degrees of fluidity, or, in other words, different degrees of heat. For large gray iron castings, the metal should be about 775° F., and for thin work, where the spangled effect is desired, this heat is right. For wrought-iron pipe, heavy malleable castings, and small castings used without a flux a good temperature is about 840° F. For nails and other small work, hung on wires or immersed in baskets, about 880° F. is the best heat. The surface of the molten bath at the place where the article is about to be dipped should have thrown on it a few handfuls of sal ammoniac, which, whenever it is melted, should be followed by a few drops of glycerine, to restrain it from spreading over the entire surface.

Dipping. The manner of dipping the articles depends upon their nature. Washers, for instance, are strung on wires, nails and small articles are put into wire baskets, and large articles are simply held with tongs. The immersion should be made as quickly as possible, without causing sputtering, and the article should be held beneath the surface of the molten zinc until it is as hot as the zinc itself. This time cannot be judged by rule, and the only teacher is practice. When the article, say, a thin casting, has been immersed some time, it should be rinsed around a little. Before removing it, clear a space on the surface where it will emerge, and dust that part of the surface with a little sal ammoniac in powder. With one pair of tongs raise the article out of the metal, and with another pair, not dipped into the actual bath, complete the withdrawal. Some goods, such as galvanised hollow-ware, require immersion for only a few seconds, and the surface need not be sprinkled with sal ammoniac before withdrawal. Indeed, slight differences in the minute details of the practice give better work with different articles, and all these details can be learned only by practice. Wire and netting are run through the bath by a reel arrangement, and some galvanisers of corrugated sheets adopt a revolving wheel device to throw up the sheets after coating. The particular practice must be adapted to the particular work to secure the greatest possible economy.

Cooling. The articles are sometimes allowed to cool in the air, are sometimes immersed in cold water at once, and, sometimes, again, the cooling water is heated, so that the cooling may not be too sudden. If the article has taken on any of the sal

ammoniac floating on the surface, a wet brush may be used to remove it.

Dross. Every galvanising kettle accumulates dross. This is caused by impurities and dirt which accompany articles into the bath and remain behind, and sometimes by having the metal at too high a temperature. The dross should be removed periodically, as it retards the work and causes fuel expense if it remain. It is removed with a dross scoop [2], and must be done smartly, and deposited quickly, before it has time to harden on the scoop. The good zinc is sometimes recovered from the dross by heating to a high temperature—over 1,000° F.—with lead. The mass, on settling, has the lead at bottom, with the dross next to it, and the good zinc at the top, whence it may be removed and utilised.

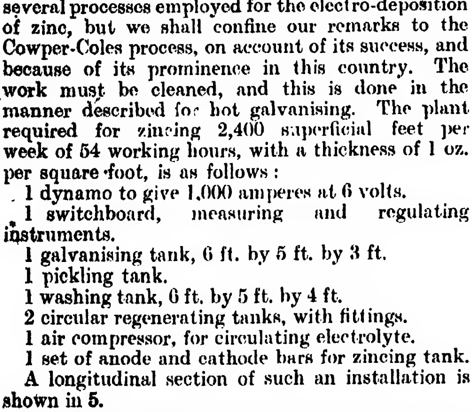
Electro-galvanising. The second process of galvanising, to which we shall devote some attention, is the electro-deposition of zinc. Where the highest degree of adhesion of the zinc to a piece of iron or steel is sought, it is attained best by the method of electro-deposition. Thus, for boiler tubes, and for the hulls of torpedo boats, electro-zincing or electro-galvanising is superior to the "kettle" method. Exhaustive tests have shown that electro-galvanising does not diminish the tensile strength of the material to which it is applied, as does hot galvanising. Also, the coating imparted can be gauged much better than with the more common process.

The Cowper-Coles Process. There are several processes employed for the electro-deposition of zinc, but we shall confine our remarks to the Cowper-Coles process, on account of its success, and because of its prominence in this country. The work must be cleaned, and this is done in the manner described for hot galvanising. The plant required for zincing 2,400 superficial feet per week of 54 working hours, with a thickness of 1 oz. per square foot, is as follows:

1 dynamo to give 1,000 amperes at 6 volts.
1 switchboard, measuring and regulating instruments.
1 galvanising tank, 6 ft. by 5 ft. by 3 ft.
1 pickling tank.
1 washing tank, 6 ft. by 5 ft. by 4 ft.
2 circular regenerating tanks, with fittings.
1 air compressor, for circulating electrolyte.
1 set of anode and cathode bars for zincing tank.

A longitudinal section of such an installation is shown in 5.

The Zinc Bath. Various zinc baths are used by different workers. That recommended by the inventor of the process consists of zinc sulphate 350 oz., sulphuric acid 1 oz., and water 10 gal. To obtain good



5. ELECTRO-GALVANISING PLANT

bright deposits of zinc, the solution should be kept as free as possible from impurities, and if the electrolyte be too acid, a rough dark zinc coating will be given.

The work to be zinced is secured to dogs fixed to cross bars, which rest on copper strips attached to girders carrying the anodes, which are of lead instead of zinc. It was found that zinc anodes failed to keep the solution up to normal strength, disintegrating and causing a rough uneven deposit, and as the solution is regenerated by circulation between the electrolytic tank and the regenerating tank, lead anodes were tried with success.

Regenerating the Electrolyte. The accepted and economical method of regenerating the electrolyte is by adding to the regenerating tank zinc dust or tultz, preferably mixed with sand or coke, so as to form a filter bed and to prevent the dust from entering the depositing tank, where it would increase the electrical resistance. By the system of circulation caused by the apparatus, the electrolyte flows into the bottom of the depositing tank by gravity, the impoverished and therefore lighter liquid being drawn off over a sill at the end of the vat. When the articles are first placed in the bath, it is found well to use as high a current density as possible, and after a few minutes to reduce it to about 15 amperes per square foot.

Such, in brief, are the chief features of the process of electro-galvanising. On the score of economy, it has much to commend it for certain classes of work. When not in constant use, a large hot plant demands a very great expense to keep the mass of zinc in a molten condition, a necessity which does not exist with the electrolytic process, and this consideration is sometimes of paramount importance.

Sherardising. A process known as *sherardising* has been recently introduced, and it is properly a process of galvanising by quite a new method. An account of galvanising would be neither complete nor up-to-date if it did not take notice of it. By the process of sherardising, the articles to be rendered non-rusting are cleaned by pickling, polishing, or sand blasting, as already described, and are then placed in a closed iron receptacle, charged with zinc dust and heated to a temperature of 500° F. to 600° F., for a few hours, and allowed to cool. The drum is then opened and the iron articles removed, when they are found to be coated with a homogeneous zinc covering, depending in thickness upon the temperature and the duration of the treatment.

Sherardising Plant. The zinc used in the process of sherardising is the ordinary zinc dust of commerce, the market price of which is about 20s. per ton lower than zinc ingots, or *virgin spelter*, as it is usually called. The process offers another important economy in that greasy articles can go straight into the sherardising drums without cleaning. The receptacle into which the zinc dust and the articles to be treated are placed is preferably airtight. The air is then exhausted, or if this be impracticable, carbon, in a fine state of subdivision, and to the proportion of 3 per cent. of the zinc dust, is added in order to prevent the formation of zinc oxide to an undesirable extent, as this dulls the appearance of the final coat. The usual type of receptacle employed is cylindrical, or polygonal in shape, arranged to be rotated or oscillated during the process of heating. The cylinder, when charged, is placed in the furnace, a cast-iron shell of suitable shape, with a series of Bunsen burners in its lower part. The receptacle is rotated or oscillated by hand power.

The coating given by the process of sherardising is brighter in its metallic lustre than that attained by electric deposition, although the spangled effect of hot galvanising cannot be imparted.

THE NURSE AND HER WORK

Nursing as a Career. Training and Prospects. The Home Nurse. Night and Day Duties. Preparation for Infectious Cases. Bed-making

By Mrs. ROBERT E. NOBLE

THE girl who is contemplating the career of a nurse for her life's work should count the cost carefully. The work, though interesting, is exceedingly arduous, and the physical and mental strain of service in the wards makes great demands on the nurse's strength and staying power. Many would-be nurses spoil their chances of attaining any high degree of success by a disadvantageous use of the years that must elapse between school and hospital training. A daily round of petty social duties, hours of idleness lengthening into two or three years without any definite work, totally unfit a girl for the strenuous and methodical routine of hospital work. Some daily task or study should be undertaken which will necessitate the cultivation of habits of punctuality, neatness, tact, and patience. These qualities are indispensable for successful work as a nurse, and must be acquired sooner or later by any girl who wishes to make headway in the profession.

How to Enter the Profession. The age for training varies slightly in various hospitals, the limit being usually from twenty-three to thirty-five. Some nurses begin their training at a lower age, spending a few years in a children's hospital until the necessary age for adult training is reached. Others study special subjects, such as the nursing of fevers, massage, etc., but more benefit is derived from these special courses if they are taken at the end rather than at the beginning of the full course.

Several months before the intending nurse wishes to begin her training she should write to a number of hospitals, and ask the matron for a copy of the rules for probationers. Having carefully studied the regulations, the next step is to obtain a personal interview with the matron of the particular hospital selected. This interview is of the greatest importance for the candidate for training, since the practised eye of the matron enables her to detect quickly the presence or absence of those qualities, physical, mental and moral, which are essential to the successful nurse. But, since standards of judgment vary considerably with the individual, an intending nurse who has made up her mind to work at the profession in a whole-hearted manner should not be disheartened if her first application does not meet with a satisfactory reception. If she is not strong enough for general training she may be able to take up some special branch, such as the nursing of children, massage, or midwifery.

Choice of a Hospital. When making her choice of a hospital at which to seek training, the candidate cannot be too careful. Many inferior institutions which cannot offer real training advertise for probationers. Such advertisements should be regarded with the greatest suspicion, for a really good training-school is never in want of applicants, and it is absolutely essential to train at a school which can confer a recognised certificate at the end of the course.

Many institutions have attached to them a preliminary training school, in which the probationer passes a few weeks before entering on her work in the wards. She is there taught, by means of lectures and practical work, elementary anatomy, physiology, hygiene, bandaging, the making of dressings, the use of instruments, sick-room cookery, housework, etc. With this useful preparatory knowledge, the probationer signs her agreement for three years' training and enters upon her full course.

The salary she earns depends upon the hospital she enters. For probationers, it varies from £8 to £15 a year, with board and lodging, and generally uniform. In a few cases the probationer pays for her training during a part or the whole of her course.

The Nurse's Ward Duties. Her work in the ward keeps her usually both busy and interested. At first the multifarious duties are confusing and fatiguing, but the methodical arrangement of the work lightens it as far as possible for all concerned. Then the exact times of entering on and leaving duty vary in each hospital, but punctuality is the first of all necessities. The nurse must not remain in the wards when off duty," neither must she visit other wards unless sent by someone in authority. She rises each morning about 6.30, and breakfasts about 7.15, being ready, after prayers, to go on duty in the wards at eight o'clock. During the morning the probationer will polish the metal-work of the ward, taps, etc., wash up the breakfast things, dust the ward, scrub the lockers and doctors' tables, and help with the patients' luncheon and dinner. In turn all the probationers go to their own dinner, having in most hospitals about three-quarters of an hour for the purpose.

Returning to their duty in the ward, the probationers clear away the dinner things, wash the knives and forks, make beds, dust and sweep the ward, and help with the patients' tea. Then, at about five o'clock, comes half an hour's interval for their own tea. During the evening they again make the patients' beds, help to wash the patients, serve supper, tidy up the ward, and prepare it for the night by making up fires, and so on. Then, after their own supper and prayers, they retire to their own rooms, and all lights are out by eleven o'clock.

The Probationer's Opportunities. This, in brief, is an account of the daily routine of the probationer nurse. Her work is hard, and every minute of her day is filled. But she has the advantage of associating with young women of her own age, with similar interests and ambitions. During her first year in the ward she does little actual nursing, but she has abundant opportunities for learning. Skilled nursing is going on around her; if she keeps her eyes and ears open, and is always on the alert, she will gain invaluable experience and a thorough insight into her work. As far as possible the nurses help the probationers by teaching them and by seeing that their allotted tasks are well performed.

The work of the nurses necessitates more skill than that of the probationers. The former watch and attend to the more critical cases, give medicines and stimulants under the supervision of the sister

of the ward, and assist with the general work of looking after patients and keeping the ward in order.

The nurse's salary varies from £18 to £30, with uniform. During their three years' course, nurses in training attend various lectures bearing on their work, on such subjects as physiology, anatomy, pharmacy, and dispensing. They take notes at these lectures, and attend weekly classes held by the sisters, in which further instruction is given. At the end of the various courses examinations are held, which each probationer is required to pass.

In turn, all the nurses are on "night duty." The whole of their daily routine is then changed, since they sleep between the hours of 1 and 8 p.m., and go on duty at about 9 o'clock in the evening, remaining there, with short intervals, until the return of the day nurses at 8 a.m. next morning.

Besides the necessary duties set apart for meals, all the day nurses have definite off-duty times each day. Probationers get a regular off-duty time of from one to three hours daily, with occasional half-days, and a whole day about once a month. The nurses get longer "off-duty" times; but, unless they have a special "pass" signed by the matron, every nurse is expected to be in hospital at 10 p.m. The annual holiday varies from two to four weeks, according to the seniority of the nurse in training. A probationer whose work is unsatisfactory may be required by the matron to withdraw without finishing her course, in which case no certificate is granted.

The Branches of the Profession. At the end of her full training, the nurse has various courses open to her. She may obtain a staff appointment, and remain at the hospital as staff nurse or sister. Many nurses proceed to study some special branch of nursing—mental, infectious cases, massage, midwifery—and find their additional knowledge invaluable when acquired at the conclusion of the three years' general training.

About two-thirds of the nurses trained take up private nursing at the conclusion of their hospital course, either working independently or associating themselves with the work of an institution. In the latter case, the nurse only gets, perhaps, a percentage on the money she earns; but she has a small and regular salary, and her risks are few. By the co-operative system a number of nurses combine together to minimise expenses, and the risk of having to refuse cases becomes less. The independent nurse is fortunate in retaining all the money she earns, but her risks are greater, and she may lose her connection by her inability to accept all the work offered. Many nurses "specialise" after leaving the hospital, although in the wards they all have experience of both medical and surgical nursing. Then a large number of nurses take service abroad, working chiefly under the Colonial Nursing Association as missionaries. Others take up district nursing, which includes the various ways in which the poor are nursed in their own homes. To carry on this phase of work successfully, the nurse must not only be skilful in her profession, but must also have a deep sympathy with the poor. She should be interested in the life and social condition of the people, and be prepared to work hard for a smaller remuneration than she would obtain in other branches of her work.

Poor-law nursing offers a good opening for an energetic nurse. Many of the various infirmaries and asylums have excellent training courses, but the nurse should carefully ascertain if the school is recognised and can confer a certificate.

Special Appointments. Nurses who have obtained full training in an adult hospital are eligible for appointments under the Local Government Board. These posts are very responsible, and give great scope for an energetic nurse who wishes to work her way up until she becomes matron of a large hospital. It is in an infirmary or asylum that the nurse has the opportunity of seeing the course and nursing of infectious diseases, etc.

During the last few years a number of training nurses have taken up naval and military nursing. For work in naval and military hospitals candidates must have been through the full training course in a general hospital. The rate of payment is good, varying from £30 for a sister to £200 for a lady-superintendent. In addition to these salaries the nurses are given furnished quarters and an allowance for fuel, light, and food.

Whatever work the trained nurse decides to adopt, she will find the three years' general training invaluable. The habits of neatness and methodical work acquired in the ward must be retained throughout her career. A slipshod nurse prohibits her own success, and in this, above all other professions, personal neatness and daintiness is essential.

The mental qualities of the nurse are very important. She must have plenty of patience and tact, and a keen insight into human nature. A quiet manner, accompanied by a firm but gentle attitude towards the patient, is very necessary.

It is absolutely necessary, too, that the nurse should have good health. Any particular form of physical weakness soon reveals itself under the strain of hospital life. A slight, short girl, of light weight, would find the effort of lifting and assisting heavy patients too great. The nurse's eyesight also should be strong, and her senses of smell and hearing perfect.

Given these conditions, a girl who is really interested in the work of tending the sick should find in hospital nursing admirable scope for her talents. She will not only have a healthy and interesting occupation, but will be acquiring skill which will ensure her a certain income, and may enable her to secure later in life an important and responsible appointment.

The Home Nurse. A good nurse will ever keep in mind that she has three distinct duties to perform—her duty to the patient, her duty to the doctor, and her duty to herself. Not one can she afford to neglect without affecting the others also. Her first duty is to aid in every possible way the recovery of the patient, and this can only be done by rigid obedience to the doctor's directions and attention to her own health. Towards the patient her attitude should be firm, yet kind and gentle. A dictatorial and overbearing manner is to be condemned in a sick-room, and the patient is far more likely to be persuaded to take food or medicine, or perform any other uncongenial task, if the nurse approaches the subject tactfully.

The home nurse should cultivate an even and cheerful temper. She must be very sympathetic, but must never allow complaints or criticisms of the doctor's treatment. She must bear in mind that confidence is a great factor in recovery, and her patient's chances of getting well soon are damaged when distrust of the doctor creeps in.

An observant and intelligent nurse is the doctor's most valuable helpmeet. She is constantly with the patient, and has, therefore, exceptional opportunities for noting slight changes in his

condition. The doctor only comes at intervals, and to a certain extent he is dependent upon the nurse's watchfulness and her accuracy in reporting details, however slight. It is always better to tell the doctor too much rather than too little: he can then sift the wheat from the chaff and make the most of all the information he has received. The nurse will do well to keep a careful record of all that happens between the doctor's visits, noting the patient's pulse, respiration, and temperature at given intervals, the amount and character of the patient's sleep, and any other records the doctor may wish to have.

The Doctor's Visit. It is one of the nurse's important duties to prepare for the doctor's visit. Everything should be in readiness for him, since his time is valuable, and it is exciting and worrying to the patient to see hasty preparations being made. Hot and cold water and a hand-basin should be ready for use, together with some antiseptic soap and clean towels. When the doctor arrives the nurse should, if possible, see him for a few moments in a room adjoining the sick-room. She can then give the doctor the record of the patient's state, telling him all she can of his condition since the previous visit. This should be done out of sight and hearing of the patient. She should be ready to take the doctor's thermometer after use, wash it carefully in some disinfectant solution, dry it carefully and replace it in its case, returning it to the doctor without shaking down the index. Any steel or silver instruments the doctor may have occasion to use she should clean in the same way, afterwards polishing them in a piece of leather before restoring them to him.

All semblance of fussiness in the sick-room is to be avoided.

The Nurse's Dress. In the matter of dress, the home nurse should exercise a careful choice. Simplicity should be the keynote to her costume. A plainly made frock, of serge in the winter and of some washing material in the summer, will be most suitable. In nursing an infectious case a washing material should invariably be chosen. The dress should be made sufficiently loose to allow of perfect freedom of movement. The skirt should be made short enough to clear the ground. She can then have long cuffs and sleevelets, kept up by elastic, that can be taken off while work is performed that long sleeves would hinder.

In matters of personal cleanliness and neatness the nurse cannot be too careful. There is nothing more depressing to the patient than a dirty, slovenly, untidy nurse. She should choose colours that are restful to the eye, blue and grey materials, and her large apron should always be fastened neatly and be spot'ess. It should be provided with a wide bib held up by straps passing over the shoulder, crossing behind and fastening at the waistband. The apron itself should be large enough to well cover the skirt, both long and wide. It should be furnished with a large, deep pocket, in which the nurse should keep in readiness her scissors, keys, etc. On her feet she should wear well-fitting, moderately loose shoes or boots. These should have low heels and fairly strong soles. Special ward shoes are now made for nurses, sometimes with rubber soles and heels. Many of these are excellent, and can be adopted for wear by the home nurse for her comfort and that of her patient.

In choosing her other garments the nurse should have due regard to warmth, lightness and comfort Well-fitting clothes, with wool or silk next the skin, are a sine qua non. Woollen stockings should also be worn, since cotton lead to much discomfort if the feet get hot and tired.

Hospital nurses complete the attractive simplicity of their dress by wearing small caps on their heads, and their example may be followed by the home nurse who knows how to dress her hair with the necessary simplicity. Personal ornaments of all kinds should be banished from the sick-room.

The Importance of Regular Meals. Good health is only compatible with a proper amount of good food. The nurse should make every effort to take her meals regularly. If her work for the patient is carried out unaided, she should contrive carefully to leave him asleep or comfortable while she gets her own meals. These should not be hurried over, and she should, as far as possible, avoid both the haste and the kinds of food that are likely to produce indigestion. After the night's rest the nurse should take a light meal, such as a cup of tea and a slice of bread-and-butter, before entering on her daily round. It is especially important to avoid entering the sick-room fasting if the patient is suffering from an infectious disease.

As a general rule, the nurse should take all her meals away from the sick-room and out of sight of the patient. They should be light and nourishing. Stimulants and excessive tea-drinking should be avoided. The work of a sick-room is exhausting, and necessitates a certain amount of strain. This is, however, best counteracted by plenty of nourishing food, suitable exercise, and sleep.

Successful nursing cannot be carried out with insufficient sleep. A full seven hours is essential. The nurse's nights will be broken and often lost, and she will therefore do well to arrange, if possible, to sleep between 2 p.m. and 9 p.m. Between these hours, by skilful management, she can generally be spared from the sick-room. Most of the essential offices for the patient, washing, and meals have been carried out in the morning, so during the afternoon there will only be his tea to prepare, and a few lighter duties, which can generally be entrusted to a willing helper. It should be remembered that the mental freshness and alertness of the nurse react on the patient.

Personal Details. The nurse should sleep in a well-ventilated, darkened room. She must be careful for the sake of her general health to indulge in a daily bath, or, better still, two—cold early in the morning and warm before retiring to sleep. The usual details of the toilet should be particularly carefully attended to.

Exercise is also an important point for the home nurse to consider. Without it she will not enjoy refreshing sleep and a healthy appetite, and so her work will suffer. A few minutes may, with advantage, be spent in the open air both morning and evening, and a brisk walk for a minimum of half an hour is indispensable to good health. The nurse who has her patient's mental as well as physical welfare at heart will be quick to relate anything interesting she may have seen or heard in these daily outings, so that the patient will come to look forward to her return for a pleasant chat and a renewal of interest in the outside world. Without this the atmosphere of the sick-room may easily become dull and depressing, and the nurse must always bear in mind that cheerfulness is closely associated with skill and sympathy in bringing about the recovery of the patient.

The sick-room should, of course, be chosen with the greatest care. Where a choice is possible it should fall on the brightest and quietest

room in the house. It should be bright, since recovery is retarded in a sunless room. The room should be quiet, as sleep is an essential factor in recovery, and the trivial and generally unavoidable noises of the average household are annoying to an invalid. But, on the other hand, it is difficult to impose such restraint on every member of a household that no doors shall be banged and no loud voices heard for a long period. Such conditions are quite impracticable where there are children, and even in an adult household there will be moments of forgetfulness, and the irksome quiet will be disturbed.

For these reasons a room at or near the top of the house is generally preferable to those nearer the ground floor. In the case of an infectious disease it is almost essential to put the patient in such a room.

The room chosen should be airy and lofty. The room should be provided with a fireplace and a window that will open top and bottom. A casement window is not desirable in a sick-room, since it makes the regulation of the incoming air very difficult; a sash window is more easily managed and more conducive to adequate ventilation. The chimney greatly assists in ventilation; the fireplace should be free, and the "register" open, to allow of the escape of vitiated air through it. A small fire is always useful in a sick-room. It may be used to burn scraps of rubbish, dressings, and such-like, that might become sources of infection unless destroyed by fire. It also creates a draught, the current of warm air passing up the chimney and drawing after it the air of the sick-room that has been exhausted by breathing and contaminated by contact with a sick person. If the weather is too hot to admit of a fire, a small lamp placed in the grate will act beneficially in producing the desired draught.

Infectious Disease. In the case of infectious disease, it is of the greatest importance that the room chosen should be near the top of the house and away from parts much frequented by other members of the family. Hot air rises, so that the draught in a house is towards the upper parts, especially if a window on the top landing is kept open a few inches. Thus disease germs escaping from the sick-room will not be drawn into the house if an upper room is selected for the use of the patient.

Carpets and woollen curtains must be banished from the room, also upholstered chairs, but the room should be arranged to look cheerful, because during the long convalescence and isolation entailed by an infectious complaint the patient is very prone to depression.

The nurse must be careful not to leave food—particularly milk—exposed to the air of the sick-room, as germs are so quickly absorbed. All dirt should be disinfected and burnt, and the dishes used by the patient disinfected before being returned to the kitchen.

The sick-room, if possible, should face south, south-west, or west. The early morning light will in all probability disturb the invalid, and shorten his hours of sleep, and if attempts are made to exclude it, they can only be successful at the expense of fresh air and efficient ventilation. On the other hand, the bright afternoon sunshine, and particularly the last gleam before the sunsets, are invaluable in cheering the invalid. The afternoon is often tedious, and a little depressing to a sick person, and this last glow of the sun is cheering in its influence.

The ceiling, walls, and floor must be carefully dusted. All the woodwork should then be wiped over with a damp cloth, which is kept moist by a little hot water, to which an antiseptic has been added. The fire should be lighted, and the temperature of the room allowed to reach about 60° F.

The room should be uncarpeted, and all unnecessary furniture removed. In nursing an infectious disease, this banishing of all upholstered furniture and carpets is indispensable. To give an air of comfort to the room, strips of carpet or rugs may be used, since they can be so easily taken up and shaken and replaced.

Ventilation and Temperature. For simple means of ventilation, see Health, page 4019.

A good nurse will make the temperature and ventilation of the sick-room the subject of very careful study. The temperature usually ordered for the sick-room is from 60° to 70° F., and with a little care the standard can be kept up, so that within the twenty-four hours the variation will only be two or three degrees. A well-made thermometer is necessary for this purpose, and should be hung near the patient, somewhere near the level of his head.

The fire-irons should be taken away from the room. If left in the grate they are likely to slip and disturb the patient, or the nurse, however careful she may be, may accidentally catch them with her skirt and cause them to fall with a clatter that will jar upon the patient's nerves. An old walking-stick will make an efficient substitute for a poker. A little sand should be powdered over the hearth to deaden the sound of the falling ashes, and the coal should be packed before it is sent to the sick-room in paper bags, each one containing about 2 lb. of coal. By this means the nurse can noiselessly replenish the fire, without the use of tongs and without incurring the risk of soiling the hands. It is in the early morning, between 1 a.m. and 5 a.m., that the nurse will find the vitality of the patient at its lowest ebb. He will then be in a condition to feel the cold more, and she should cover him with an extra blanket, and be careful to replenish the fire lest it should burn low and the room get chilly as a result. She will then find it a great advantage to be able to make up the fire quietly, as the patient is very likely to be sleeping at that hour, and, if disturbed, he might not find it easy to sleep soundly again.

The Bed. The choice of a suitable bed is of very great importance. Generally speaking, a wide bed is a disadvantage, since the nurse has the additional strain of doing everything for the patient at arm's length. The solitary advantage offered by the wide bed is that the patient can use one side during the day and the other at night, thus obtaining the necessary coolness and freshness which is so conducive to rest.

A small iron bedstead, with a light but strong frame, resting on castors that make it possible for the bed to be moved without shaking the patient at all, is the ideal one. The length of the bed should be about 6 ft. 6 in., and its width either 3 ft. or 3 ft. 6 in., and it should be fitted with a strong chain mattress. The chain mattress should be covered by a good hair mattress to give the necessary "spring." Sometimes bran and hay mattresses are used. These offer the advantage that, should they get wet or soiled, the covers, which should be made detachable, can be removed and washed and refilled quite quickly and easily, and with practically no expense.

The bed should be placed between the door and fireplace, if possible near the middle of the room, and it should, unless the smallness of the room prohibits it, be allowed to stand clear of the walls and other furniture, so that it has around it in all directions a space of at least 2 ft.

The advantage of this is obvious. It permits of the free circulation of the air round the bed, and enables the nurse to approach the patient easily from either side.

Care should be taken to see that the bed is not so arranged that the patient is facing the light. In some complaints the effect of direct sunlight on the eyes is very injurious. In measles, for example, the eyes are abnormally weak and susceptible to injurious influences, and in cases of brain trouble or affections of the eyes similar precautions are necessary to prevent the light from producing unnecessary strain or injury.

The nurse will find that it is often very advantageous to have a second bed in the sick-room. If the patient is well enough to stand the exertion of being moved, he will benefit greatly by the use of one bed during the day and the other at night. His sleep will be more easily induced, and much more refreshing under these conditions.

In choosing the sick-room care should be taken to select a room in which the wallpaper is soft in colour, with a restful pattern.

Night in the Sick-room. It is of the greatest importance that the patient should have an abundance of sleep, and to secure this the nurse should take every precaution possible. Once the patient has settled down for the night she must be absolutely quiet and on no account rouse him from his first sleep. First of all she should sponge the patient's face and hands with warm water and change his nightshirt. His bed must be either remade or at any rate made comfortable, and it is a good plan to give him a fresh pillow. The fire should be made up for the night, and a supply of coal in small paper bags should be put in readiness. Some light, warm food should be prepared for the patient and given the last thing before he settles down to sleep.

The character of the patient's last meal will, of course, depend upon the complaint from which he is suffering. In any case it should not be cold, as that is likely to keep him awake, and it should be digestible food, such as a glass of warm milk or a cup of beef tea. The nurse herself should take a good meal just before preparing the patient for the night. It will then be unnecessary to disturb the patient during the night. In the early morning, at about five o'clock, she will probably find that he will be glad of a light meal, perhaps a cup of tea and some bread-and-butter.

The Nurse's Night Duties. The nurse should provide herself with a comfortable easy chair and some noiseless occupation if she is to keep watch during the night. As a rule, it is well for her not to read, or she may become drowsy and inadvertently fall asleep. Her occupation must, however, be silent, as many a nervous patient has been kept awake by the click of a knitting-needle or the rasp of a thimble.

The nurse must place the lamp so that the light is screened from the patient's face, and her chair so that she can see every movement on the part of the patient without giving him the impression that he is under such close observation. By skilful arrangement of mirrors the nurse can often see the patient distinctly in a glass when she is apparently with her back turned towards him.

Whilst the patient is asleep the nurse should make careful notes of his condition and any changes in it. She should note down in writing the exact amount and character of the sleep enjoyed. She should notice exactly how much sleep the patient gets. The character of the sleep should also be noticed, and whether he awakes refreshed or otherwise. She should state also whether the sleep is sound, broken by dreams, or talking, or movements.

When the doctor has ordered medicine to be given every two hours the nurse should be careful to ascertain from him if she is to wake the patient to administer it. It may happen that the prolonged sleep of the patient is merely a sign of extreme exhaustion, in which case it is of the utmost importance that he should be roused at stated intervals for medicine and nourishment.

If the patient is wakeful it is sometimes a good plan to take away his hot pillow and give him a cool one rather than to turn the same many times. An extra pillow is also useful in many cases. For example, in nursing pneumonia the patient may be so weak that he slips over on to his back instead of resting on the affected side. In this case a pillow against his back will give valuable support. Then in nursing cases of abdominal disease a pillow under the patient's knees will enable him to relax the muscles which otherwise exert a painful pressure upon the abdomen. Also, a rheumatic patient finds the pain in the knee joints eased if they are raised on a soft feather cushion.

The moment the patient awakes the nurse should have either medicine or warm food in readiness for him, after which he will probably fall asleep again. Gentle friction of the patient's back and limbs may induce sleep in a restless patient, and the friction must be continued for a short time after the desired effect has been produced, or its cessation may awake him.

How to Prevent Bed-sores. The nurse must be constantly on the watch for bed-sores, as they form easily and are cured with difficulty. Speaking generally, a bed-sore is regarded as a sign that the nursing has been neglectful, but this is not an infallible rule, for they are occasionally merely signs of extreme debility in the patient. They most readily make their appearance on projecting parts of the body that press on the bed, such as the base of the spine, the shoulder-blades, and calves.

Certain parts of the skin become bright red, and every part of the body should be daily examined during a long illness for these unwelcome signs.

At the least sign of redness the part affected should be washed night and morning with soap and water, thoroughly dried, and rubbed with eau-de-Cologne or a little good whisky until the skin is dry. Methylated spirit will serve the purpose. Should the patient perspire freely the skin should be powdered with a mixture of equal parts of zinc oxide and starch.

An air pillow should be used to support the affected part, and it should be shaped with a hole in the middle to diminish the pressure on the part where a bed-sore is impending.

A small dressing, the exact size of the bed-sore, is applied. A piece of lint wrung out in carbolic oil may be used, or boric-acid ointment, or resin ointment. Over this a larger piece of lint spread with vaseline is applied, and the whole kept in position by means of strips of adhesive plaster. A solution of silver nitrate will harden the skin, but it has the disadvantage of blackening it also. The alternative treatment before the skin is actually broken is to paint it with collodion.

Care must be taken in fixing the dressing to attach strapping or plaster to parts of the skin some distance from the bed-sore.

In very severe cases bed-sores make their appearance on parts of the body where no pressure exists—for example, on the front of the thigh. These sores are the result of loss of tone in the blood-vessels

of the skin. The treatment in this case is heat and cold applied alternately. A small piece of ice is wrapped up in flannel and held to the part affected for about ten minutes until the skin is pale; this is followed by the application of a sponge wrung out in very hot water until the skin is hot and red. Absorbent cotton-wool should be used to remove the moisture and powdered boracic acid applied.

Visitors. No visitors should be allowed in the sick-room when the case is infectious. The nurse should find out from the doctor exactly how many visitors it will be safe to admit. They should be only allowed to come at stated times and to stay as long as is not harmful to the patient. The visitor should not enter the room suddenly, as the shock might be bad for the patient. On the other hand, he should not delay his coming once the patient knows that he is expected, as the waiting is also bad for the nerves. The visitor should never lean against the bed or jerk it, but should sit in a position in which the patient can see him clearly. He should not stay long, and should leave without any indecision. The patient should be given some light food soon after the visitor's departure, and the nurse should notice whether the visit has unduly excited or depressed him.

Under certain circumstances the patient will perhaps complain of the pressure of the bed-clothes on sensitive parts of the body. For example, after an abdominal operation, or in cases of rheumatic fever, the weight of the bed-clothes on the affected parts will cause unnecessary suffering. If the bedstead have bedposts, this pressure may be relieved by passing a strong piece of string under the bed-clothes diagonally and tying it to the posts of the bed. By this means, if they are well tucked in each side under the mattress, and fastened with safety pins top and bottom, he will be kept warm without feeling the weight of the clothes.

A small bed-cradle is sometimes necessary to keep the weight off a limb. A satisfactory substitute for a cradle may be made by cutting a tunnel through an ordinary bandbox.

In long and tedious diseases the patient is inclined to slip to the bottom of the bed. This may be prevented by slightly raising the foot of the bed by wooden blocks under the castors. In heart disease the patient will tend constantly to slip down low in the bed, especially during sleep. This position is very bad for him, as it renders breathing more difficult.

When he is still weak, but well enough to move his hands and arms, it is a good plan to tie a piece of rope with a loose end to the foot of the bed, by means of which the patient can raise himself or can get assistance in turning.

The Convalescent. The nurse must always be on the alert, when the patient is recovering to detect any change for the worse. There is always the risk of a relapse, and complications of the disease may set in at any time. In some cases special precautions must be taken. For example, attention must in some cases be given to the diet, that it may be not only digestible, but that no foods are included that might prove dangerous.

The convalescent must be well protected against draughts and cold. He should wear a flannel bed-jacket, buttoned up to the chin, with long sleeves, whenever he sits up in bed or is occupied in some way that uncovers his arms and chest.

Great attention must be paid to the convalescent's diet. It should be both abundant and nourishing, for he has not only to build up fresh tissue, but to repair the waste due to the ravages of disease. All indigestible foods should be avoided, but, subject to the doctor's directions, the patient's fancies should be humoured. With returning health the appetite improves, and, if the food is served daintily, and carefully prepared, he will welcome his meals. Light food, such as soup and milk puddings, may be abundantly given.

The nurse should watch the patient carefully, lest he overtires himself. After long weeks of inactivity he will be too ready to over-exert himself and to over-rate his slowly returning strength. He should sleep for nine or ten hours every night, and a short rest during the daytime, after each meal, will hasten his entire recovery.

Cleaning the Sick-room. The sick-room must be kept scrupulously clean. It is the nurse's duty either to see that the necessary cleaning is done properly, or, in some cases, to do it herself. Every morning the hearth must be quietly tidied, and the ashes collected. If the disease being nursed is infectious, a disinfectant should be poured over the dust and ashes before they are taken from the sick-room. The floor must then be well swept. If this is done slowly and gently there is no need for a cloud of dust to arise and cause discomfort to the patient. The best plan is to roll up the strips of carpet or rug on the floor and then to sweep up the dust towards the centre of the room, to avoid bringing some of the dust the whole length of the room. Another satisfactory method is to sweep towards the fireplace, and take up the dust in the grate and burn it straightaway in the fire. This is one of the many little ways in which a fire in the sick-room will be useful for other purposes besides that of heating. Should there be no fire, it is a good plan to take up all dust and fluff after sweeping it together by means of a damp cloth.

The sweeping process must be followed by that of dusting, and the whole room should be thoroughly wiped over with a duster at least once a day. All furniture should be removed with the exception of the bed. The woodwork of the room—door, skirting, window sills, etc.—should be wiped over daily with a damp cloth wrung out in a dilute solution of some antiseptic fluid. The latter should preferably be a fluid free from characteristic smell, as that is likely to cause discomfort to the patient by affecting the air of the room. A careful nurse will leave no part of the sick-room undusted; the tops of picture-frames and screens, the legs of the chairs and tables, window-ledges, and medicine bottles, will one and all be freed from every trace of dust and dirt. The windows of the sick-room should be kept bright and clean. Nothing is more depressing that the dull outlook of a room with smeared or dirty window panes.

The Patient's Bed. The bed-clothes should be chosen with care. The mattress should be covered with a light woollen or cotton sheet. Linen is unsuitable, as its surface is cold and likely to chill the patient, but, as in the case of the use or discarding of a feather bed, the ordinary habit of the person concerned must be taken into account, and no abrupt change brought about. The use of an under blanket beneath the sheet is not desirable for ordinary patients. In some cases it may be used with advantage, as in very cold weather, but, generally speaking, it is better to dispense with it. It tends to wrinkle, and so to produce the irritation which encourages bed-sores. In nursing cases of acute rheumatism it is necessary to place the patient in a blanket with no under-sheet, but this is an exceptional case. Blankets absorb the perspiration from the

body, and become moist, and so predispose the skin to bed-sores. Sheets are therefore preferable.

The under bed-clothes should be spread quite smoothly over the mattress, and well tucked in; if an under-blanket is used it should be wide enough to tuck in tightly. The upper bed-clothes should also be of suitable width, and tucked in well; if too narrow they will be a constant source of discomfort. The warmth of the bed should be secured by the use of plenty of thick new blankets or blankets that have not been washed, as washing tends to make them thin. The maximum warmth should be obtained with the minimum weight over the patient. In any case the weight of the bed-clothes should be carefully distributed, so that there is as little pressure on the patient's chest as possible, and the greatest weight over his feet. The ordinary counterpane should not be used: it is too heavy and too closely woven for health. The pressure so produced may seriously interfere with the patient's breathing and the same ill-effects are caused by bed-clothes that are too heavy. An excellent substitute for a counterpane is a clean sheet folded and used at half its width as a counterpane. The whiteness is very attractive, and clean-looking, and lends to the bed and room a cleanly and cheerful appearance.

The patient should be provided with at least two soft pillows, well beaten up whenever the bed is made, and at other intervals during the day. Two pillows are more comfortable than a pillow and a bolster, as they are more easily turned and smoothed. The nurse will find that the patient's sleep will, to a great extent, depend upon the comfortable nature of his pillows; if too high, they will make him suffer from stiffness of the neck and shoulders, and if too low, they will be an incentive to headache and restlessness generally.

The Draw-sheet. The draw-sheet is an essential addition to the bed of a patient suffering from some complaint that necessitates many turns in bed. It is easily prepared by folding an ordinary sheet along its length until the folds are only one-third or one-quarter the ordinary width of the extended sheet. Thus, the sheet is reduced in width, its length is unaltered, and it presents two or three thicknesses. The bed is made in the ordinary way by spreading an under-sheet as smoothly as possible over the mattress. Over this the draw-sheet is laid. It is placed so that the greatest length goes down the bed. On one side, just enough of the folded sheet is used to tuck in firmly, and the excess on the other side is rolled up into a smooth roll, which is placed under the mattress. Sometimes safety pins are used to secure the draw-sheet in position.

The draw-sheet is placed across the bed so that, when the patient is on it, it will extend from about the length of his armpits to his knees. The advantage is obvious. Suppose that for any reason the draw-sheet becomes soiled or damp, as when poultices are in use; if there is no draw-sheet, the undersheet would have to be changed, giving much trouble. If, however, there is a draw-sheet, the remedy is easily applied. The tucked-in side of the draw-sheet is rolled up towards the patient. The clean roll is then loosened. The patient is gently raised by the nurse by a kind of leverage movement of her arms when placed under his shoulders and just above his knees. The assistant then draws the roll of soiled draw-sheet towards her in such a way that a fresh length of the clean roll now rests beneath the patient. This process may, with advantage be gone through two or three times every day, the sensation of cool comfort being very soothing to the patient. In nursing some cases, it is advisable to place a slip of double-faced macintosh between the under-sheet and the draw-sheet. It should be securely fastened in position by safety pins, attaching it to the mattress. The draw-sheet should overlap the macintosh by 6 in. or 8 in., for if the macintosh should come in contact with the patient, it may be a source of trouble in the form of bed-sores.

How to Change the Upper Sheet. The upper bed-clothes should be untucked all round, and one of the patient's pillows temporarily removed, so that he will lie more flat on the bed. The upper blanket is then taken off, and the clean sheet, which has previously been well aired and warmed, is spread over the bed. Over this the upper blanket, which has been removed, is placed, so that the patient is covered by four layers of covering, soiled sheet and second blanket, over which is placed the clean sheet and upper blanket. The lower layers have to be removed, so that the clean sheet and blanket will cover the patient. The nurse will need assistance in the interchange of sheets. The assistant should stand at the head of the bed and hold the clean sheet and upper blanket firmly, one hand being placed on either side of the patient's head at about the level of his shoulders. The nurse should stand at the foot of the bed and, using both hands, placed well apart from each other, steadily draw out the soiled sheet and its accompanying blanket. In doing this she must take great care not to raise her arms, for then the cold air will rush into the bed and chill the patient. The withdrawn blanket can then be placed over the bed, now taking the position of upper blankets, and then the bed-clothes should be tucked in as before. If necessary, the process may be carried out across the width of the bed instead. In this case, the nurse and her assistant will stand on either side of the bed and the sheet be withdrawn at the side instead of from the bottom. By either of these processes, the clean upper sheet is put in position with little or no difficulty, and with the minimum exertion to the patient.

Changing the Lower Sheet. The clean sheet, which is to replace the soiled upper one, should be well aired and warmed, and then rolled lengthways for half its width, and placed on a chair in readiness. The bed-clothes should then be untucked and the upper ones so arranged that the free edges of sheet and blanket are folded back out of the way. The draw-sheet and macintosh are then unpinned and rolled up towards the patient for a few inches. The assistant stands on the opposite side of the bed, and, holding the draw-sheet and macintosh securely, she should, by means of them, gently turn the patient on his side, so that half the soiled sheet is free. From her side of the bed, the nurse then quickly rolls this up lengthways till it lies in a roll down the middle of the bed. She then takes the clean sheet and places the clean roll beside the soiled one, and carefully smooths the unrolled part of the clean sheet over her half of the bed, tucking it in securely, and seeing that the sheet is arranged straight and without wrinkles.

The assistant hands her the draw-sheet and macintosh, and the nurse first gently lowers the patient so that he lies across the two rolls. She then pins the macintosh and tucks in the draw-sheet on her side of the bed. The assistant meanwhile takes out her roll of draw-sheet and macintosh. The nurse holds this with both hands, placed not too near together, and uses the draw-sheet gently to turn the patient on to his side so that he faces her. In doing so, he passes over the

two rolls and now puts on the clean sheet. The assistant then quickly draws away the soiled sheet and unrolls the remaining half of the clean one and spreads it smoothly over the bed and tucks it in. Then she takes the draw-sheet roll from the nurse, allows the patient once more to be on his back, and secures the macintosh and draw-sheet in position. The patient is now lying on the clean sheet, which has replaced the dirty one without being unduly fatigued.

If the nurse is obliged to do the work single-handed, she will find it is best to work from the bottom of the bed to the top, instead of from side to side. She can easily roll up the soiled sheet to the level of the patient's back, and replace it with the clean sheet, which has been previously rolled up to half its length. Then using her right arm to support the patient, she can raise him enough to roll up or push aside the soiled sheet and unroll the clean one to take its place.

The edges of the clean and soiled one should be pinned together, and while the nurse raises the middle of the patient's body the assistant should gently pull the soiled draw-sheet towards her, till the clean one is in the right position beneath the patient. If the patient is very heavy, it is advisable to change the draw-sheet in the same way as the under-sheet, as this obviates the necessity of lifting him.

Changing the Patient's Night Shirt. The clean night shirt or night dress should be well aired and warmed and put in readiness for use. Then the patient should be raised slightly in the bed, and his night shirt freed from the weight of his body, and unbuttoned. The arm near the nurse should be withdrawn from the sleeve, and the soiled night shirt drawn up to form a roll over the patient's chest and shoulders. Care must be taken not to allow the cold air to come into contact with the patient. Then the nurse should hold the clean night shirt over her wrists and forearms by passing her hands *downwards* through the collar and front, and out at the bottom. She then passes her hands *upwards* through the bottom of the soiled shirt, and out through its collar. By the same movement she gets the clean night shirt over the patient's head and quietly slips away the soiled one. It is then an easy matter to slip the patient's arms into the sleeves, to fasten the buttons, and to raise the patient to draw the night shirt smoothly into its position.

If the patient cannot sit up, the night shirt must be split up the back as far as the collar. The soiled one can then be withdrawn without disturbing the patient, and the clean one arranged to replace it. The free edges should be tucked down on either side, so that he is not cold. The night shirt should be changed night and morning, unless the condition of the patient is so serious that the doctor has ordered otherwise.

The Invalid's Meals. The nurse should consider herself responsible for the arrangement of the patient's meals. Although she may not actually prepare them herself, she should be sufficiently skilled in the culinary art to supervise its preparation. She must always bear in mind that an invalid's appetite is capricious, and that within the limits of strict obedience to the doctor's orders and the dictates of common-sense she should humour the patient's personal wishes and fancies.

Invalid cookery is a branch of the culinary art apart from the preparation of more solid meals. The food must be well cooked and digestible, and so prepared that with the minimum exertion the patient takes the maximum amount of nutriment. Food values must be carefully taken into account, and innutritive articles of food discarded for those that are more valuable as components of a nutritious diet.

In many cases the actual food to be given will be prescribed by the doctor, in severe cases even the amount being specified. These orders must be adhered to rigidly. It sometimes happens that even a slight deviation from the prescribed dietary will bring about a serious relapse.

How to Serve the Meals. A bed-table is a great convenience in the sick-room, either one of the elaborate forms now obtainable at varying costs or of a more simple character, consisting of a flat surface of wood supported on four short legs. The front edge of the wood is hollowed out to form a cavity, into which the invalid's chest can fit. Such a table will stand quite firmly on the bed if its legs are made to rest securely among the bed-clothes.

The meals should be brought up on a little tray covered with a spotlessly white cloth or serviette. The cutlery and glass used should be well polished and glistening and the cruet neatly arranged. All preparations should be made out of sight and hearing of the patient. If he has time to think about any particular food he may refuse to eat it when it appears. It is a mistake to ask the patient if he fancies any special food unless it is at hand for him. During the delay he is quite likely to change his mind.

The food should be served daintily and in small quantities. Food that is supposed to be hot should be really hot, not lukewarm, and everything should be properly flavoured before being served.

After the patient has eaten, anything that remains should at once be taken away. The doctor's orders should be asked for as to whether the patient is to be roused from sleep in order to eat. Sometimes the prolonged sleep may be a sign of exhaustion following great weakness, and in such a case the doctor will order the nurse to rouse the patient at fixed intervals in order to give him food. Sometimes the patient's disinclination to take food is merely a sign that he cannot digest it. In this case a fast of a few hours will not do harm, and may do a great deal of good in enabling the digestive organs to right themselves. If eating is generally followed by an attack of sickness then the nurse should give very small quantities of barley-water or milk, letting the patient take a few drops only at a time, in sips from a teaspoon or from a feeding-cup.

Administering the Medicine. The nurse should keep the medicine bottles in a little cupboard where they will not continually remind the patient of his unpleasant duty with regard to them. The nurse should use a graduated medicine glass to measure the medicines, and be careful to administer the exact dose. A small inaccuracy often repeated may lead to serious results. If the medicine is to be given three times a day, it is administered at 10 a.m., 2 p.m., and 6 p.m.; if every four hours, the additional dose is taken before breakfast. Medicines ordered for every six hours are taken at 12 and 6 o'clock both day and night. The nurse should always find out if she is to wake the patient to give him medicine. Medicines taken before meals are generally intended to assist the appetite and digestion and should be administered about ten minutes prior to the meal.

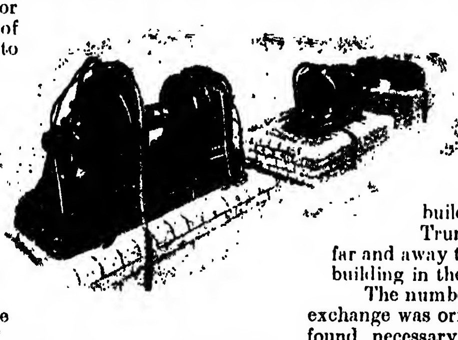
TELEPHONE TRAFFIC MARVELS

London's Huge Central Exchange. Eighty Thousand Wires in One Building. Trunk Working

Continued from page 6080

By D. H. KENNEDY

THE central energy system is a very good instance of the application of the adage inculcated by Mr. Carnegie—namely, to "put all the eggs in one basket, and watch that basket." Elaborate arrangements are made to secure from any possibility of breakdown the central source of energy. Usually, energy is obtained from the local municipality or supply company, and by means of a magneto generator transformed to continuous current at a voltage of 30. On the left in 27 can be seen the No. 1 generator, with its coupled motor, as used at the Ealing Exchange. The generator has six poles, and the commutator has a very large number of segments (176), the object being to secure that the top of the current wave shall be practically flat. The motor receives current from the municipality at 105 volts alternating. The combination is designed to supply from the generator side a maximum current of 200 amperes. In order to secure immunity from breakdown, a duplicate set (No. 2) is provided, and made, as far as possible, independent of No. 1. Where circumstances allow of it the stand-by motor-generator is served from the mains of a separate company, so that even in the case of a general breakdown of one company the exchange can still be worked.



27. MOTOR-GENERATORS FOR CHARGING

Near the door of the power-room can be seen the ringing machines, two of which are mounted on one bed; the same complete duplication of plant is carried out in this case. The feeder cables from the generators are carried through a power switchboard, and thence to the accumulator room [28]. Here, again, the same duplication is in evidence, two complete sets of eleven cells being provided. They are of the Chloride pattern, and have a total ultimate capacity of 2,000 ampere hours. During the early period of the exchange development only seven plates are installed, the remainder of the cells being shut off by a lead partition, and as the need arises additional plates can be added until the full capacity is absorbed. At the near end of the cells the main fuses are in view, and along the sides of the cells can be seen the leads which go through each cell to a voltmeter fixed upon the power switchboard by means of which the individual voltages can be read by turning a twelve-position switch. The fifteen smaller cells visible between the windows are used in connection with the meters, as these instruments require 30 volts. It should also be noted that the special design of the generators makes it possible to work the exchange direct without the interposition of the accumulators.

82. ACCUMULATOR ROOM

The London Central Telephone Exchange. Truly startling in the matter of telephone development has been the experience of the Post Office in the City of London. In April, 1902, was opened the new Central Exchange in Carter Lane under the shadow of St. Paul's. It was arranged for an immediate installation of 5,000 subscribers, and with an ultimate equipment of 14,400. Within three years it had not only become necessary to complete the equipment of the exchange up to its entire capacity, but, in addition, a second exchange with a capacity of 18,000 subscribers had been designed, and at the present time is completed and in operation, so that in this one building there is equipment for over 30,000 subscribers. The accompanying junction equipment involves an additional 3,000 pairs of wires, and the same building also houses the London Trunk Exchange, so that it is far and away the most important telephone building in the world.

The number of cable ducts entering the exchange was originally 110, but it has been found necessary to increase these to 214. Paper-insulated, lead-covered cables were exclusively used for the subscribers' lines. The original types were 2⅝ in. in diameter, and contained 434 wires for 217 subscribers. In the meantime, however, great advances in cable-making have been made, and many of these 217 pair cables have been supplanted by cables of the same external diameter, but containing 606 pairs of wires—that is, the capacity of the ducts has been practically trebled.

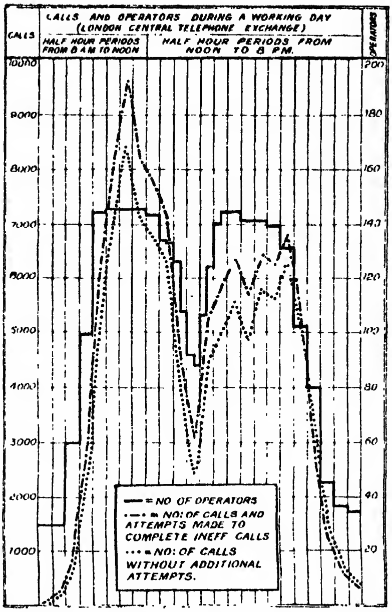
The cables are led into the sub-basement, where they are connected to the silk and cotton cables, which are led on to the main frame. From this point they are carried up a special cable chute to the third and fourth floors, where the intermediate distribution frames, relay and meter racks, and the switchboards are situated. In the original central installation, twenty-six subscribers' sections and sixteen junction sections were provided, completely equipped with multiple, so that each subscriber's line was connected to no less than forty-two jacks in the multiple, making with the answering jack, a total of forty-three. When it is

remembered that three wires are led *to* and three wires *from* each jack, it will be seen that the number of soldered joints on each subscriber's line was approximately 300. This goes a long way towards explaining what many regard as paradoxical—namely, that as the number of subscribers at an exchange increases, so does the cost per subscriber. The number of operators' positions at these sections was 126.

When the installation of the second exchange equipment was contemplated, a careful study was made of the number of transactions completed on the multiple, as compared with the number of outgoing junction transactions. It was found that only 1 in 5, or 20 per cent. of the calls were for Central subscribers, and, as a result, it was found more economical to dispense with the multiple on the subscribers' sections ("A" positions), its place being taken by an addition to the number of "B" positions. Subsequent experience has fully justified the wisdom of this change, which at one and the same time greatly reduced the capital expenditure and cost of maintenance, and simplified the operating in that it eliminated the less frequent type of call, so that all calls, whether for the Central or other exchanges, were dealt with in precisely the same manner. The number of direct lines now connected to this exchange exceeds 14,000; many of these lines serve more than one station, so that the total number of stations exceeds 20,000, the total number of operating employes being 414.

Traffic Studies. In order properly to proportion the staff to the work in a large exchange, a most careful study of the traffic is necessary. This is, of course, greatly facilitated by the position meters, and the extent to which such study is carried out can be best shown by actual figures, which relate to the Central Exchange, and refer to the 22nd day of March, 1907. In the diagram at the top of this page is depicted, in graphic fashion, first, the number of operators actually at work each half-hour; secondly, the number of calls plus attempts made to complete ineffective calls each half-hour; thirdly, the number of calls without the additional attempts.

It will be observed how the traffic, insignificant at eight o'clock, rapidly rises between nine and ten, reaching its maximum at eleven. The influence of the luncheon interval—which in the City takes place between one and two—is very pronounced. The afternoon peak is usually a little earlier, but on this particular day it was delayed until five o'clock. The operator curve should follow the call curve very closely. In this case it does so, except in the afternoon, but the agreement, on the whole, is fairly satisfactory. The scales are arranged in the ratio of one operator to fifty calls per half-hour, so that at all times they are working well within the normal load. It must, however, be remembered that in this case all the calls are junction calls, and these are usually given the value of two, as two operators are in all cases concerned.



In the accompanying table is given a complete and most valuable set of statistics relating to the Central Exchange for the same day as that which has been shown graphically.

As the majority of the subscribers contract for the message rate—that is, they pay £5 per annum plus 1d. per call—it was originally anticipated that the number of calls per subscriber would be low, and that each operator would, therefore, be able to cope with 180 subscribers. No. 5 shows that the calls per line per day now reach the comparatively high figure of eight, and, therefore, No. 8—the number of lines per "A" position—is only a little above ninety-seven.

Comparing Nos. 14 and 20 shows that the proportion of "Central" traffic has increased, and is now 29 per cent.

Nos. 29 to 49 refer to the incoming traffic, and a comparison of No. 30 with No. 14 shows that there are five calls received by the Central Exchange subscribers to every four originated by them. This means that business flows, as one would expect, *into* rather than out *from* the City.

No. 36 confirms the statement previously made that the "B" operator can deal with over 250 calls per hour, this high average being due to the use of machine-ringing keys and the automatic character of the signals provided for her assistance. The joint influence of call-wire working and of a large number of junctions is shown by a comparison between Nos. 31 and 39, the traffic per

call wire junction being just treble the traffic per ringing junction. Nos. 40 to 44 refer to special positions connecting the third and fourth floors. The positions reserved for incoming ringing junctions are called "C positions."

Nos. 50 to 54 refer to special junction transfer positions, which have been introduced for the purpose of eliminating from the work of the ordinary operator all the difficult "outer London" calls. These take longer than usual to operate, and would unduly impede the work on the ordinary positions. Immediately such a call is received, the "A" operator transfers it to the junction transfer record operator, who writes out a ticket, and hands it to one of the six position operators referred to in No. 51. The difficulty of dealing with these calls is evidenced by the fact that No. 54 shows that these junction transfer operators handle 659 calls each, as compared with No. 10 for the ordinary "A" operator, the number in the latter case being 784.

Some Telephone Figures. Nos. 19 and 49 show that nearly 16 per cent. of this traffic has to be dealt with in the busy hour, and this is the basis on which the equipment of the positions has to be made.

No. 55 shows that in one day more than a quarter of a million calls were dealt with. If we take this as the average, and allow for 300 working days, it will be seen that in a year we have for *one exchange alone* the astounding total of seventy-five millions of communications, which is comparable with the telegraph traffic of the whole kingdom.

The figures given in Nos. 58 to 60 do not include the engineering staff, but the average number of calls per employe during the hour—namely, seventy-three—is very satisfactory.

As a final effort to convey some faint conception of the magnitude of this huge installation, we may inform the reader that the internal exchange work alone accounts for over 7,000 miles of wires, and that the total number of joints necessitated in its construction exceeded 4,500,000.

Since 1895 all the long-distance telephone lines connecting various "telephone areas" have been in the possession of, and worked by, the Post Office. In each large town there is a Post Office trunk exchange, and this is connected with the local exchanges, which usually belong to the National Telephone Company, by means of junction circuits.

Long Distance or Trunk Telephony. The methods of working are quite different from those employed in ordinary local services, and it is proposed here only to describe them briefly. In local exchange work the wires are numerous, and being usually short, are not very expensive, and the cost of the operating is one of the principal factors. All this is inverted in connection with the trunk system, where the cost of a single circuit may exceed £20,000, and the cost of operating it may be in comparison a minor factor. It is clear, therefore, that every effort must be made to keep such a valuable line fully employed, and, consequently, in a trunk exhange the number of lines per operator is very small—usually not exceeding five.

For the purposes of description it will be best to take a concrete case and describe the method of operating. A London to Birmingham transaction will serve as an example. Imagine, then, in each of these cities a trunk exchange connected by trunk lines. The lines are worked in groups, but we must at first confine our attention to one. It terminates in front of the operator in the shape of a jack and signal lamp. The operator is provided with pegs and cords, having supervisory lamps similarly arranged to those already described in connection with central energy working, and she also has access to junction wires and call-wire keys, which have already been referred to.

Making a Trunk Connection. Let us suppose that a London "Central" subscriber, No. 300, wishes to communicate with a Birmingham "Central" subscriber, No. 1,000. He first calls the Central Exchange, and when answered, merely says, "Trunks." The Central "A" operator connects him to a record circuit which terminates in the trunk exchange on a special "record transfer switch.' This lights a lamp in front of the record transfer operator. Behind her, ranged along each side of a long table, are operators with headgear instruments waiting to take particulars of trunk conversations required. A connection from each of these record operators terminates on a plug on the transfer operator's keyboard. Immediately the lamp lights, when No. 300 Central is connected, the transfer operator lifts an idle plug, and connects it to the record junction. This puts No. 300 London Central directly into communication with the record operator, who takes down his number and the number and town of the subscriber with whom he wishes to communicate. She then informs him that he will be called as soon as a trunk is at liberty, and he rings off. Down the centre of the table runs a long travelling leather band, and on this the record operator places the ticket. At the end of the table it falls into the hands of a distributor, and from her is received by a check girl, who carries it to the trunk section, where it is put in proper order, according to the code time shown on the ticket with other calls awaiting turn.

As soon as a trunk is at liberty, the London operator asks the Birmingham operator for "1,000 Birmingham Central." The Birmingham trunk operator speaks on the call wire to the Birmingham Central, and obtains connection by a junction with the Birmingham subscriber. Simultaneously, the London trunk operator speaks on a call wire to the London Central "B" operator, and obtains connection to the London Central subscriber 300.

Checking the Time. Having obtained connection to both the London and Birmingham subscribers, the London trunk operator finally makes the connection, and times the ticket by means of a calculagraph machine, which records on the ticket the time at which the transaction began. As a further check on the time, the London trunk operator presses a time-check button, and at the end of three minutes the lamp immediately above this button lights. The operator then enters the circuit, and asks whether a second three minutes is required. If so, she presses the time-check button again, and at the end of another three minutes notifies the subscriber, and terminates the transaction. The ticket is again inserted into the calculagraph, and a pressure on the handle records the time of completion of call and *also* the *elapsed* time.

Recently, however, a system of telegraph call-wire working has been introduced. A telegraph circuit is superimposed on one of the trunk circuits, and telegraph operators, in addition to the trunk switch operators, are provided at each town. Particulars of all calls are passed forward by this means in advance of the transactions, and, therefore, it is possible to reserve the trunk circuits themselves entirely for the conversations of subscribers. This method has been wonderfully successful in increasing the revenue from trunk circuits. An average of sixty minutes paid time is sometimes obtained.

SINGING PRACTICE

The Registers. Volume and Tone. Correct Attack. Faults to be Avoided. Exercises and How to Practise Them

By MARY WILSON

THE human voice is characterised by three distinct qualities of tone, called its registers. The word "register" has been described by Manuel Garcia as "a series of consecutive homogeneous sounds produced by one mechanism, differing essentially from another series of sounds equally homogeneous produced by another mechanism, whatever modifications of *timbre* and of strength they may offer. Each of the three registers has its own extent and sonority, which varies according to the sex of the individual, and the nature of the organ."

There are three registers, called respectively:

1. Open or chest, or *Voce di petto.*
2. Closed or medium, or *Voce di gola.*
3. Head, or *Voce di testa.*

In bygone days, before the study of physiology became general, it was firmly believed and taught that the chest or open notes were actually produced in and emanated from the chest; that the medium were actually produced in and emanated from the throat; and that the head notes were produced in and emanated from the head; and owing to this belief these names, chest, medium and head, first came into use. But the student must banish this absurd idea, all the notes being produced in, and emanating from, the larynx, or voice-box. Although by some authorities these names, chest, medium, and head, are not approved of, to avoid confusion it is advisable that the student should retain them.

The first to be considered is the open, or chest register, which subdivides into the lower and upper chest registers.

The Lower Chest Register. The deepest and strongest tones of the voice belong to the lower chest register. In singing these notes the feeling is as though they were produced in the lowest part of the lungs. If the hand is lightly placed upon the lowest part of the chest, the vibrations can be strongly felt.

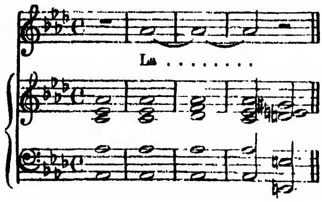
When these notes are correctly sung the whole length, breadth and thickness of the vocal cords vibrate, and the windpipe and pharynx are very much expanded. As the voice ascends the scale, the great tendency of the larynx or voice-box is to rise; this must be carefully guarded against.

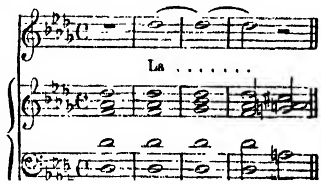
The Upper Chest and Medium Registers. All that has been said with regard to the lower chest register equally refers to the upper chest register, except that the vibrations are felt a little higher in the chest, and can be easily detected if the hand is placed upon the upper part. In singing the notes of this register, the whole of the vocal cords do not vibrate. In both registers the utmost care must be used that the notes are not forced. The mouth should feel full of sound. Men (basses and baritones particularly) have better chest notes than women. In female voices, the contralto has the best chest notes; light sopranos have scarcely any.

The medium or closed register like the chest register also includes two series of tone — the lower and upper medium. Some professors call the medium voice the *falsetto*, but since the word "falsetto" refers to notes "above the natural compass of the voice," the word here is a misnomer, for the voice of the medium register is as natural, if not more so, as that of either of the other registers.

The Lower Medium Register. The sensation felt when these notes are sung is as though the voice emanated from the throat. In singing the notes of this register the vocal cords come closer together; consequently the vibrations are quicker, the volume of tone is

Ex 1. Soprano, Mezzo-soprano, and Contralto Voices. ♩ = 100.





reduced, and scarcely any sensation is felt in the chest.

The pharynx is not so fully expanded; the soft palate and uvula rise, and close part of the nasal cavities, allowing the voice full scope to enter the mouth. Let the student remember that the breath must be directed on to the lips. On no account must the larynx be allowed to rise.

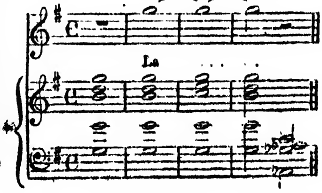
The Upper Medium Register. In producing the notes of the upper medium register the breath must be directed against the middle of the hard palate; the feeling then is as if the voice were produced in the upper part of the mouth, vibrating in the cheek bones. In singing the notes of this register also, the larynx must be kept low.

The Head Register. The sensation experienced when singing the notes of the head register is as though the sound emanated from the back of the head, vibrating in the posterior nasal cavities. The chink of the glottis is very small, the vocal apparatus contracted, and the vocal cords, being at their greatest tension, are very close together. As the student ascends the scale, the aperture or chink of the glottis becomes smaller and smaller until, finally, upon reaching the highest note, the opening is very minute. To produce these notes scarcely any breath is required, and the mouth must be kept wide open.

The soprano, mezzo-soprano, and tenor voices are the most noted for the head register. Occasionally one finds a contralto or baritone who possesses one or two head notes; but, generally speaking, when such is the case it is more than likely that the so-called head notes are nothing but the upper medium notes that have been trained as head notes. In this, as in the other registers, the larynx must be kept low.

Soprano and Mezzo-soprano Voices.

Soprano Voices.



Soprano, Mezzo-soprano, and Contralto Voices.

Timbre. Every human voice is divided into two classes—the singing and speaking voices; and each voice has, generally speaking, two timbres—the closed or sombre, and the open or clear. Quite irrespective of volume, each sound uttered by the voice possesses a number of shades, and these constitute its *timbre*. For example, take the vowels A E I O U, pronouncing them, Ah, Ay, Ee, O, Oo. Sing or recite each of these vowels on the same note, and with the same intensity of sound, listening carefully. The *tone* of each will be found to be quite different.

Beauty and Quality of Tone. It has been said that no two voices are alike. This being so, each voice must have some special characteristic; but, besides this, it must be either resonant or muffled, mellow or nasal, clear or throaty. The student should bear in mind that the qualities which constitute "beauty of tone" are resonance, purity, and clearness.

Although all tone is formed in the larynx, its quality depends almost entirely on the resonance chambers. If Nature has endowed the student with open, free, and good resonance chambers—chiefly the pharynx and nasal cavities—together with the free use of the soft palate, uvula, roof of the mouth, tongue, and teeth, it may be affirmed that the quality of the voice will be good—that is, presuming that the vocal cords are not defective. Numbers of people, some through force of habit, some through idleness, never use their resonance chambers to the utmost, and this causes the tone to sound faulty. In such cases this defect can be easily overcome by care and thought.

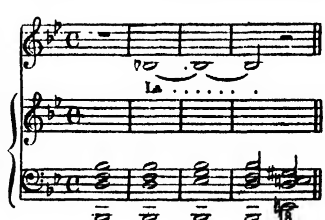
The voice should never be forced, and, after a correct method of respiration has been acquired, the student's undivided attention must be directed to the quality of tone.

Volume. Volume must not be confused with intensity. Volume is the size or magnitude of the voice, its loudness or softness; and to cultivate it the student must have some knowledge of, if he has not altogether mastered, the art of breathing. To acquire volume, the student must keep his larynx low, all the muscles of the throat free, the breath well under control—too much breath must not be expelled nor any undue pressure put on the vocal cords—the soft palate and uvula must be raised, the chest well expanded, and the tone directed to the front of the mouth, but there must be no forcing.

It should be noted that an intense tone is not necessarily a loud one. It is caused by the pressure of breath on the vocal cords. There are various degrees of intensity. These depend entirely upon the nature of the phrase to be sung or recited; the greater the passion to be portrayed the greater must be the pressure—but not force of breath—upon the vocal cords.

Attack. To attack a note properly is to begin it correctly, not scoop up or slur down to it, but to start it in the very centre. The breath must be well controlled; the attack must be

Mezzo-soprano and Contralto Voices.



Contralto Voices.

decided—not necessarily loud—quick and light. Signor Randegger compares it to "touch" in pianoforte playing, and he says "it corresponds to it in quickness, distinctness, lightness, and elasticity."

There is always a tendency in attacking the first note of a song or exercise to let the air rush out, leaving insufficient breath to finish the phrase. It is essential, therefore, that the whole of the vocal apparatus should be *prepared* and in readiness ere the order is mentally given for sound to be produced.

Unfortunately, "poor attack" is a very common fault with students of singing and untrained singers. This is chiefly owing to nervousness, which may cause the singer to attack the tone a little higher or lower than indicated; he will then slur down or scoop up to the correct tone; this is a general fault, but none the less bad. Sometimes a pupil through sheer fright dare not start to sing. Anyone at all afflicted in this way must exert all his will power to overcome his nervousness.

It not infrequently happens that "tightening the throat" to prevent the breath from escaping causes the attack to be incorrect. To repeat what has already been said over and over again, the diaphragm and rib muscles only—*not the throat muscles*—must regulate the breath control. Let the student remember that the attack must be distinct, decided and quick.

Faults to be Guarded Against. Some of the most general faults to be guarded against in singing are these:

1. Bad production—throaty and nasal singing.
2. Breath escape.
3. Tremolo and slurring.
4. Fatigue of the vocal apparatus.
5. Forcing the voice.
6. Tightening the throat muscles.
7. Faulty intonation.
8. High larynx.
9. Wrong position of tongue, soft palate, and uvula.
10. Facial contortions.
11. Movement of the shoulders.
12. Standing on the toes.

Bad production is due to two causes, the first of which is the root of the tongue pressing on the epiglottis, and so preventing a free passage of the breath. It is not an easy fault to overcome, so the student must exercise a good deal of will power and perseverance. Let him open his mouth naturally and fairly wide, and to see what he is doing he must practise before a mirror. Let the tongue be quite limp and lie naturally on the floor of the mouth, keeping the tip against the lower teeth. If he is not already able to keep his tongue "down," he must practise the exercises for the tongue given later.

The second cause of throaty or guttural singing is that the root of the tongue rises and forms a barrier at the back of the mouth. As the natural passage is thus blocked, the breath strikes against the barrier, and some forces its way round the sides of the tongue, some passes into the nasal cavities, and some is driven back into the throat.

When nasal singing is permitted, the tone sounds as though it were actually issuing from the nose. As a matter of fact, in certain cases some of the tone does escape through the nose. It is the result of not raising the soft palate and uvula, and the tongue at such times is often elevated at the root; in this way the breath is prevented from entering the mouth, and an undue amount is forced into the nasal cavities and nostrils. To remedy this, practise the exercises for soft palate and uvula given later on. In some cases nasal singing is due to adenoids. When such is the case, let the student see a doctor and have them removed.

Breath Escape. With beginners, breath escape is a very common fault. It is due almost entirely to a lack of proper breath management, together with a too slack tension of the vocal cords.

What actually takes place is that the breath, for want of control, rushes out through the vocal cords, which are not prepared to receive it. The result is that the greater part of the breath slips through, while only a small portion is used to make the cords vibrate; consequently the listener hears almost more breath than voice.

Let the student sing his exercises *very softly*, feeling all the time that the ribs are well expanded, and that every particle of air coming from the lungs is being used to make the note. This fault, which is really a grave one, since it prevents the voice from carrying, besides impoverishing it, must be corrected as soon as it is detected.

The horrible trembling of the voice, known as the tremolo, gives the listener the impression that the singer is trying to sing two notes and can pitch neither.

It is generally the result of over-straining, or it may be caused by training the chest register too high, forcing the head notes, a wrong method of respiration, ill-health, or nervousness.

If it is caused by over-straining, let the student practise *very softly*, not longer than a quarter of an hour at a time; if by training the chest register too high, be guided by the diagram referring to registers [page 6182], and practise all scales downwards, singing in the medium register as far as able. If by forcing the head notes, let the notes of the head register be sung *very softly* until all signs of the tremolo have disappeared.

If it is caused by a wrong method of respiration, give special attention to carry out all rules laid down for correct breath management; if through ill health, see a doctor at once; and if, lastly, through nervousness, concentrate on a thorough knowledge of exercises and songs. Slurring is dealt with later.

Fatigue of the Vocal Apparatus. Fatigue may be due to various causes, such as forcing, overwork, bad production, wrong method of study, general health, colds, tonsilar enlargement, elongated uvula, adenoids, and so on.

Much has already been said on the dangers of *forcing*. To overwork the voice in the hope of quickly developing it is one of the gravest faults into which a student can fall. A correct timetable for practice is given on page 6190.

The utmost importance is attached to a correct method of study, because when a wrong method is employed, it impedes the progress of voice cultivation very considerably.

The voice is most susceptible to every degree of health; it may be regarded as the barometer of bodily health. It will be observed, therefore, how very important is a high standard of general health. The student must never practise whilst suffering from a cold or sore throat.

Forcing the Voice. Frequently, the beginner in his eagerness to possess a big voice is apt to force it—that is, he is not content to let it develop slowly and naturally but must needs strain or drive it until he has gained size, but, alas! lost the quality. This fault

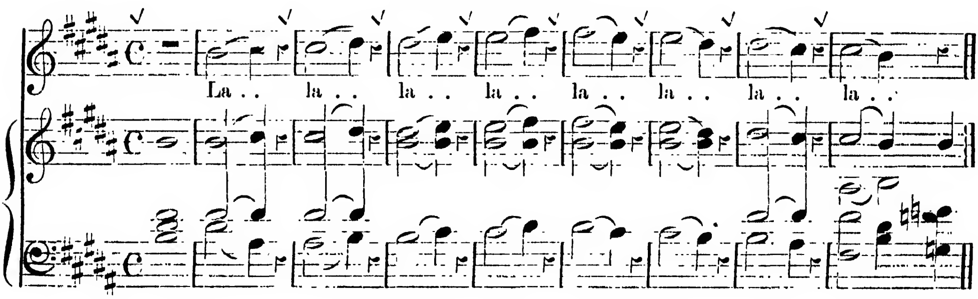
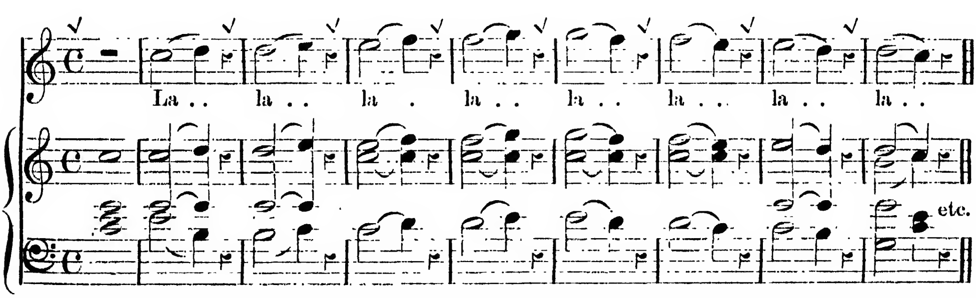
Soprano Voices.





must be rigorously guarded against: if carried too far it spells ruin. Let the student who is thus inclined to force limit himself to singing *softly* until the fault is quite overcome.

The fault of tightening the throat muscles is most prevalent amongst sopranos and tenors. It is generally caused by a faulty method of respiration, and sometimes by singing with the larynx high. Let it be remembered that there must be no feeling of strain or contraction of the throat whatsoever; that a correct method of respiration must be acquired, and that the larynx, or Adam's Apple, be kept low.

Faulty Intonation. A person with faulty intonation is said to sing "out of tune," and to be either "sharp" or "flat." When "sharp" the note he means to sing is a shade higher in pitch than he intends it to be. This is caused either by tightening the throat muscles or by lack of musical ear. If the former is the case, apply the rules given for tightening the throat muscles.

If the "musical ear" is at fault, let the student strike a note on the pianoforte before attempting to sing, listen to it carefully, *mentally* aim at the pitch of the note, sing it, then strike the same note on the pianoforte again, and compare it with the note already sung.

This remedy also applies to lack of musical ear in "flat" singing. Flat singing may be attributed to ill-health, bodily and mental fatigue, lack of musical ear, but most frequently to carelessness.

High Larynx. It is utterly wrong for anyone to sing with a high larynx or voice-box. Because the larynx rises, it may be argued by some people that it is quite correct to sing with it high, but this idea must be abandoned. The larynx rises merely to let food pass more easily down the gullet, not in any way to assist in the production of tone.

Before uttering a sound, let the student open his mouth, lightly place his thumb and first finger on his larynx, or Adam's Apple, then swallow; the Adam's Apple will be found to move upwards and then downwards. When it is down it must be kept so, and in this position let the student sing a note. Let him continue practising this until able to put it into position unconsciously and naturally. When the larynx is *low*, the tone will be open, free and pure.

The Position of the Tongue. At the beginning of this course of study, the student will probably find it difficult to keep his tongue flat, and at the same time loose and free. Notwithstanding, he cannot be too assiduous in his endeavours to control it. If the student opens his mouth and tries to keep his tongue flat, he will find that in nine times out of ten it will immediately rise, either at the tip or the root.

To remedy this, let him take a hand-mirror; open his mouth rather widely, place and keep the tip of the tongue against the inside of the lower teeth, then try and draw the remainder of the tongue backwards, feeling as though the root of the tongue had disappeared. Practise without uttering a sound. Should the tongue still rise, let the student take a paper-knife and lay it along the tongue, trying to realise the sensations felt when the tongue is flat. Slowly, and without moving the tongue in the least degree, withdraw the paper-knife.

When he has repeated this exercise several times, let him again practise without the use of the paper-knife, and persevere until he is able to keep his tongue perfectly flat. On no account must he attempt to sing with the paper-knife in his mouth.

More often through carelessness and ignorance than any other cause are the soft palate and uvula allowed to "hang down" when singing, and thus impede a good production. If they are kept in this position, the tone sounds either nasal or as though it were produced through a thick curtain. The most beneficial exercise for keeping the soft palate and uvula "up" is to stand with the mouth well open, keep the tongue in position, and draw in a slow, deep breath through the mouth, directing the air towards the palate. The student will feel as though he wanted to yawn, and upon looking into his mouth he will observe that his soft palate and uvula have almost disappeared. Let him continue to practise in this way until he is able to raise them without obtaining the effect of yawning.

Mannerisms. Nothing makes a singer appear more ludicrous than facial contortions. Perhaps the most general of these contortions is the raising of one or both of the eyebrows. Other faults are undue raising of the upper lip at either corner, pushing forward the chin, inclining the head to one side, perpetual moistening of the lips, assuming a set smile, constant blinking of the eyelids, quivering of the lower lip, and a nervous twitching of the face generally. All these stupid faults can be overcome if the student will practise carefully before a mirror.

On no account must the shoulders be allowed to rise when singing; should they do so, it may be taken for granted that a wrong method of breathing is employed. As already pointed out, the shoulders should be kept down and well back, in an easy position. This is quite easy if the pupil acquires a proper method of breathing and practises before a mirror.

Another foolish mannerism, which may be easily overcome, is rising on the toes when a high note is sung. This fault is most general with tenors. If the student is inclined to raise himself on his toes, he will be wise to check it at once. Let him observe and carry out the rules for a correct position, then there will be no fear of his falling into this absurd habit.

Order and Length of Practice. The student will do well to follow out the following time-table for daily practice.

1. Long sustained notes on "La" or "Ma," slow exercises, half an hour.
2. Scales, arpeggios, and advanced exercises, half an hour.
3. Solfeggi, half an hour.
4. Songs, half an hour.

On no account must a single practice exceed half an hour.

The above table applies to advanced students only. Elementary students must never practise longer than one quarter of an hour at a single practice. If at first a fifteen minutes' practice is too long, practise ten minutes. The exact order and length of practice for elementary students will be given with each exercise.

The student should never continue practising until he feels fatigued. Sufficient time for rest should be allowed between each practice. An hour or more should elapse after a meal before attempting to sing.

Practising Hints. As regards the duration of each practice, hours of practice, and order of practice, it is of the *utmost importance* that the student should be consistent. He must have method in his work, and never be spasmodic. Unless he practises carefully, thoughtfully, and regularly, he might just as well never practise at all.

The student is well advised never to force his voice, or to shout; not to be too self-satisfied, and think he is perfect when he is only beginning;

never to practise to a pianoforte that is out of tune, and never to hurry over the production of his voice.

Let him *study with his brain* more than with his voice; it is useless to practise in "parrot fashion"; he must know and think why he is singing the various exercises; keep his jaw loose and free; avoid all mannerisms; keep to simple and regular diet; and, above all, work hard and diligently, and remember that "of learning there is no end."

Singing Exercises. Alike both in male and female voices, two elements are absolutely necessary for the production of voice—the breath and tension of the vocal cords. The size and depth of the voice greatly depend upon the size and development of the larynx. As already mentioned, men's larynges are much larger than women's; that is why their voices are deeper and less acute.

Now the art of respiration has been studied, and something learnt of the various registers, the student's attention may be directed to the first singing exercises. The female voices will be taken first and then the male ones, but the following remarks apply equally to both of the sexes.

(1) Stand in the position indicated in Respiration [page 6051].

(2) Let the jaw fall naturally.

(3) When the phrase allows, inhale slowly and fully.

(4) The sign √ marks the place where the breath has to be inhaled.

It is to be hoped that the student will, if he has not already done so, study the course on THE THEORY OF MUSIC beginning on page 37, so that he may be thoroughly conversant with the terms used in his singing exercises; for example, *mf* (*mezzo forte*) = moderately loud, *f* (*forte*) = loud, and so on. He is urged particularly to study TIME on pages 38–41. The student should try to realise that the more general musical knowledge he possesses the better will be the results he will obtain.

The cultivation of the female voice may begin when the student is in her eighteenth year. The male voice must not be cultivated until the student is nineteen years old.

In practising the exercises 1, 2, and 3 in this article the mouth must be sufficiently open to admit the *width* of the thumb between the upper and lower teeth. The tongue must lie flat and naturally, with the tip touching the inside gums of the lower front teeth.

The consonants must be very distinctly articulated, and the exercises practised for several weeks—*mezzo forte*, then *forte* and *piano*—usually whilst standing before a mirror.

Breath must be inhaled as directed in the first exercise for inhalation, and during inhalation the note about to be sung—especially in Ex. 1—must be sounded on the pianoforte, and listened to carefully. The student must then *mentally* aim at the pitch of the note. This will help to ensure a correct intonation.

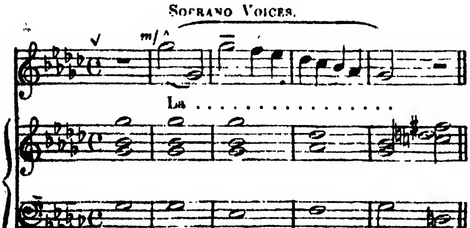
Ex. 3. ♩=100 CONTRALTO VOICES.

MEZZO-SOPRANO AND CONTRALTO VOICES.

Soprano, Mezzo-soprano, and Contralto Voices.

Soprano and Mezzo-soprano Voices.

Soprano Voices.



When singing the notes of

(*a*) the lower medium register inclusive the breath must be directed on to the lips ; 
(*b*) the upper medium register—inclusive—to the roof of the mouth ; 

(*c*) the head register—to the back of the head ;  and upwards

(*d*) the upper chest register—inclusive—to the front of the mouth ; 
(*e*) the lower chest register—inclusive—to the front of the mouth. 
A Practising Time-table. The following practising table should be adhered to if the best results are to be obtained.

First and second weeks, Exs. **1**, **2**, and **3** in this article.

Third week, Ex. 3, Randegger's "Singing Primer" [page 68]. Exs. **1**, **2**, and **3** in this article also to be practised.

Fourth week, Ex. 4, Randegger's "Singing Primer" [page 79], also exercises of previous weeks.

Fifth week, Ex. 5, Randegger's "Singing Primer" [page 83], also exercises of previous weeks.

Sixth week, Ex 6, Randegger's "Singing Primer" [page 86], also exercises of previous weeks.

Seventh week, Ex. 7, Randegger's "Singing Primer" [page 89], Exs. **1**, **2**, and **3** in this article, and Concone's "Solfeggi," Ex. 1.

All voices must be kept well within their natural compass in practising, and "La"—pronounced as in the word "father"—is the best syllable on which to practise. The first song may be taken about the ninth week.

Concone's solfeggi for the different voices are these: "Soprano, Mezzo-Soprano, and Tenor Voices: Fifty Lessons for the Medium Part of the Voice." "Contralto Voices: Forty Lessons for Contralto." "Baritone and Bass Voices: Forty Lessons for Bass or Baritone." Randegger's editions of the above are recommended, because the phrasing is excellent.

Before beginning to sing a new solfeggio, the student should study it, fully realising with what object the exercise was written, whether for "placing" the voice, the legato or staccato style of singing, sustaining, phrasing, portamento, *mezza voce, messi di voce*, blending of the registers, or attack. As before stated, "La" is the most satisfactory syllable to use for solfeggi, and it is

sung to the first note of each phrase, *not repeated with every note.*

A student may find he produces better tones on Ma, Na, Pa, or Da, in which case he must practise on the syllable most suitable.

When he is fairly familiar with the exercises, he must practise them on the different vowel sounds—ah, a, ee, o, oo, prefixing the different consonantal powers.

Basses and contraltos are advised to omit for several weeks the exercises that are to be sung quickly.

The Break. The student may find it difficult to pass smoothly, and without feeling a jerk, from one register to another. This " jerk " is most frequently noticed when passing from a lower to an upper register, especially from the chest to the medium. It is commonly called the " break."

Perhaps of female voices the most troubled in this way are the contraltos. Many untrained ones have a very pronounced " break " somewhere between D (below first line, treble clef) and F (first space, treble clef). No rule can be laid down as to which note the voice must " break " upon—it depends entirely upon the nature of the voice—but on no account must the chest register in any female voice be taken above E (first line, treble clef).

It is often possible to carry the chest register higher than this note, but however easy it may be to the student to do so, it is a very injurious practice. Besides coarsening and hardening the voice, it makes the medium and head registers very weak, and is one of the chief causes of " tremolo." The same applies to the medium register ; it must never be carried up beyond F (fifth line, treble clef). Such a practice would make the " head notes " thin and shrill. The most beneficial exercises written for the " blending of registers " may be found in Randegger's " Singing Primer," pages 27–37.

Occasionally it is advisable when singing a descending scale passage to carry the lower medium register beyond its usual limit, and so not use the chest register. When sung in this way the passage is much smoother. On *no account* must the chest register in an ascending scale be taken above its limit. If this is done, the passage is coarse and broken.

As male voices use the chest register almost entirely, they are not affected by this " break."

The above exercises recommended for female voices may be used to advantage by the male voices, tenors beginning on (8va lower) , baritones on (8va lower) , basses on (8va lower) 
Male Voices. Male voices use the lower registers—chest and medium or " voce mista." The production of the " voce mista," or the " mixed voice," which, with tenors, begins at (8va lower) , baritones , basses  is very similar to the production of the upper medium register in female voices. When singing these notes " the cavity of the mouth must be completely filled with voice, which, energetically directed towards the arch of the palate, will rebound from it, rendering the sound full and sonorous " (Randegger).

The three exercises already given for female voices are recommended for male voices, and are to be practised in the same order, 1, 2, and 3 ; but instead of beginning on F (first space, treble clef), the tenor must begin with E flat (first line, treble clef), and practise to G (above treble clef) ; the baritone with B flat (immediately below middle C), and practise to E flat (fourth space, treble clef) ; the bass with G (fourth space, bass clef), and practise to C (third space, treble clef). It must be borne in mind that the notes actually sung by the male voices are an *octave lower* than those indicated by the treble clef.

As the voice develops the compass may be extended, either upwards or downwards, or in both directions, as is natural to the voice. The student is advised to limit his compass for several weeks. The directions given for female voices apply equally to male voices.

When singing the notes of the chest registers the throat must be kept well open, the larynx low, and the breath directed *on to the lips.* To produce the " mixed voice." correctly the mouth must be more open than for the chest voice, the tongue lie quite flat, and the breath directed *to the roof of the mouth.*

Signor Randegger says : " Every student of singing should pay particular attention to the various physical sensations experienced in producing the tones of the different registers."

The vibrations of the notes of the different registers are felt :

(*a*) Lower chest, in the lowest part of the chest.

(*b*) Upper chest, in the upper part of the chest.

(*c*) Lower medium, in the lower part of the mouth.

(*d*) Upper medium and " mixed voice," in the front part of the face and towards the forehead.

(*e*) Head, in the back part of the head.

Continued from page 5956

INSOLUBLE COLOURS

The Importance of Water in Dyeing. The Treatment of Water. Operations Preliminary to Dyeing

By HERBERT ROBSON

Insoluble Colours. The insoluble colours can be divided into two classes—those which are added to the dyebath in the usual way, but require a special solvent other than water to dissolve them, and those which are produced on the fibre. It might at first seem that the mordant dyes ought to fall into this second class, but, although the actual colour produced is undoubtedly affected to some extent by the nature of the particular mordant, yet in the case of the mordant colours a previously existing dye is employed, and the resulting shade depends mainly upon it, whereas in the case of the developed colours the dye is wholly manufactured in the bath, so to speak.

The first class is represented by the sulphur dyes, and the second, which may conveniently be styled that of the *developed colours*, may be divided into aniline black, paranitraniline red, and other diazotised colours.

Sulphur Colours. Canarine, discovered in 1821, might be ranked as the first of the sulphur colours, but it is an inorganic salt prepared by oxidising potassium sulphocyanide. The first of the organic sulphur colours (also called *sulphine* or *sulphide colours*) was Cachou de Laval, made in 1873 by fusing sodium sulphide with various organic bodies, such as bran and sawdust. It was followed *longo intervallo* by Vidal Black (1893).

The great fastness of the sulphur dyes is now bringing them rapidly to the front, although their use is at present confined to cotton dyeing. The dye is dissolved in sodium sulphide solution, and an average dye requires its own weight of sodium sulphide. Extra marks, however, require twice their weight, and the highly concentrated brands treble. Until quite recently these dyes have been put upon the market in a very impure state, so that enormous percentages of them were required; but this state of things is now much improved. This, perhaps, constitutes the most noticeable progress of the past three years (1904-6), and, together with the greater range of shade now offered, has brought this group into favour. Perhaps the average amount is now 10 per cent. of dye. Some of the very concentrated marks will give full shades with 5 per cent. or even 4 per cent. On the other hand, 50 per cent. of an impure sulphur dye may be necessary to produce the colour desired. These percentages are heavy, but the dyes are cheap.

The bath must be made with Glauber's salt and also carbonate of soda (soda ash) to increase the affinity between the dye and the cotton. Various special precautions have to be taken. Wood only must be used for the dye vat. The goods, although entered at the boil, should not be allowed to boil in the bath. Steam should be shut off as soon as the goods are in. During the dyeing, the goods must be kept immersed, as contact with the dye and with the oxygen of the air tenders the fibre, and at the same time tends to make it assume a bronze appearance.

As regards the quantity of sulphide of sodium to be used, the best rule is to put just enough to dissolve the dye. The colour will come out very thin if any notable excess of the sulphide is used. The bath is kept standing, and reinforced with dye and sulphide as may be required. The dyed goods are centrifuged, rinsed, and fixed with bichromate and sulphuric acid, with sulphate of copper or peroxide of hydrogen, or by steaming. Overaction of the fixing agent must be avoided, as it tends to weaken the material. In all cases the goods are rinsed free from fixing agent and then soaped to neutralise any excess of acid and also to take away the harsh feel left in the fibre by the dyeing. When the soap has been rinsed out nothing remains but to dry the goods.

Sulphur Dye Baths. A very essential precaution in dyeing with the sulphur dyes is to use baths as short as convenient. While the average cotton-dyeing bath has twenty times the weight of the goods, it should be restricted to about twelve times the weight in the case of the sulphur dyes. In some cases a simple air oxidation suffices to fix the colour so that the dye can be used like indigo. Such dyes are much preferred, and naturally so, as not only does the fixing in other ways cost time and money, but almost always alters the shade, thereby making it very difficult to dye to pattern. There are already more than 200 brands of sulphur dyes now upon the market, and the range is daily increasing. To begin with, black was the only colour producible with the sulphur dyes, but the makers have gradually added grey, brown, olive, blue, yellow, etc. At the time of writing a red has been put on the market (Thiogene Rubine O), which gives a darkish red, turning to a plum colour by after treatment with copper sulphate. Messrs. Bayer have also brought out a good violet (Katigen Violet B). The range of shade producible with sulphur colours is still comparatively limited, but it is growing constantly, and the sulphur colours are gaining in importance daily.

Since this course was begun the gamut of colour dyes has been almost completed. Quite lately a pure red has been added to the group. Thio Indigo Red B, sent out by Messrs. Kalle & Co., is a very remarkable dyestuff. It may be regarded as indigo in which the two imido groups are each replaced by an atom of sulphur. It therefore has the relationship with indigo on the one hand, and with sulphur colours on the other. Thus it may be reduced, like indigo, in the vat, or dissolved in sodium sulphide solution like a sulphur colour. The range of pink to red shades that it gives have notably assisted to complete the series of sulphur dyes. The dye combines well with indigo, with the other sulphur colours, and with basics, thus giving a range of shades with remarkable qualities of fastness.

Insoluble Azo Colours. In 1880, Read Holliday & Sons, of Huddersfield, patented a process of forming azo colours direct on the cotton fibre. The soluble azo colours are not cotton dyes, as no mordant has been found to fix them on this fibre, but Messrs. Holliday showed that they could be *made* on the fibre. The principle of the process of producing an azo dye is this. An amine, such as

naphthylamine, is taken, dissolved in hydrochloric acid, and then diazotised by treatment with sodium nitrite; the diazo compound so produced is then combined with a phenol or an amine, and a colour is produced; this may then be treated with sulphuric acid, and thus converted from an insoluble to a soluble form. Messrs. Holliday, in their process, cause the cotton fibre to be impregnated with a solution of the amine: the fibre is then passed through an acid bath of sodium nitrite, whereby the diazo compound of the amine is produced on the fibre, which is now passed into another bath containing an amine, or phenol, or some other body capable of combining with the diazotised amine to form a colour: what this will be depends upon the amine that has been used.

At the time little use was made of the discovery, and attention was urged to it once again when another English chemist created a sensation in the dyeing world.

Primuline, already mentioned as a direct cotton colour, dyes unmordanted cotton a primrose yellow. Mr. A. G. Green, now the principal of the Leeds Technical School, made the remarkable discovery in 1887 that by diazotising Primuline on the fibre with nitrous acid, followed by a treatment with a phenol or an amine, a range of very fast and beautiful colours was produced, varying with the developer used, for instance:

Beta-naphthol	gave	red
Beta - naphthol - disulphonic acid R ..	,,	maroon
Resorcinol	,,	orange
Phenol	,,	yellow
Meta-phenylene-diamine	,,	brown

As these were produced in the fibre, they were called "ingrain" colours, and the Germans call this class "ice colours," as a very low temperature is necessary for the diazotising bath.

Insoluble Azo Dyes. As regards the insoluble azo dyes, however, the number in use is very limited, but at least one, paranitraniline red, familiarly known as *para red* in the dyehouse, is highly important. It is produced by steeping the goods in a solution of sodium beta-naphtholate—that is, a solution of beta-naphthol in caustic soda, usually with the addition of Turkey red oil—drying and developing at once. The developing bath is made by dissolving paranitraniline in a hot solution of hydrochloric acid. Cold water is added, and when the bath is quite cold nitrite of soda is added. Naphthylamine Bordeaux is the next most important insoluble azo colour. It is prepared by diazotising alpha-naphthylamine. This has lately become more important in view of the vogue of "wine shades," and also because effective means of discharging it on the fibre, to produce white and coloured patterns, have been discovered. Dianisidine Blue is obtained by developing dianisidine with beta-naphthol.

Toluidine Orange, Amidoazo-toluol Garnet, and a few other insoluble azos have found limited uses and are produced in a similar way.

Aniline Blacks. Aniline black is generally divided into two classes—oxidation blacks and steam blacks. The formation of aniline blacks depends upon the oxidation of aniline. Its use is practically confined to cotton, because wool and silk, having reducing properties, seem to prevent the oxidation of the aniline. It is possible, however, that a previous treatment of the animal fibre with an oxidising agent, such as permanganate of potash or bleaching powder, will remove the difficulty, as the reducing powers of the fibre have vented themselves upon the oxidising agent, so that afterwards the aniline black can be applied by the same processes as for cotton.

Cotton is dyed in various ways with aniline black. When the oxidation is effected by a liquid, the black is called an "oxidation black." When, however, it is effected by air aided by steam, the black is a "steam black."

Oxidation Black. The following are some methods of preparing an oxidation black: (1) Make the bath with 40 per cent. hydrochloric acid (34° Tw.), 10 per cent. aniline, and from 10 per cent. to 14 per cent. bichromate of potash. The bath should weigh about 16 times as much as the cotton. The aniline is dissolved in the acid and the bichromate in water first. The aniline is then first added to the rest of the water and then the bichromate. The cotton is worked cold in the liquid for an hour. When the colour of the cotton is fairly strong, heat up the bath slowly to 140° F. to 150° F. At least three hours should be occupied in the dyeing as the slower the process is the less chance there is of the black turning green on exposure to the air. On lifting the cotton it is well rinsed, soaped, and rinsed again.

(2) The bath is made with from 16 per cent. to 20 per cent. hydrochloric acid, 20 per cent. sulphuric acid, 8 per cent. to 10 per cent. aniline, 14 per cent. to 20 per cent. bichromate of potash, and 10 per cent. of ferrous sulphate. If this bath is made considerably shorter than the previous one described it will produce the black without heat and with less tendency to weaken the fibre. The ferrous salt helps to prevent greening of the black. It is, of course, oxidised to ferric sulphate in the process.

Prevention of Greening. Cotton dyed aniline black by either of these processes is usually given an oxidising bath of bichromate and sulphuric acid as a precaution against greening, but the black is sometimes topped with methyl violet with the view of concealing any greening that may actually happen. Sodium chlorate is also used as an oxidising agent in the production of aniline black, especially on piece goods, but it requires the assistance of other agents. Lightwood used chloride of copper for the purpose, and ferrocyanide of potassium has also been employed. Probably the best yet known is ammonium vanadate or vanadium chloride.

The cotton is impregnated, for example, with 5 per cent. to 20 per cent. of hydrochloride of aniline, 2 per cent. to 10 per cent. of chlorate of potash, and a very small quantity of the vanadium salt (about three-thousandths of the weight of the aniline salt). The black is developed by oxidation in a current of air kept damp by steam and passing over the cotton at a temperature of about 80° F. A much better and quicker development is obtained by the use of the Mather & Platt, in which the goods are passed through hot steam in a closed chamber. The temperature used depends upon the kind of black in question, being about 200° F. for ferrocyanide black, but for Lauth's sulphide of copper black about 160° F. only.

Steam Black. The following is a good recipe for a steam black: Dissolve separately 6 per cent. aniline, 9 per cent. hydrochloric acid, and 12 per cent. sulphuric acid in 200 per cent. of water. Dissolve separately 12 per cent. of sodium bichromate in 200 per cent. of water, and mix the two solutions. Enter the cotton cold, and as soon as it is dyed, which takes two or three minutes, wring it and steam it for twenty minutes at 14 lb. pressure.

Artificial Indigo. The artificial synthesis of indigo is of decidedly earlier date than the putting of the product upon the market, but for a long time the cost of its manufacture prevented it from competing with the natural dye. In 1870, Baeyer & Emmerling made it from isatine, but isatine itself was not synthesised from coal-tar products until 1878. In 1880, Baeyer prepared indigo from cinnamic acid, and in 1882 Baeyer & Drewson prepared it from ortho-nitro-benzaldehyde by the joint action of acetone and caustic soda. This artificial indigo was put on the market in 1893, in combination with hydrosodic sulphide, under the name of indigo salt, by Kalle & Co. Another synthesis of indigo, from phenyl-glycocoll, by Heumann, was published in 1890. The process belongs to the Badische Anilin und Soda Fabrik, and forms the basis of the method by which that company now prepares its indigo rein (indigo pure), which was put upon the market in 1897. All these artificial indigos are identical with one another and with the indigotin of the natural dyestuff.

Operations Preliminary to Dyeing. Even if goods are to be dyed in the grey state they must pass through a preliminary treatment before they can be properly dyed. They have gathered grease and dirt in the processes of spinning and weaving, the wool has been purposely oiled, and the cotton warps have been stiffened with size, which will act as a resist to the dye. The goods, therefore, must be bleached or thoroughly scoured, or wetted out.

In these and in the dyeing processes the quality of the water used is of the first importance. A vast volume of it is required in the dyehouses, and an abundant supply of pure water is a prime necessity. Water must therefore be considered, to begin with.

Water. The question of "hard" and "soft" waters from the point of view of the steam user has been considered more exhaustively in another course. Here we must speak of water simply from the point of view of the dyer.

In bleaching or washing, the presence of the salts of lime and magnesia entail a waste of soap. In the neighbourhood of London a laundry with a supply of water marking 15° of hardness considers that it has "good water," and yet every 1,000 gal. of this water will destroy more than 20 lb. of soap before it gets to work on the clothes. The available water in some districts is capable of wasting twice or thrice this amount of soap without useful result.

In washing off after milling, a large quantity of water is used, and this, if hard, forms a soap curd in the fibre. This curd makes satisfactory dyeing impossible. Hard water can never be used for washing and scouring goods which have afterwards to be dyed.

Even a trace of iron in the water—and this is frequent—is disastrous throughout the operations of the bleacher and dyer. The student of this course has already seen that iron salts are used as mordants for dark shades. It does not require explanation, therefore, that iron in the water will dull bright shades. The lime, magnesia, and iron salts form insoluble soaps in combination with the wasted soap in scouring or bleaching. These are deposited in spots on the cloth, and will not only infallibly lead to uneven dyeing, but, in the case of the iron, will cause dark stains on the goods.

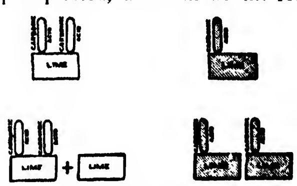
Apart from iron, the dulling effect of which is the same throughout all his operations, the bicarbonates of lime and magnesia, and in a less degree bicarbonate of soda, are most troublesome to the dyer.

The principal fault of water containing carbonate of soda is that it neutralises any acid used in mordanting or dyeing. The bicarbonates of lime and magnesia waste the mordants and dyes in a similar manner to the destructive process we have pointed out in the case of soap. They precipitate many mordants and dyestuffs, and reduce bichromates to neutral chromates, which give up much less chrome to the fibre, and are consequently less efficient as mordants.

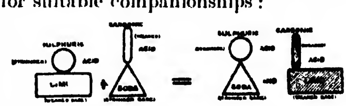
This will be sufficient to show that for the sake of economy and good results the dyer must purify the water he uses. Fortunately, the "permanent" hardness due to the presence of sulphates is of little consequence, although waters used for washing dyed goods should be fairly free from permanent hardness.

In the case of a fairly soft water, the dyer frequently is content to neutralise the carbonates present in the mordanting or dye bath with an acid. If sulphuric acid is added, for instance, the carbonic acid is driven off as a gas, and the carbonate is converted into a sulphate. A safer and simpler method, and absolutely necessary in the case of many water supplies, is to purify all water used for the boilers, and throughout all processes, by a preliminary treatment. This purification may be done by simply boiling the water, and thus converting the bicarbonates into carbonates by driving off part of the carbonic acid. On a large scale this is obviously impracticable.

Possibly, the simplest method and least expensive is to add lime-water (hydrate of lime) in a quantity calculated according to the degree of hardness of the water. This added lime is converted into carbonate at the expense of part of the carbonic acid in the bicarbonate, which consequently also becomes a carbonate, and the now insoluble lime salts are precipitated, and can be filtered off.



There remains, however, the permanent hardness to be considered, and for the sake of the boilers it is desirable to remove the sulphate of lime present. This can be done by adding carbonate of soda to the water in the form of soda ash. Then a double decomposition occurs, due to the familiar chemical law that the strongest base will combine with the strongest acid, Nature's great chemical example of her liking for suitable companionships:



The sulphate of soda does not form scale, and the carbonate of lime is precipitated as before.

It is evident that, apart from the question of initial cost, an efficient water softener must be simple to work, almost automatic, in fact, and that it must ensure certainty in adding the reagents in correct proportions; allow these proportions easily to be varied, according to the water to be treated; be able to run at varying speeds without adjustment; mix the reagents intimately with the water; allow complete removal of all suspended matter and thorough cleaning of the filtering material without removal. As an example, and as embodying these desiderata, the "Criton" Water Softener may be looked upon as an efficient apparatus, and this has been fully described on page 4096.

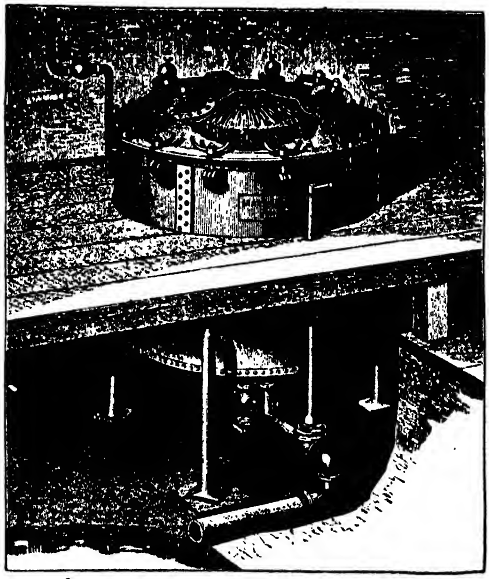
As the preliminary operations, and in particular bleaching, vary with the different fibres, we must consider them under the headings Cotton, Wool, and Silk.

Wetting Out Cotton. The grease and dirt is removed in this operation with a mild alkali, and the fibre is uniformly impregnated with water in order to allow the dye to penetrate it evenly. Air bubbles in the fibre are quite sufficient to cause uneven dyeing, and these are removed in wetting out. The usual method is to boil the goods with water containing 2 lb. or 3 lb. of soda ash per 100 lb. of goods. The addition of a pure, well-made soap assists the operation. In some cases the wetting out is done in the machine used in dyeing; for instance, raw cotton and sometimes hanks and warps are treated with boiling water for half an hour or more in the machine before the dyebath is made up, and piece-goods are given a few ends through boiling water on the jigger. More frequently a boiling-box or low-pressure kier [2] is used. Sometimes water alone is used—for instance, in cases where the dyestuff to be used would be affected by the soda—and in some cases it is advantageous to substitute a smaller proportion of caustic soda. This is quite sufficient preliminary treatment, as a rule, for dark shades.

Bleaching Cotton. The most perfect bleach is naturally needed by the calico printer, and in some cases, even for light shades, the dyer is content with steeping the goods already wetted out in a weak bath of bleaching powder, without heat, for a few hours, washing, souring with dilute hydrochloric acid and washing thoroughly.

The steps of the process are much the same in the case of yarn:

1. The yarn is steeped in water for a night to remove the grosser impurities, and to open the fibre to the action of the lye.
2. It is packed evenly into the low-pressure kier and boiled in lye. The circulating action of the kier is shown in the illustration. In this a rather long boil is necessary. The lye should be prepared with 3 per cent. of caustic soda. This frees the yarn from grease.
3. The alkali is thoroughly washed out in pure water.
4. The bleaching operation proper follows, and retains its old name—"chemicking." The apparatus used is very like a washing machine. It may consist of a wooden box, with a perforated bottom, placed over a cistern. The yarn is packed into the upper compartment, and the cold bleaching powder solution at about 2° Tw. is prepared in the lower. The liquor is pumped through a large rose over the goods and runs back into the cistern, and this constant circulation is kept up for six hours or so. This destroys all traces of colouring matter in the yarn.
5. The bleaching liquor is thoroughly washed out in pure water. All the washing operations can be very conveniently done in the chemicking machine described above.
6. A little hydrochloric acid is added to the water in the lower cistern, and the acidulated water is sprinkled over the goods as before for half an hour or less. This is called "souring," and neutralises all traces of "chemic" left in the goods.
7. The acid is thoroughly washed out of the goods. Plenty of water should be used, as traces of acid left in the yarn will tender the goods.

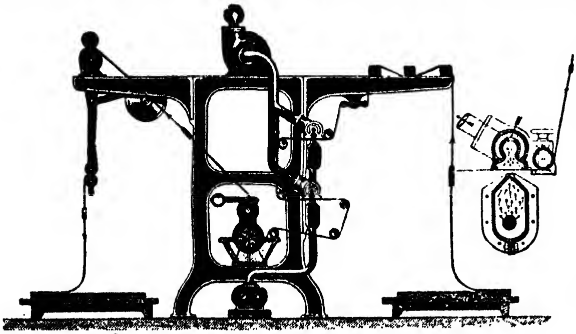


2. LOW-PRESSURE KIER (Mather & Platt)

Permanganate of potash, peroxide of sodium or of hydrogen, and other bleaching agents have been used for cotton, but their cost does not allow them to compete with chloride of lime

It must be remembered that this is merely the outline of the process. As a rule it is a separate industry, and the dyer receives his goods in the bleached state.

Singeing. This is a step of the bleaching process, especially when the cloth is to be printed, but frequently it is advisable to singe goods to be dyed in the grey, and it is a necessary process in lustre-mercerisation and Schreinerising. When yarn has to be singed, as, for instance, in the case of fine counts that are to be given the appearance of silk, either by mercerisation or by a mechanical process, this is a work of the spinner who "gasses" the yarn—that is, passes it at a high speed several times through the flame of a Bunsen burner. Many forms of machines are used for cloth, and the singeing is done by coal, coke or gas, and even electricity has been tried. Sometimes the cloth is passed over a hot plate heated by fuel, and at one time the difficulties in the way of employing the direct flame of the gas for cloth singeing made the plate machine,



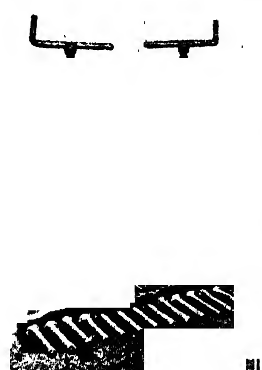
3. FELIX BINDER SINGEING MACHINE (Mather & Platt)

the principal one used for the purpose. It is still largely employed, but an inventor, Felix Binder, turned his attention to the gas singeing machine and made it efficient. As it is of more universal application than the plate machine, we describe and illustrate the Felix Binder machine [3], improved and manufactured by Messrs. Mather & Platt.

Binder found that the defect of gas singeing machines was that the hood and other parts became too hot. He remedied this by providing means for cooling the heated parts. The cloth to be singed passes over a wide slot in the underside of an exhaust chamber. The flame from the burner below is drawn gently through the cloth by means of a fan connected by pipes to the exhaust chamber. It will be noted in the diagram that this arrangement is duplicated, and that each side of the fabric comes under the action of the flame. The device is shown more clearly in the enlarged diagram at the side; the arrow to the right shows the direction of the cloth and that at the side the direction of the air sucked by the fan. The exhaust chamber is surrounded by a water-jacket through which a current of cold water flows, indicated by the arrow in the middle. The darts show the direction of the jets of flame. The burner consumes gas and air supplied by the Roots blower at the foot of the machine. The cloth passes over guide rollers through a damping trough, and is plaited down at the side of the machine. This is perhaps the most efficient singeing machine available; the consumption of gas varies from 16 to 200 cubic ft. per hour, and in this time the amount of cloth singed will vary from 12,000 yards to 18,000 yards.

Wool. Wool "in the grease"—that is to say, as it is obtained from the sheep's back—in addition to dirt, contains a heavy percentage of fatty bodies insoluble in water, known as "yolk," and a body soluble in water called "suint," consisting principally of potassium salts of organic acids. As these are removed before spinning, however, this is not the dyer's business. The woollen spinner, however, is obliged to oil the wool in spinning to give it suppleness, and whether from the yarn or cloth this must be completely removed before dyeing or bleaching. This is a simple enough operation if good olive oil has been used, but much trouble in the dye-house has resulted from the use of mineral oils, which are unsaponifiable.

Stretching. In the case of yarn it is usually necessary to "set" the fibre before dyeing, or otherwise it would shrink and become entangled. This is done by stretching the yarn in a frame between pairs of iron rods and boiling for half an hour or so. The upper pairs of rods can be raised by the action of screws, and the yarn very tightly stretched in the frame. In this state the whole frame is put into a boiling-box and after treatment for some time the hanks are pulled half round, the boiling is completed, and the hanks are taken from the rods and allowed to cool. The stretching machine shown in 4, made by Messrs. Elkanah Hoyle & Sons, of Halifax, has thirteen white metal spindles in each row. The hanks are put over the spindles and stretched tight by means of the strong screws. A hook at the end of a rope running through a block overhead is put into the eye-bolt and the whole frame is swung into a vat and boiled as described. This not only prevents the hanks from snarling, but puts a finish on the yarn.



4. YARN-STRETCHING MACHINE
(Elkanah Hoyle & Sons)

Scouring. The yarn is scoured in a solution of soap alone or of soda and soap, but the bath is not heated above 110° F. It is frequently done by hand, the hanks being hung on sticks as in dyeing, and moved forwards and backwards in the bath by two men standing on either side of a wooden tank, heated by steam. The position of the hanks on the sticks is changed from time to time, and when sufficiently scoured the yarn is washed thoroughly, squeezed and dried. A variety of machines have been devised for the operation, and in some of these the yarn is treated continuously, the hanks being made into a chain or placed loose on a travelling apron and carried through the scouring and washing baths between squeezing rollers. Cloth is not always scoured before dyeing when it is to be dyed black, but for the best work it is always necessary. A very ordinary form of machine is the "dolly." This practically consists of a pair of squeezing rollers revolving over a tank containing the bath of soap and soda. The pieces are sewn together in a continuous band and passed in rope form—that is to say, not opened out—through the bath by means of guide rollers and through the nip of the squeezing rollers. A trough immediately below these catches the dirty wash water, which is run off. In some cases the cloth would be creased in the dolly, and an open width machine is used instead. Practically the only difference is that the squeezing rollers are wider, and that a device is added to keep the cloth in tension and thus prevent it from creasing. In either case the scouring is continued until the pieces are perfectly clean, and they are washed in clear water and dried.

Crabbing. When the cloth is a mixture of different wools, and more especially when it is a union material—wool and cotton—the goods must still further be set by crabbing. This operation is described more particularly in this course in the chapter on mixture dyeing. The diagram shows a treble crabbing machine [5], made by Elkanah Hoyle & Sons, of Halifax. This is the standard machine used for Bradford textiles, and also for the light cloths of Huddersfield and Leeds. The first pair scours and extracts all the greasy matter from the goods. In the second pair warp and weft are "set" so that they will not cockle, and a lustre that cannot be removed is given to the goods. The third pair is the same process, but washed off in boiling water. Each pair of rollers is fitted with a cast-iron trough with a perforated boiling-pipe from end to end.

Bleaching. Wool is bleached in an entirely different manner to cotton, as the fibre would be totally destroyed in the lye boil. It is not usual to bleach it except for white cloth and for light shades. The scoured yarn or cloth is hung on poles in a brick chamber and "stoved," or "sulphured," as the operation is called. About 8 per cent. of sulphur is put in an iron pan in the middle of the room, and a red-hot iron is thrust into it. The room is then closed and the goods are left to the action of the gas—sulphur dioxide—for about

ten hours. Air is then allowed to blow through, and the goods are removed or washed.

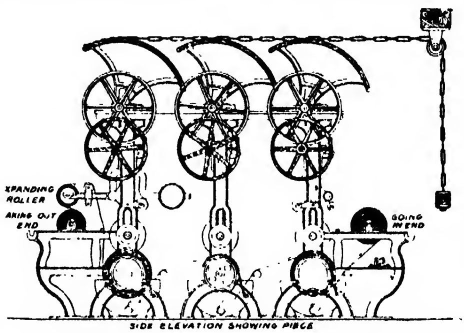
Sometimes a solution of sulphurous acid is used, or the goods are first steeped in sodium bisulphide and next in hydrochloric acid. In this case the sulphurous acid, being in a nascent state, acts very powerfully. Sulphur bleaching, however it is effected, is only temporary in its effects. The yellow tint of the natural wool will return, especially if the goods are washed once or twice. To counteract this, such things as white flannel are blued in the familiar manner of the laundry.

A much more permanent bleach is obtained with hydrogen peroxide, "oxygenated water," as the French call it, or with sodium peroxide. Hydrogen peroxide is very unstable, but it claims priority of use, and the process is very simple. It is, however, more expensive and less easy to keep than sodium peroxide; and this is generally used where the cost of the process is justified. It is highly important that no metal vessel should be used and that the water should be free from even a trace of iron. For 100 lb. to 150 lb. of wool the bath is made with 7¾ lb. of sodium peroxide, 3 lb. phosphate of ammonia and 8 lb. sulphuric acid in 100 gallons of water. All these ingredients must be free from iron. The sulphuric acid is first added to the water, then the phosphate and the peroxide are slowly stirred in. When the bath has been properly prepared it will have an alkaline reaction due to ammonia; it is now allowed to stand for about twenty minutes, and the scum that rises is removed by a wooden scoop or other suitable utensil. It is then ready to receive the scoured and properly rinsed goods. The wool is entered and the temperature raised to 110° to 120° F., and maintained at this for twenty-four hours, according to the thoroughness of the bleach required. The goods should be turned from time to time; and the bath may require the further addition of ammonia to maintain its alkaline condition, the necessity for which can be ascertained by the use of red litmus paper. When sufficiently bleached the wool should be lifted and allowed to drain into the bath—squeezed if practicable—and then thoroughly rinsed.

This gives a pure and brilliant white unattainable by any other means.

Silk. The object of the preliminary operations in this case is not only to prepare the material for dyeing but also to make it soft and lustrous. This is done by removing more or less of the silk glue, and according to the degree to which this operation is carried the material is called "boiled-off silk," "souple silk," or "écru."

Boiling-off. The silk is worked for an hour rather under the boil in a bath made with about 30 per cent. of soap. The gummy, soapy liquor that results is known as "boiled-off liquor" and is used in the silk dye-bath. The silk is then washed in water in which a little soda ash is dissolved, and scoured. For this process the silk is put into hempen "pockets" and boiled, sometimes as long as three hours, in a soap solution about half the strength of the previous bath. It is then washed thoroughly in soft water and dried.



5. TREBLE CRAB (Elkanah Hoyle & Sons)

Soupling. The raw silk is first scoured by working for about an hour in a lukewarm bath made with about 10 per cent. of soap and a little soda. It is then worked in a solution of aqua regia in a stone trough, bleached after the manner of wool by sulphuring, and, without removing the sulphur, is softened by working in a solution of cream of tartar at about the boil or a little under. The process requires experience and should be studied in special works, such as Hurst's "Silk Dyeing."

Écru Silk. This is simply scoured in a lukewarm bath of soap and soda. This removes the fats but very little of the gum. In this state it may be dyed black, but for other colours it is bleached.

Bleaching. Silk can be sulphured in the same manner as wool, but the white obtained is very fugitive. The best agent is peroxide of hydrogen. The scoured silk is simply treated in an alkaline bath of peroxide. It is entered cold, left for twelve hours, turned, left another twelve hours, and then the bath is made lukewarm and the process is finished in another three hours. This is slow, but an unhastened cold bath is better in peroxide bleaching, whether for wool, or silk.

The weighting of silk has been mentioned on page 5780. The boiled-off yarn is sometimes stretched between wooden rods, and gains as much as 3 per cent. in length without injury, while the lustre is increased. It may be steamed in the stretched state, which still further increases the lustre, or twisted up very tight and allowed to remain in this condition, which also has a glossing effect.

RUSSIA BECOMES A GREAT POWER

"Ivan the Terrible." The Days of Peter the Great. His Achievements at Home and Abroad. The Rule of Catherine II.

By JUSTIN McCARTHY

IVAN II., called The Great, who married the niece of Constantine Palæologus, took the title of "Ruler of All Russia." He marched against Novrogod and took possession of the city in 1481, killing numbers of its inhabitants. The retreat of the Tartars from Moscow in 1488 had the effect of freeing Russia from the Tartar-Mongol, but Russia's greatest enemy at that time was Lithuania, which was close to Moscow. The war with Lithuania and Poland began in the reign of Ivan III., and was continued by his son Vasili, who retook Smolensk.

The First Tsar. Ivan IV. succeeded Vasili in 1533 when he was only three years old. He was known as "Ivan the Terrible," and is one of the best-known of the Russian rulers. He reigned for fifty years, and was the first Russian sovereign crowned as Tsar. He did much during his reign to improve the arts and commerce of the country, as well as extending its territory, and he made a commercial treaty with Queen Elizabeth of England. Ivan the Terrible persecuted the Boyars, of whom he is said to have slain many thousands, and his cruelty was indeed so great towards the end of his life that he is generally believed to have become mad in his later years. He died in 1584—it is said from grief for having killed his own son in a fit of anger. His weak-minded son, Feodor, succeeded him, and he in his turn was succeeded by Boris Godenoff, who was chosen by the Duma.

The Beginning of Serfdom in Russia. Boris Godenoff was a man of great administrative ability, but his rule was not a fortunate one for Russia. He abolished the peasants' rights of free removal, thus instituting serfdom—the curse of Russia for many generations. To secure the succession for himself and his family, he exiled Feodor and his mother and caused the assassination of the young child Dimitri in 1591. Some years after this there appeared in Poland the famous impostor who called himself Demetri, the murdered son of Ivan IV., who succeeded in passing himself off as the rightful heir. He found many supporters, and was recognised as her son by the mother of Dimitri. He was crowned at Moscow in 1605, but the Russian people were soon disappointed in him, for he had married a Polish woman and was merely an instrument of the Poles. His imposture was soon discovered, and he was murdered in the following year in the palace where he had so lately been installed. Prince Vasili, who had risen against him, was proclaimed Tsar, but the Russians refused to acknowledge him, and Russia remained in a state of unrest until the Sobor elected Michael Romanoff, one of a family already popular in Russia.

Michael was the first sovereign of the House of Romanoff. He made peace with Gustavus Adolphus by ceding Schlüsselburg to the Swedish king. His reign saw insurrections of the peasants and wars with Poland. Under his son Alexis, Russia was further modelled into a state, and the administration was reformed, but there were, notwithstanding, many popular risings, and many troubles in the Church. The Patriarch Nikon endeavoured to attain the same supremacy in the East that the Pope had in the West, but the popular Church—the Old Faith, as it was called—opposed him, and he was eventually deposed and exiled. In this reign Poland was at last conquered by Russia, and the Russians also recovered Smolensk. Alexis was succeeded by Feodor in 1676, and on his death, six years later, his half-brother, Peter, was chosen Tsar.

Peter the Great. Peter the Great was the Russian sovereign to whom the country owes her sudden rise into power. He was born at Moscow on June 9th, 1672, four years before his father's death. When Feodor, his half-brother, knew that his death was near, he named Peter as his successor, excluding his own brother, Ivan, who was believed to be of weak mind. Ivan's sister, the Grand Duchess Sophia, opposed this nomination, and an insurrection of the militia, encouraged by her, rose against it. By Sophia's influence it was eventually arranged that Peter and Ivan should be crowned as joint rulers, Sophia acting as Regent during their minority. In 1689 Peter, who in the meantime had received an excellent education under the guidance of a Genevese named Lefort, called on his sister to resign the Regency, and, the military force of the country being on his side, Sophia had to give up the struggle. She was shut up in a convent, where she died. Peter gave his brother the nominal position of sovereign, but did all the work himself, and after Ivan's death, in 1696, he set to work to create a navy for Russia as well as a mercantile marine. The training of the navy was interfered with by the fact that Russia had only one port, and Peter, with the promptitude and disregard for principles of national equity which characterised him, declared war against Turkey and captured the port and sea of Asov.

How a King Went to School. Feeling that he had now made for himself and his country a settled position in Europe, he determined to study in the great capitals of Europe where civilisation was already established, the improvements which practical science had made in all departments of life; but he had first to suppress a revolt of the Strelzi, or militia, a peculiar military institution in Russia. He then visited the Baltic provinces, Prussia, Hanover,

and Amsterdam, where he worked as a common shipwright, and also studied astronomy, astrology, geography and natural philosophy. In 1697 he went to London, and at Deptford he again worked, entirely unknown, as a shipwright. While there he arranged for the emigration and settlement in Russia of a large number of surgeons, engineers, artillerymen, and artisans, for whom he was to find employment. When he returned to Russia he suppressed the Strelzi, which had given him so much trouble, and organised the new army according to the principles of the great European states.

Reform in Russia. A strong anti-reform party was springing up in Russia among the classes who, in every country, are opposed to all innovations. As his wife, Eudoxia, had associated herself with the anti-reform organisation, he obtained a divorce from her. Then he set about the work of reconstruction. He established naval and military schools, encouraged trade with foreign countries, remodelled the Press after the fashion of civilised Europe, and arranged for the publication in Russia of the best foreign books. In 1700, in alliance with Poland and Denmark, he engaged in a war with Sweden, then a powerful country. Charles XII. of Sweden, who had just succeeded to the throne, displayed his genius for war and compelled the Danes to sue for peace. In this success he was materially assisted by a squadron of English and Dutch under the command of Sir George Rooke, the famous English admiral.

Peter attacked Sweden, but Charles XII. defeated the Russians at Navva. Peter, however, continued his long contest with Sweden, and after some defeats he completely crushed Charles XII. and his army at Pultowa in 1709. Charles was not dismayed. He induced Turkey to declare war against Peter, and in this war Peter was reduced more than once to a condition which seemed desperate. He held out with his characteristic perseverence, and in 1711 he concluded a treaty by which he got out of the struggle with the sacrifice of the city of Asov and the land belonging to it.

Foundation of St. Petersburg. Peter had in 1703 laid the foundation of the new Russian capital, St. Petersburg, and in 1712 the seat of government was transferred to it. In the same year Peter married again. His second wife, Catherine, was the daughter of a peasant woman and a Swedish dragoon. After one of the Russian victories she became the mistress of Prince Menschikoff and then of Peter. In 1716–17 the Imperial pair made a prolonged tour throughout Europe, during which Peter obtained new ideas for the improvement of Russia. Some of Peter's reforms were again opposed by many of his nobles, and Peter punished his opponents with unrelenting cruelty. His son by his first wife, Alexei, was accused of joining the opposition to his father's plans, was tried, condemned to death, and actually died in prison. A treaty of peace was concluded with Sweden in 1721, by which the Baltic provinces and part of Finland were yielded to Russia.

A year after Peter forced a war on Persia, with the result that three of the Caspian provinces became part of Russia's dominions. The last years of Peter's reign were mainly occupied with projects worthy of his better days, for enlarging and adorning his new capital, and for the spread of education throughout his dominions. Suddenly he was attacked by a serious illness, and died, February 8th, 1725.

Russia under Menschikoff. On Peter's death, his wife, Catherine I., was acknowledged Empress of Russia. Catherine was wholly under the directions of Menschikoff, the Russian field-marshal, by whom she was first introduced to Peter, but who afterwards lost Peter's confidence because of his extortions of money for his own ends, and also because Peter suspected him of treacherous dealings with the enemies of the Emperor. Catherine restored him to favour, and during her reign and that of her successor, Peter II., he governed Russia with an absolute rule. He was already making arrangements for the marriage of his daughter to the young Tsar Peter, when an uprising against him by the old nobility proved too strong for him and his party, and he was banished to Siberia, after the confiscation of the vast estates which he had acquired by all manner of discreditable dealings. Death brought his career to a close on November 2nd, 1729. His great grandson became, in a certain sense, famous, for his was believed to be the main influence in forcing on the Crimean War, and he commanded the Russian forces at Alma and Inkerman, and in the defence of Sevastopol.

In 1727 the anti-reform party of the nobility set up the only son of Alexei, who had died in prison, as a claimant to the throne on the death of Catherine, and he became Emperor as Peter II. Peter II. was under the control of Menschikoff, and afterwards of Dolgorouki, and, like Catherine, was not in any sense the real ruler of the Empire.

Some reigns followed from 1730 to 1762 which were more remarkable for political intrigues and struggles at home than for great events in the world's history.

Catherine II. The reign of Catherine II. calls for more special notice. She was the daughter of a German Prince, and was born at Stettin on May 2nd, 1729. She was, by diplomatic arrangement, chosen when very young as a wife to the young Prince Peter, heir to the Russian throne. The young pair were married in 1745, and Peter III. became sovereign in 1762. Catherine had been brought up in comparative poverty, for many German princes had then very limited revenues. She was a charming woman, endowed with great political capacity, and was, indeed, one of the most capable women who ever occupied a throne. But she was unscrupulous and corrupt; she seemed to have no moral principles; she loved to be paid court to and surrounded by admirers; she enjoyed political intrigue, and personal intrigue still more. She and her husband never got on well, and in the earliest days of her married life her conduct was the cause of much scandal. After her husband

succeeded, in 1762, the quarrels became more frequent. Catherine was banished from the palace and constrained to live in a separate home. She had made many devoted friends and adherents by her commanding abilities, and by her attractions and her encouragement to her lovers. A conspiracy on her behalf was got up by several powerful nobles; Peter was dethroned and Catherine became Empress. Very soon after Peter was murdered, and there were many suspicions that Catherine knew of the plot to kill him.

Catherine and Potemkin. Catherine II. displayed great ability in carrying on the government, and the dominions and the power of Russia were greatly increased during her reign—increased with an utter disregard for all principles of international equity or for justice and morality. Catherine had moments of generosity and mercy, but she never shrank from cruelty where cruelty could serve her purpose. She had always some special favourite to whom for the time she entrusted the guidance of her affairs. The most notorious of these was Potemkin, a man of a noble Polish family, which, like many others, had been reduced to comparative poverty. He had a handsome person, and he entered the Russian army, where he distinguished himself, and soon attracted the attention and admiration of Catherine. She gave him the management, the government, in fact, of a large territory in the south of Russia, and De Ségur, in his "Mémoires," tells of an ingenious performance by which he secured the full confidence of the Empress.

An Elaborate Deception. Catherine announced that she was about to visit the region over which he ruled in order to see the prosperity it was attaining under his control. Potemkin, determined to make an immediate impression upon her, caused a great number of wooden houses to be constructed and arranged as separate towns and villages along the way the Empress had to traverse, and he hired a number of peasants and others to enact the part of contented and happy residents. This extraordinary piece of stage-play proved a complete success. Catherine was deceived by the imposture, and delighted with the evidence that the country was already rising in domestic prosperity, for which she hoped to have the principal credit. She conferred honours lavishly on Potemkin, and placed him at the head of the army. In the war with Turkey, in which the great victories of Bender and Ismail were won by Suwaroff, who served under him, Potemkin took all the credit, and made a triumphant entry into St. Petersburg in 1791. The favour Catherine showed to him made one of the many scandals of her reign. Potemkin was a clever man, ready and adroit, but unscrupulous and licentious. He made himself enormously rich, mainly at the public expense, and in spite of his extravagance he left an immense fortune when he died, in the October of 1791.

Success Abroad. The several partitions of Poland and its subjugation to the rule of Russia were reckoned by Catherine as among the triumphs of her reign. During her reign, also, there were wars with Turkey, which ended in another increase to the Empire, and there was a war with Sweden, which had for the time a like effect. The acquisition of the Crimea gave Russia the command of the Black Sea. Catherine professed the most advanced ideas and the fullest sympathy with the rights of the peasant class and the poor; but her rule was one peculiarly oppressive to those classes, for the power of the landlords over their serfs was greatly increased, and serfdom was restored in some territories where it had been abolished. She was a woman of great ability, and had literary gifts which might have won for her a more honourable renown than she acquired as an Empress. The impression made on students of Catherine's reign is that she was, all through it, playing the part of an Empress, according to her ideas, and thought only of captivating, on the Imperial stage, the vast audience who followed her movements with ever quickening wonder and admiration. Her memoirs are full of interest, and must hold the attention of every reader, but may shock many by their freedom of opinion and expression. Catherine died of apoplexy on November 17th, 1796. She had been much admired by many brilliant French writers and diplomatists, whom she did her best to attract to her Court and to keep around her. She was one of the ablest women who ever sat upon a throne, but it would be hard to decide whether Russia was the better or the worse for her life and her reign.

Catherine's Successor. Catherine was succeeded by her son Paul I. His reign though short, did much harm to the condition of the people. Paul's foreign policy was capricious; he restored to the condition of serfdom some of those who had before been made crown peasants; set up a severe censorship of the Press; prohibited the introduction of any published matter from foreign countries, and made the organisation of the secret police more effective than ever. There can be little doubt that the mind of Paul was unsound, and that many of his acts were to be ascribed to disordered intellect. He became so odious to many of those around him that a palace conspiracy was got up to compel him to abdicate, and when Paul resisted, a struggle took place, in which he was killed, on March 24th, 1801.

Paul was succeeded by his eldest son, Alexander I., the progress of whose reign brought him into prominent association with some of the greatest events in modern history. When he came to the throne all Europe was becoming disturbed by the French Revolution, and the history of Europe became for many years only the record of that Revolution's workings.

GARDENING
1

Following BEE-KEEPING from page 5203

By HARRY H. HAVART

BETWEEN the wide expanse of pasture land which it is proposed to transform into a market garden, or beautify as an adjunct to a mansion, and the tiny plot of the suburban house, covered with builders' debris and overrun with weeds, there does not, at first sight, appear to be much connection. Yet, vast as the science of horticulture is, the same principles can be applied, with certain modifications, to the garden of the millionaire and to the tiny pot-plant struggling for life on the window-sill of a city slum.

It may appear superfluous to remark that anybody who desires to attain a knowledge of gardening must begin at the beginning, but there is a reason for saying so. Buying plants from a nursery in the springtime and putting them in the ground is not gardening, any more than paying a man to do all the hard work is, and, therefore, to acquire proficiency in horticulture, a novice must go right "back to the land" in its original condition.

The First Step in Gardening. The first step to be taken is to find out the nature of the soil one has to deal with. The chief constituents of all earth are one or more of the following substances in various proportions—clay, sand, gravel, lime, and decayed vegetable matter. Take a spade and turn over a few spits (a spit is a layer of earth the depth of a spade's blade) of the soil on the land or garden it is proposed to cultivate. Dig down to some little depth, as the character of the soil often varies somewhat two or three feet below the surface.

Now examine a spadeful of the earth. If it be thick and "stodgy" with clay, it is what is called a heavy soil, and will need a good deal of improving. If it contain a fair amount of sand mixed with clay, so that it is not sticky and sodden, it is a natural loam, the most precious of all soils to the gardener. Should there be so much sand, however, as to make it dusty and crumbly, it is known as a light soil, and wants careful handling. Where a large amount of chalk enters into the composition of the ground, as in many parts of Kent, and on the Surrey hills, the soil is called a calcareous one, and in its natural state is specially suited for the culture of many sorts of vegetables. The richest of all soils, though not the most useful for general purposes, is peat. This may be distinguished by its very dark colour, and the presence of decayed vegetable matter. It is met with most frequently in damp situations, and really represents the first stage in the transformation of vegetable matter into carbonaceous matter.

Draining and Levelling. When once the nature of the soil is known, it must be drained and levelled if the area is of considerable extent. Town and suburban gardens are, of course, already drained, and are generally of such limited area that they require no levelling. A simple and effectual way of draining is to dig a series of narrow trenches, six yards apart, from the highest points of the ground to the lowest, laying at the bottom of these trenches, which should be 3 ft. or 4 ft. deep, so as not to interfere with the roots of plants, a row of common earthenware pipes 3 in. in diameter. These must communicate with a larger, or main, drain pipe, which empties itself into a pond or stream, if one exists, or, if not, forms the nucleus of a pool, which, by this easy and natural process, becomes an admirable site for the water garden.

It is not necessary to give much attention to levelling a garden. The need for it is non-existent in the small suburban garden, and, as far as the market garden is concerned, levelling is a waste of money and time, except when sites for rows of glasshouses have to be prepared. For this purpose, however, and also for the formal part of the garden near the mansion, and in the preparation of tennis lawns, bowling greens, and other flat ground, some levelling must be done.

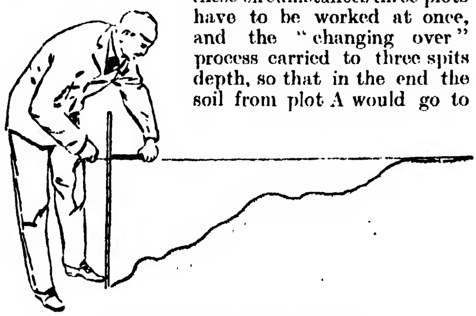
How to Level the Garden. This can be accomplished by very simple means. A peg, a length of cord, a stick marked with feet and inches, and a spirit-level are all the implements that are required. At what is judged to be the highest point of the ground to be levelled, a peg, with the cord attached to it, must be driven in. From thence the cord must be extended over the whole area until the lowest point is found. This is done by sliding the loose end of the cord up and down the measured stick at various points [1] until, by means of the spirit-level, the difference between the highest and lowest points of the ground is discovered. For the sake of illustration, suppose this to be 4 ft. Therefore it is necessary, in order to establish a common level, to throw 2 ft. of the soil from the highest part of the land on to the lowest part.

In practice more than this must be done, and the low parts to be filled should be built up to at least 6 in. higher than the spots from which the earth is taken to allow for subsidence, and also for compression when the roller is applied.

Digging and Trenching. The question of removal of soil brings us to the all-important subjects of digging and trenching. Digging is, of course, the simple act of turning over earth with a spade, but trenching is a term which the novice will need to have explained to him. Perhaps the definition given by J. C. Loudon, one of the greatest authorities upon gardening, is the simplest: "Trenching is a mode of pulverising and mixing the soil, or of pulverising and changing its surface, to a greater depth than can be done by the spade alone." This changing about of the soil in a garden is necessary for the purposes of aerating and sweetening it, as earth which is left too long undisturbed is apt to get foul and stagnant.

The simplest form of trenching is what is known as two-spit, or bastard trenching. Let us call two parts of the garden A and B. First the top spit and then the second spit of A are removed to a neutral spot, and the same is done with B, keeping the respective spits separate. Then the top spit of B is placed where the second

spit of A was, and the second spit of B put on top of it, while the top spit of A is placed at the bottom of plot B, and covered with the bottom spit A. In other words, the soil in the two plots A and B is taken up, turned upside-down, and made to change places [2]. For many gardens, especially suburban ones, where, as a rule, the soil is shallow and rests on a solid bed of clay, this form of trenching is sufficient, but where the soil is deep the operation of trenching is more complicated. In these circumstances three plots have to be worked at once, and the "changing over" process carried to three spits depth, so that in the end the soil from plot A would go to



1. LEVELLING THE GROUND

C, from B to A and from C to B, but inverted, so that what was once the top spit of A would be the bottom spit of C, and so on.

The Nature of the Soil. During the process of trenching, which may well be carried out while levelling is going on, much improvement can be effected upon bad soils. One remedy for a bad soil is to have the whole of it carted away to the depth of about 3 ft., and replaced with good rich loam from a nursery. This is, no doubt, a splendid method to adopt where expense is no object, but it is impossible in the ordinary market or private garden. These, as a rule, have too much clay in them.

The drawback to a heavy clay soil is that, being impermeable, it will not allow the rain to pass away, and, as a consequence, gets very sour. It is obvious, therefore, that anything which will tend to lighten or break up this heavy clay will be of advantage. This being the case, the autumn is the best time to commence the formation of a garden. The ground should be trenched as already described, and left as open as possible. Then, when the winter frosts come, the water which the clay contains will freeze, expand, and to some extent force the particles apart to admit air, and thus the soil will become somewhat more open and workable by the time the springtime arrives.

Manure. In these early stages the only manure, if any, which should be applied is a layer of horse manure, with plenty of straw. This should be placed at the bottom of the trenches—that is, after the earth has been dug out, and before it is replaced. Though this does little to lighten the soil, it increases its fertility to some extent.

Before beginning digging operations it will probably be found necessary to clear the ground of weeds and long grass. None of this refuse should be thrown away or wasted, but carefully stored and thoroughly burned, and the ashes dug into the ground. This process should be repeated at intervals with anything in the shape of rubbish that is capable of being burned. It is well, however, to change the situation of the bonfire each time, as even the heat and the action of the flames on the earth are beneficial to a heavy soil.

Road sweepings, with the grit they contain, to say nothing of the minute particles of horse manure, are of great value under similar circumstances, and although it is difficult to say whether it is legitimate to remove them from the side of the road before the scavengers come along, it is an easy matter to negotiate for a load or two.

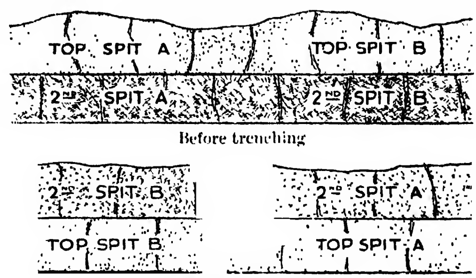
It is not sufficient merely to deposit the ashes, grit, and other lightening materials upon the ground. They must be dug over well and constantly until they and the soil are thoroughly well mixed up, as otherwise no beneficial results will be obtained.

Improving the Soil. By dint of patient and constant work it is thus quite possible to turn what was once regarded as a hopeless mass of clay into a fairly open, if somewhat heavy soil, while the presence of clay underneath at a depth of from 2 ft. to 3 ft., according to the distance trenched, is an advantage rather than otherwise, as it retains the moisture during the hot summer months, and so enables the roots of the plants to keep cool and prevents them being parched.

Improving a soil which is too light or sandy is not such an easy matter as improving a heavy one. The process may, of course, be reversed, and some clay introduced to thicken the ground, but the mixture rarely proves to be a satisfactory one. To make the best of a very light soil, it is necessary to trench it very deeply and openly before planting in the spring. This has two beneficial results. As the soil is thus rendered loose, the roots of plants can easily penetrate to a great depth in order to get at the moisture which is so necessary for their welfare; while, on the other hand, this treatment allows the rays of the sun to penetrate the ground freely, and so draw the moisture towards the surface.

When once the operation of trenching has been carried out, it is better to temporarily discard the spade for the garden fork in turning over the soil. Lumps of clay can be broken up more finely with a fork than with a spade, in addition to which the operation is not so fatiguing to the worker.

Foreign Elements in the Soil. In the course of these digging and forking operations, many large stones are sure to be met with. These should all be removed and set aside, as they have a use in the garden. If it is not proposed to form a pool for



2. TWO-SPIT TRENCHING

the culture of water-plants, these stones should be buried very deeply at the lowest point of the garden, where they will form a sort of rough drain and render great service in helping to carry away superfluous moisture from the garden.

Occasionally it happens in the course of digging that what appears to be a reddish-brown "vein" is struck. If this occurs, immediate action should be taken, as it indicates the presence of iron in the soil. Now, iron in a soil has a great tendency to render it

unproductive, so that prompt treatment is necessary, and a dressing of lime should be dug into the affected part. The iron is invariably in the soil in the form of an impure sulphate, and the lime combines with the sulphuric acid in the iron sulphate, and forms sulphate of calcium, thus sweetening the soil and eliminating the dangerous compounds.

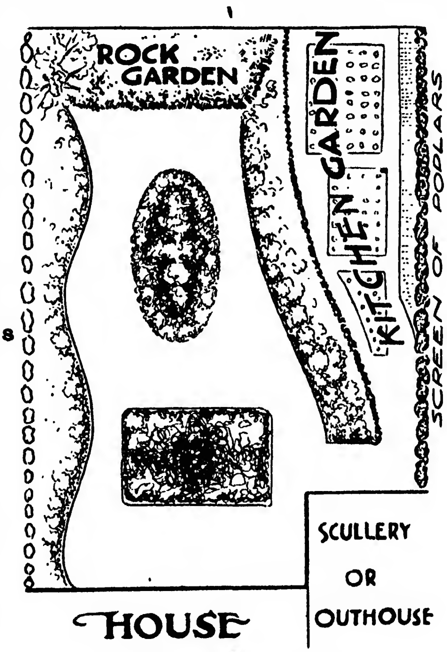
Magnesia, manganese, sulphur, phosphorus, soda, and chlorine are all found in varying proportions in soils of different natures. Where they do not occur naturally, and are required for the welfare of one plant or another, they must be supplied by artificial means, and this is the fundamental principle of chemical manuring, of which more will be said.

LAYING OUT THE GARDEN

Before beginning to lay out a garden it is obviously necessary to decide what sort of a garden is required. There is the garden for pleasure only, which is a flower garden pure and simple; the garden for profit—as distinguished from a market garden—the owner of which has merely an eye to the abolition of greengrocers' and fruiterers' bills; and the general purpose garden, which is a combination of the two, and is the garden usually met with, as well as the most useful.

The majority of very small town and suburban gardens are unsuited for the culture of fruit and vegetables, with the exception of a few kinds, and must, perforce, be gardens fo· pleasure only; but there is no spot, however barren and smoke-ridden it may be, which will not lend itself to gardening of some sort. The roof of the old Southwark Police Court, situated in one of the dirtiest and dingiest parts of London, was turned into a beautiful little garden by the gaoler attached to the place, who had as many as twenty or thirty different sorts of plants growing there at one time. How to deal with very small gardens, however, cannot be considered in this article.

The Aspect of the Garden. The very first thing that should be done with a piece of ground which has been levelled for gardening purposes is to determine its position with regard to the points of the compass. An ideal garden of moderate dimensions is oblong in shape, with the long sides facing north and south, while the house is at, and facing, the east end of the plot. In such a position the building protects the contents of the garden to a considerable extent from the cutting east winds, while there is a good expanse of south wall for the culture of fruit. Many a fruit-tree or half-hardy plant, which would die of exposure in any other situation, will thrive on a south wall, or in the border at its foot. Moreove-, a south wall gets the benefit of the sun for the whole of the day, in summer and winter, and is its own protection from north win?s. The terms south, north, and so on, when applied to walls in gardens, do not mean that they are situated in that particular part of the ground, but that they have a southern or northern aspect, as the case may be.



3. PLAN OF A SMALL GARDEN
Showing kitchen garden and screen of poplars

The novice visiting a garden of any pretensions for the first time frequently wonders why it is situated at one side of the house instead of at the back. It is just this question of exposure to sun and winds from different quarters that has provided the reason, and the same rule holds as good for the 12-ft. patch as for the nobleman's broad acres. The worst position of all for a garden is one in which the house faces west or south-west, as the garden has practically no shelter from the icy blasts from east and north. In laying out such a garden, therefore, plants of the most hardy nature must be chosen.

One of the first questions which will enter the would-be gardener's mind, as he stands at a back window and contemplates the waste which he is to make fertile, is: "How much of this ought I to devote to fruit and vegetables, and how much to flowers?"

A great deal depends upon local conditions. If the district is one well furnished with markets in which fruit and vegetables are procurable at reasonable rates, it is better to devote the bulk of the space to floriculture, reserving a little for the choicer products of the kitchen garden. If, on the other hand, vegetable produce is dear, and, as is often the case in country districts, consists chiefly of inferior local varieties, it is wise to make the kitchen garden at least half of the total area. This remark applies to gardens from which it is hoped to derive both pleasure and profit.

The Kitchen Garden. Having decided what proportion of the ground to be laid out is to be devoted to kitchen garden purposes, the next step is to mark it off nd divide it from the flower garden. Useful though they are, vegetables grown, as they should be, in symmetrical rows, like regiments of soldiers, are not a particularly alluring prospect in a garden landscape, and it is usual to separate this portion of the garden from the pleasaunce by a hedge of some description—a subject to be dealt with later.

In the smaller gardens it is usual to find the kitchen garden consisting of a corner lopped off indiscriminately from whatever part of the ground happens to be situated at the farthest point from the house, irrespective of situation or aspect. This is a mistake. The question of aspect is just as important for the successful culture of fruit and vegetables as of flowers, and, speaking as a general rule, with the orthodox oblong garden the vegetable portion will best repay attention if it is formed of a strip running parallel with the flower garden for practically the whole length of the ground. It may

be stopped within a few yards of the house or eased off into nothingness, so as to give the broadest expanse of bed or lawn near the house [3].

If a very large garden is in course of preparation the kitchen garden is, of course, a thing apart, and is kept away from the flower garden altogether. In these cases a position on a southern or western slope is usually assigned to it if such be available, but the laying out of places of such dimensions is not usually entrusted to an ordinary head gardener. A specialist, known as a landscape gardener, is invariably called into requisition, and the resident gardener and staff work upon the lines which he lays down.

Improving the Aspect. Though the question of aspect is one of the utmost importance, a good deal may be done to improve a bad situation. Where a garden is swept by east or north winds, a screen of trees, such as poplars, will assist matters materially. Certainly, unless large-sized trees are obtained in the first place—and this is a somewhat costly business—they take some time before the benefit of their presence is felt; but when once established, the advantage they offer is permanent. It should always be borne in mind, however, that on no account should a screen of trees be placed close to a house. In the first place, if the house has any pretensions at all to architectural beauty, the presence of trees, or tall-growing shrubs, in its immediate vicinity will sadly mar its dignity, while, in addition, big trees close to the house should be strongly discountenanced from a hygienic point of view. A house hemmed in by big trees is always damp, and they offer obstruction to light and air.

The Garden Walks. The question of walks and paths and where to put them is one of paramount importance in laying out a garden. At least 90 per cent. of gardens of all kinds in this country are wretchedly undersized little places, and yet the tendency is to reduce the available space in them by the introduction of needless walks, leading nowhere in particular, and serving no good purpose. It is a good plan when beginning operations to draw a rough sketch of the ground, marking upon it the different spots at which the kitchen, rock, water, and other gardens, if any, are to find a place.

Then, starting from the house, decide the simplest and quickest routes by which the different parts can be reached. Here a certain amount of discrimination is necessary. There is no need for the paths to radiate with geometrical accuracy like the spokes of a wheel from the back of the house. A graceful curve, which perhaps the presence of a tree or a rise in the ground will give a pretext for, is not only desirable, but to a small garden will give the impression of increased size. At the same time it is absurd to have a lot of serpentine walks wriggling about the place just for the purpose of conveying the idea of great length, while bisecting and trisecting lawns with walks until they look like a problem in geometry is an equally foolish proceeding.

Grass Walks. Unless a garden is of unusual dimensions, three or four main gravel walks, at the most, will be all that will be required, and, for the rest, let the turf come right up to the beds or borders, so that what would under ordinary circumstances be gravel paths are simply grass walks. There are many advantages to this system. The rich green turf forms a far more beautiful setting for a bed of flowers than a gravel path does. It is easier to keep turf in good order than it is to be continually weeding gravel, and although it is urged as a drawback that turf walks are unfit for walking upon after rain has fallen, this is only the case where they have been improperly drained. Moreover, should it be desired at any time to change the character of a garden, this can be far more easily done in a turfed place than in one where gravel walks, running at different angles, have to be taken up and altered.

Making Beds and Borders. Mention has been made of the words "bed" and "border." A bed is a piece of ground in the garden, prepared for cultivation, but which has no direct protection from a wall, fence, or hedge. A border may be best described as the long strip of earth close up against a wall or other means of protection. For instance, the strips running round the three walls of the ordinary suburban back garden would be called borders, while the circular plot in the centre, if there is one, would be a bed.

In making a bed, after having decided upon its shape, it is best either to peg the shape out upon the ground with sticks and string before commencing operations, or else plan it out in whitewash, like marking a tennis crease. This will prevent the possibility of a mistake. The simple precaution in making a border is to stretch a string taut between two pegs from end to end to ensure a correct edge, as nothing looks worse than an irregularly shaped border, unless the shape of the wall or garden demands it. If the whole garden is a new one and the ground has been treated on the lines laid above, no other preparation is necessary, but where it is proposed to cut a new bed or border out of an existing garden, the ground must be well worked as advised before planting.

The Front Garden. What to do with the front garden is a great source of perplexity to town gardeners, for it is only near the busy centres that the front garden proper finds a place. Most of them solve the problem by planting laurels and privets, a method which, if it has the merit of simplicity, is certainly not the best possible solution.

Though many flowers might be grown in such situations, particulars of which will be given in due course, there is always the danger of their being stolen; but a much wider range of trees and shrubs is available for town use, which have the advantage, moreover, of not being so greedy or exhausting to the soil as the laurel and privet. Of these, some are evergreen, and include rhododendrons, yuccas, azaleas, aucubas, hollies, and euonymus; while those that are deciduous (lose their leaves in winter) comprise weigela, ailantus, cotoneaster, philadelphus, mountain ash, sumach, elder, ash, plane, elm, and others of our native forest trees. Collections of some of the different sorts of ivies, too, will be found very useful in helping to beautify the town and suburban front gardens.

Simplicity should be the keynote of front gardening, and the idea of putting a monkey puzzle opposite the front door and surrounding it at a respectful distance with standard rose-trees is dying out, even as the rhododendron is beginning to oust the laurel from pride of place as a necessary adjunct to such arrangements.

THE WHOLESALE TRADE

Opportunities for Wholesale Trading. System in the Wholesale Trade. Commercial Travellers. Commercial Careers in the Colonies

FOR many business men the wholesale trade holds out inducements which retail shopkeeping cannot offer. The wider field of operation and the relative magnitude of individual operations are greater in the wholesale trade. For the employe the work is usually more agreeable, the hours shorter, and salaries quite as good, while there are prize posts, such as those of buyers, managers, and commercial travellers, which the retail trade cannot offer in the same proportion, so that promotion is more probable to a good man. But in the wholesale trade it is more difficult to establish oneself in business. The capital required is larger, and the skill in buying and selling is greater. Profits also are much lower, and in these days, when competition is keen to the point of warfare, special ability is required to organise and maintain a wholesale business at a high standard of efficiency. The increased tendency of manufacturers to sell direct to retailers militates against wholesalers. Few manufacturers refuse to give wholesalers better terms than they allow to retailers, but the difference between wholesale prices and retail prices frequently falls far short of a working profit. Hence the manufacturer who goes direct to the retail trade can usually cut out the wholesale merchant. In many trades this tendency to dispense with the services of the middleman, who was formerly the sole medium through whom the retailer did business with the manufacturer, is most pronounced, and the risk of embarking capital in such a wholesale trade is very great.

Opportunities for Wholesale Trade. The most promising fields for wholesale trading are in those departments of trade where the retailer cannot to a large extent purchase from the individual manufacturers on account of the small consignments which such a policy would demand. Thus the drug trade, many departments of the drapery trades, and the grocery trade offer far better prospects for wholesale ventures than, say, the glass and china trades and the boot and shoe trades. It may be agreed that where variety in stock is limited, and where, therefore, purchases of individual "lines" are fairly large, the wholesaler will have a hard fight to show reasonable profits, and this difficulty is likely to become accentuated.

The most promising centre for a wholesale trade to be run on as small a capital as possible is in the district where the goods to be sold are manufactured. Of recent years manufacturers have been given to hold their goods in stock ready for delivery. The wholesaler gets to know the manufacturers who pursue this policy, and he draws upon manufacturers' stocks as occasion calls, thus avoiding unnecessary stockholding in his own premises. The advantages of this system, from the wholesaler's point of view, are many and obvious. He does not spend money before he must—and, indeed, he may receive payment for much of his purchases before he is called upon to pay for them. Also, if capital be at command, the wholesaler close to the manufacturer is likely to have opportunities of purchasing below usual prices under special circumstances, and this is a prospect denied to the competitor whose headquarters are removed from the manufacturing centre. There may be occasions, however, when a good provincial centre with many villages within its commercial sphere may offer greater promise to a wholesaler. Under such circumstances stocks must be greater, as those of the manufacturer cannot be drawn upon at so short notice, but the proximity to the selling field gives the opportunity of closer relationship with customers, and enables the wholesaler to watch his trade more closely. These are the general considerations that enter into the question of location, and they may be applied to any special case that may arise.

System in Wholesale Trade. The wholesaler, more than the retailer, has need of system in his business. His success is dependent upon a perfect system to a greater extent than is that of his humbler confrère. The consumer must usually purchase in the district where he resides, so that the retailer, or the body of retailers in a locality, has a sort of monopoly; but the retailer is not restricted in this fashion, so that the wholesaler must justify himself by quality and service. Hence the more imperative demand for absolute system in the wholesale trade. The article on system for retailers [page 6056] and the articles on business management, which appear subsequently, may be studied by the wholesale merchant with advantage. The old system of selling at as high a price as possible and of accepting as low a price as compulsion demands is out of date. To accept certain prices merely because others do so is concentrated folly. Such a business system, or lack of business system, takes no account of working expenses, and the only sound business selling practice is where every individual transaction is made to stand upon its own legs, and to yield its due share of the margin necessary to pay general expenses and a little besides. Some years ago an important association of factors in one of the chief English trading centres decided that every one of their members should make a careful calculation to find out the relation of working expenses to turnover. Nearly every member was surprised at the result. The percentage ranged from 9 per cent. to 12 per cent., and the discovery caused much heart searching and mending of procedure.

"Cash with Order" Business. The most recent development in wholesale trading, and one which promises to expand, runs exclusively upon "cash with order" lines. The drug trade is an instance where this new development has manifested itself, and much perturbation has been caused in the ranks of the older houses of the competition of a firm who restrict their dealings to a limited number of articles of everyday demand, which they sell largely in original packages at very low prices, and only upon "cash with order" terms. The heavy expenses entailed by breaking bulk, by bookkeeping, and by giving credit, are obviated, and although the prices accepted are low, they are remunerative, and success seems to be attending the new system. This method has attractions for a good buyer with limited capital, but it must be confined to articles in everyday demand and of recognised standard quality.

District Agencies. All merchants, both wholesale and retail, desire to control the sale of specialities and proprietary articles in the districts where they operate. Sole sale usually means easy sale if the article is in public demand, and as a monopoly exists, there is no scrambling for the business. It is exceedingly hard to secure the sole agency for an article with an established sale. The makers would usually be unwise in their own interests if they were to restrict their trading to one middleman. The only way in which a district agency can be made profitable is by working up the sale in an unknown or little-known speciality. Hard pushing and judicious advertising may often dethrone an unremunerative but established proprietary article from popular favour, and there is then much profit for the house that has worked the substitute into popularity. The difficulty is to know what article can be pushed to success, and made to maintain success. There is on the part of proprietors of specialities a disinclination to grant sole agencies, and this is largely due to the fact that wholesalers seldom do such agencies justice. Knowing they have the field to themselves, they do not trouble to push sales energetically, and substitutes are sought and pushed by competing houses.

Retail Shops Owned by Wholesalers. Many shops doing only a retail trade are, in fact, owned by wholesale houses. Sometimes wholesalers, with more cash at command than they can profitably invest in their proper business, encourage the establishment of the retail shops, which become "tied" houses. The name on the fascia gives no clue to the identity of the actual owners. Sometimes, again, the wholesalers have the honour thrust upon them. One of their retail customers may become in their debt, and be unable to redeem himself. To save themselves, they take over the business and hold it permanently, or only so long as they must. They may decide to sell it or to place in it a man whom they believe capable of making it pay, with or without the option of buying out their proprietary interest. Such cases are often the opportunity of the good man without much capital but with ability and application. The advantage of retail shops owned by wholesalers is that they form a certain outlet for wholesale trading. Even if the retail shop, as such, should show no profit beyond bare expenses, the wholesale profits on the goods supplied to it may make it worth holding, and may make retail shops a wise business policy on the part of wholesalers. To cultivate such a trade requires a good deal of capital, and it should never be carried on with borrowed capital. The general management of such shops is similar to those of multiple or branch shops, which they really are, and these have already been discussed on page 5929.

Maintained Prices. Several business problems of recent development confront the wholesale merchant as well as the retailer. One of these is the question of maintained prices. Combination among retailers has caused many manufacturers to give adhesion to a scheme whereby selling prices may not be below a certain minimum, which is fixed so as to yield a reasonable profit to those handling the goods. Price maintenance affects the retailer more than the wholesaler because not all articles regarding which retailing restrictions prevail are price-maintained between wholesaler and retailer. But the wholesaler must understand clearly his liability in the matter. Where the manufacturer sells goods upon the condition that the wholesaler may sell them not below a certain minimum—and even when notification of this condition of sale is made only upon the invoice for the goods—the wholesaler is bound by such a condition if he accepts delivery of the goods, and liable to injunction and damages in the event of breach of the condition.

Trade Marks. In many trades, trade marks may be made important commercial assets. To make a trade mark valuable is to be able to secure for the article carrying it a greater profit than would otherwise accrue. Trade marks are not the peculiar property of manufacturers. Any middleman can, and many middlemen do, own valuable trade marks, which make them to some extent independent of specific manufacturers. If a wholesale merchant establish trade in an article carrying a trade mark which is his property, and if he be dissatisfied with the manufacturer who has been making the article for him, he can change his manufacturer, continuing to use the trade mark as before. If the trade mark were not his property, and if he had occasion to give up one manufacturer, he would require to take up something with a different trade mark—practically to introduce a new article to his customers—and any competing house could then make profit by taking up the manufacturer and the trade mark which he had discarded.

It is usual to apply for registration of a trade mark through an agent—commonly a patent agent —familiar with procedure. The agent's fee, including official stamps, is usually about £3. The official stamps come to half the sum named—to wit, 30s., being 10s. upon the application form, and 20s. upon registration. There are other fees payable only in certain cases—such as opposition to registration by another party. The necessary forms for making application for trade-mark registration may be had at any money order office in the United Kingdom. A pamphlet, "Instructions to Persons Who Wish to Register Trade Marks," may be had free on application to the Comptroller, The Patent Office, Trade Marks Branch, 25, Southampton Buildings, Chancery Lane, London, W.C.

Packing and Packages. In these days other considerations besides price and quality decide the placing of an order. One of the most important of the other points is the method of packing and the treatment of packages. Why do many people in this, as in other countries, prefer to sell Continental cups, saucers, and tumblers, for instance? Because the English articles are sent loose in boxes, casks, or crates, while the foreign articles are neatly wrapped in packages each containing half a dozen of one article, and because the packages can be neatly stowed on shelves, whereas the loose English style demands storing in tins or baskets. Again, why are American files and other tools sold as they are in this and other countries, where formerly the British article were the only kind found? Simply on account of American methods of packing. Instances might be multiplied, but these are enough. Whatever be the variety of merchandise under consideration the seller who can provide the buyer with the goods in a form to give him less trouble than is caused by competing goods offers a substantial inducement that is never lightly disregarded.

And so with packages. Many makers and merchants charge exhorbitant prices for packages so as to ensure their return. Wise men have, where possible, introduced the system of free packages, charging the expense of these against the general working expenses. We have never known a firm who adopted this system return to the old-fashioned method, which is surely the best evidence of its

practical value. The mere saving of trouble and expense of keeping record of the packing cases, or charging them and crediting them, is itself a saving and may be set off against the loss of their cost.

Invoices and Accounts. The conditions of payment should always be made clear upon all contracts of sale invoices and accounts. To leave the point uncertain is to leave the door open for disputes, upon which the lawyers grow fat. It has been held in law that the statement "five per cent. charged upon overdue accounts" gives the creditor the right to enforce such interest. It has the tendency to make debtors pay accounts when due so as to avoid the threatened penalty or the risk of its enforcement. It is usually wise on the part of the creditor not to insist upon such interest except in extreme cases, but to refrain from claiming it is an act of forbearance on his part dictated by considerations of policy in his desire not to alienate good though slow customers. When commercial travellers are not authorised to collect accounts a statement to that effect ought to appear prominently upon *all* invoices and account forms. Unless it can be proved that the debtor has had notice that accounts may not be paid to travellers, the creditor cannot fall back upon the debtor in the event of misappropriation by the traveller; but if due notice has been given to the debtor, he pays money to the traveller at his own peril and assumes responsibility for such money reaching the hands of the creditor.

Advertising for Wholesalers. Advertising by wholesalers must be on entirely different lines from retail advertising. The retail trade is exceeding jealous of any appearance of direct trading, and a wholesaler who advertises to the consumer lays himself open to the charge that he is seeking direct trade, even though he seeks publicity for proprietary goods which he intends to distribute through the retail trade only. Thus his advertising desires must be restricted to certain defined channels. The trade papers appealing to the retailers whom he seeks as customers are the most obvious agencies of publicity he can cultivate, but they have this objection—that if the wholesaler's field of trading is limited to one section of the country, the larger proportion of the money spent in them must fall on barren ground, as they have a very wide circulation. These considerations restrict the wholesaler's advertising to circulars and catalogues. His office should contain a card index with the names of all actual and potential buyers in his district, and he should circularise them periodically and persistently. He should especially draw their attention to all novelties and seasonable goods which he wishes to sell. Every circular should be illustrated, where possible, and retailing prices should be given, so that the retailer may show them to his customers if he wish. Catalogues should be issued periodically. These also should show retail prices, for the reason already given. The catalogues should be comprehensive, of convenient size, and well illustrated on good paper. Large-paper sheets should be avoided. They usually defeat their object, as the inconvenience of consulting them causes them to be rejected for catalogues in book form. The catalogue should be expansive if novelties are of frequent introduction, so that supplementary sections or leaves may be sent. All catalogues issued by one house should be of the same size. It is objectionable, from the user's point of view, when diversity of size and form are evidenced in several catalogues issued by one house. Anything that conduces to lessen the labour of the retailer is appreciated, and the wholesaler can do a good deal in that direction, the form of his catalogues and price lists being one.

In many trades periodical price lists—say, weekly or monthly—are advisable. Trades in which prices fluctuate a good deal—such as the provision and fruit trades—and where the nature of the sales changes with the season, are well cultivated by means of these. The objection urged against such price lists is usually that they merely afford a standard below which opposing firms cut prices. There is something in the objection, and in some trades the weekly or monthly price is not looked upon as giving the final price. Even those whose names appear on them do not adhere to the prices. This has come to be a recognised practice, so that while the value of the price list may be thereby decreased, it is not abolished. The periodical list forms a guide to the retailer. He recognises that he can buy at not more than the figures it gives, and in sending an order by post he is more likely to favour the firm whose name is on the price list before him than any other house.

The Commercial Traveller. When there is little chance that a young man will ever command the necessary capital to set up business for himself in the department of shopkeeping in which he has been trained, perhaps the best career he can seek is that of a commercial traveller. The life is interesting and pleasant. The moving about from place to place lends variety to the everyday work which is lacking in ordinary routine counter or office duties.

Commercial travellers should begin young, as the only school that turns out good commercial travellers is experience of the road. Commercial travellers usually graduate by promotion from the warehouse or desk in the manufacturing or wholesale establishment where they have been employed. Perhaps the best commercial travellers are those who have been schooled behind the retail counter. The experience gained there enables them to understand better or more quickly the retailers upon whom it is their business to call. The youth who in a small retail or mixed business is sent on the road to take a few "journeys" is launched on a career to which he will probably adhere throughout his active life. Even if he should elect to be an employer one day, he will probably be in a better position to do so than he would be if he had been behind a counter during the years he has spent on the road. He has more opportunity to save money as a commercial traveller than he would have as a shop assistant. Also the knowledge he can gain on the markets is greater than would be possible even as a buyer. He learns who are his competitors, gets to know what houses can do certain classes of goods better than his own, and becomes acquainted with the best terms obtainable—all of which knowledge stands him in excellent stead if he should at any time retire from the road and put up his sign.

Promotion to a Partnership. Partnerships are more often secured by travellers than by indoor assistants. The traveller possesses in himself a goodwill which makes him a desirable partner because the personal relations which have been established between the good commercial traveller and the members of the trade upon whom he had been wont to call enable him to take to any competing house to whom he way decide to transfer his services a considerable share of the trade which he has been in the habit of doing. It is for this reason that in the majority of the advertisements inviting

applications for the post of commercial traveller the stipulation is made that candidates "must have a good connection," a state of things which demonstrates the strength of the commercial traveller's position in the ranks of the mercantile army.

Qualifications for Commercial Travellers. The first essential for the commercial traveller is a thorough knowledge of the goods he sells. The statement is not superfluous. Many men sent on the road—and perhaps this applies more to the sons of principals—have a somewhat distant acquaintance with the articles whose merits they are sent forth to laud. It is frequently stated that the phenomenal success of many American travellers is due not to mere push or "bounce," but to intimate knowledge of the merchandise they offer. There is a good deal of truth in this supposition. We know of one large American firm who adopt a unique system of keeping their travellers up to date in knowledge of their trade. Over one hundred travellers are employed, and the business is a very large one, divided into many departments, yet the commercial travellers are noted for their wide acquaintance with all the numerous departments. Once a year the buyers spend a fortnight at the head office. They assemble for a good many hours daily and listen to lectures by the buyers of the different departments upon changes in the trade, novelties introduced, and other matters pertaining to their work on the road. Questions are asked, and samples handled, and the army of men goes forth equipped for another campaign upon the road.

The calling of a commercial traveller would be an excellent training for a diplomat. The traveller must be diplomatic to a degree, a walking embodiment of urbanity and persistence. He must be alert to take advantage of any opening to secure the interest of the prospective buyer, diplomatic in bringing him to the point of purchasing, and prompt in securing a firm order when assent has been obtained. No class of men are so subject to being snubbed, especially when their calls have to be made upon retailers, for these are often given to considering the traveller a nuisance, and many of them are not slow in expressing their opinions to the objects of them. The excessive number of commercial men on the road means that the individual retailer cannot do business with more than a fraction of them, and this gives the born diplomat his chance of gaining a point of vantage. A good presence is necessary to the commercial, a pleasant manner, and courtesy in spite of all rebuffs.

Salaries. The salaries of commercial travellers are as varied as the goods they sell, and nothing of much value to the individual case can be stated about their earnings. Young men claiming the dignity of commercial travellers to a small provincial establishment may earn not more than 20s. a week, whereas the important representative of a good house may earn many hundreds a year, and may possibly write his income in four figures. The average commercial traveller lies well between these two extremes. Those who earn less than £150 a year are in the lower ranks of the army of the road, and if they have ability should have not much difficulty in reaching and passing that modest figure, while those who earn over £400 a year are among the fortunate few, and the average man can seldom reach so high.

The extent to which the commercial traveller may charge personal expenses ought to be clearly defined. When the ground covered enables him to return home every evening, it is, of course, a matter of charging only his meals, train fares, and other methods of conveyance. Even then he ought to have a fixed allowance per day—say, half a crown plus fares. If he spend more, that is his personal concern, and if he spend less he should be allowed to pocket the difference. Such an arrangement obviates any inquiry into the disbursement of stray halfpence—an inquiry which is often considered by the commercial traveller to insinuate suspicion regarding his integrity and is, in any case, not in accordance with the dignified confidence with which he should be regarded by his principals. When the traveller is away on his journeys for days, weeks, or even months at a time, the same system ought to be followed—a daily allowance for personal expenses plus railway fares, or a larger allowance including railway fares. The scale of such an allowance must be decided by the nature of the work, by the necessity of carrying samples, of hiring conveyances for these samples, and of the need for stock-rooms at hotels. When many cases of samples have to be taken a frequent allowance is 20s. per day plus or including railway fares. One great advantage of a fixed allowance for a commercial traveller is that it discourages him to treat his customers, whereas a wider discretion may encourage him in this practice, which, on both the traveller's own account and on that of his firm, is by all means to be discouraged.

Working on Salary and Commission. We have considered merely the salaried commercial traveller. There is the commercial traveller, also, who works upon a commission basis. Sometimes the traveller may receive a salary plus commission, in which event the salary is, of course, smaller than it would be in the other event. This is an excellent arrangement for both parties provided the rules which are to decide the commission are clearly defined. The man has his salary for work done and his commission for the results of that work. He has a personal incentive to hard work, much stronger than he would have upon a salary basis only. But in such a case it should be clearly stipulated upon what business he is to receive commission. Sometimes the arrangement is that only orders actually booked by the traveller count as business done by him, and that orders sent direct from customers upon whom he calls are treated as if they had not been taken by him. Such an arrangement is scarcely fair to the knight of the road. It may cause him to urge his customers unduly when calling upon them—although some men will plead that travellers cannot do this—or he may have his customers address orders to him instead of to his employers, when delays may be caused by his absence.

The only truly satisfactory method is to treat a traveller's ground as his, and to credit him with every order coming from it whether he has taken it personally or it has been sent direct to his principals. It may be well to stipulate that business from customers upon whom he has never called should be excluded from the scope of this arrangement, as they cannot be said to have been directly influenced by him. Sometimes arrangements between principals and travellers whom commission affects stipulate that only a proportion of the commission—say half—is paid upon orders not booked by the latter personally, and in many cases such a condition is fair. Sometimes travellers carry side lines, and the trade and daily Press contain plenty of offers of side lines to travellers covering certain ground. If there be a specific or a tacit agreement that the services of the traveller are exclusively engaged by one firm, it is dishonest on his part to

accept any other commission, and, in the event of discovery, he is properly discharged. When a side line is carried by the consent of his principals, that, of course, is another matter.

Working on Commission Alone. Lastly, we consider the traveller who sells goods upon commission alone. His is often a hard fate. He usually carries a good many agencies, and when he has the ear of a customer, if the goods of one be not required, those of another may be. But there is usually a bitter fight for a connection before the commission man is able to consider himself in receipt of a livelihood. Agencies on commission go begging. The makers who offer them will not pay for the work put into opening new ground, and the rule of "no result no pay" causes the travelling commission agent to put in many hard days' work without reward. Embittered by discouragement he frequently throws up the sponge, and again the agency "on commission only" goes a-begging. Young men who think of adopting commission agency as a career we advise to be quite sure of a connection first. The only way of success without much bitter waiting and unremunerative hard work is to hold a salaried position for some time, then, knowing the ground and having a personal connection, to enter the commission field.

"Standing Treat." The highways of commercial travelling are strewn with the wrecks of men of ambition, ability, and promise who have succumbed to the temptations of the road. The rock upon which most careers have split has been that of drink. The virtue of hospitality is frequently exercised by the commercial traveller in the ordinary course of his business, and too often it has led to excessive tippling. This is not the place to preach total abstinence, but if any class of men have reason to protect themselves against the dangers of alcohol, it is that of commercial travellers. The young commercial who begins by the determination to refuse to do business which depends upon "treating," and who remains staunch in that determination, fortifies himself against the danger that has betrayed thousands of his fellows. This path once entered is not difficult to follow, but the opposite path once followed a little way can be left only with extreme difficulty. The former path also is the more remunerative. It gives evidence of a principle which commands the respect even of those who do not approve it. Fortunately, there is less occasion than formerly for urging the need of care in this respect, for the practice of "standing treat" is not nearly so general as it used to be.

Bribery. Commercial travellers know, perhaps better than any other class of the commercial community, the extent to which "greasing the palm" is practised in the struggle for business. Those who seek to fill their order books by bribery are, we believe, in the minority, but the minority is a large one. Even those who follow the practice are its slaves, not its advocates. The moral sense of most of them revolts against it, and they loathe a practice which degrades them as much as it degrades the recipients. The ironmonger's porter who takes stock of the hollow-ware that the gaps may be filled up may expect his shilling; the engineer in charge of a manufacturing plant may be restrained from complaining of the belting and lubricating oil when the traveller leaves half a crown behind him at every visit; and the buyer may even look for a commission upon his purchases. In every case the acceptance of bribes of this nature is a betrayal of trust, and from our condemnation we do not exclude the case of the buyer who is the recipient of boxes of cigars, turkeys, and cases of whisky as the Christmas festival draws near. There is an accepted opinion that the acceptance of presents in kind is not degrading, but this opinion is a very wrong one. The object of the giver, whether the bribe be money or money's worth, is the same, and no servant with a keen sense of independence and a true feeling of self-respect will accept any gift from any individual or firm to whom he is in a position to give orders or for whom he can influence orders from his employers.

Prevention of Corruption Act. The law has now strengthened the hands of those who are fighting against commercial bribery. The Prevention of Corruption Act (1906) came into force on January 1st of this year (1907). It is specially directed against bribes given in the course of business. It has not yet had the inward meaning of its several clauses elucidated by counsel in open court, so that there is some uncertainty whether it will be comprehensive and prevent all forms of commercial bribery. Its exact scope and limitations will be known only after specific cases have been tried under its provisions, but we may briefly recapitulate its chief sections, which are as follows:

1. If any agent corruptly accepts or obtains, or agrees to accept or attempts to obtain, from any person, for himself or for any other person, any gift or consideration as an inducement or reward for doing or forbearing to do, or for having, after the passing of this Act, done, or forborne to do, any act in relation to his principal's affairs or business, or for showing or forbearing to show, favour or disfavour to any person in relation to his principal's affairs or business; or

If any person corruptly gives, or agrees to give, or offers any gift or consideration to any agent as an inducement or reward for doing or forbearing to do, or for having, after the passing of this Act, done or forborne to do, any act in relation to his principal's affairs or business, or for showing, or forbearing to show, favour or disfavour to any person in relation to his principal's affairs or business: or

If any person knowingly gives to any agent, or if any agent knowingly uses, with intent to deceive his principal, any receipt, account or other document in respect of which the principal is interested, and which contains any statement which is false or erroneous or defective in any material particular, and which, to his knowledge, is intended to mislead the principal;

He shall be guilty of misdemeanour, and shall be liable, on conviction or indictment, to imprisonment, with or without hard labour, for a term not exceeding two years, or to a fine not exceeding five hundred pounds, or to both such imprisonment and such fine, or on summary conviction to imprisonment, with or without hard labour, for a term not exceeding four months, or to a fine not exceeding fifty pounds, or to both such imprisonment and such fine.

2. For the purpose of this Act, the expression "consideration" includes valuable consideration of any kind; the expression "agent" includes any person employed by or acting for another; and the expression "principal" includes an employer.

3. A person serving under the Crown, or under any corporation, or any municipal, borough, county, or district council, or any board of guardians, is an agent within the meaning of this Act.

A traveller is always unwise who runs down the goods offered by a competing house. Let him praise his own without the undue use of superlatives, but let him beware of his speech when speaking of other firms and the merchandise they offer. Few men can criticise their competitors and their competitors' wares without displaying the personal dislike which is usually associated with rivalry.

Motor-cars for Commercials. We cannot leave the subject of commercial travellers without mentioning the greater saving of time

which many of them will be able to effect by the use of motor-cars. For city work the motor shows to little advantage. For men who take with them a wide range of samples, it is undoubtedly good, as one call may be made after another with greater speed, and more work may therefore be done in a day by its use. Also the chauffeur is more available for assisting the traveller with samples and cases, because the motor-car may stand by the kerb without the attention required when a horse is between the shafts. But the most important sphere for the commercial traveller's motor-car is in country districts with infrequent train service. We are convinced that the commercial community do not yet realise what the motor-car may mean for them in this respect, and believe that there is a rich harvest for firms who adopt it as a conveyance for commercial travellers. There are many districts where there are many villages in greater or less proximity. In the aggregate these villages are equal to a large town, but it does not pay to work them under existing conditions. The train service between them is probably poor, and they would take two days to do properly. The motor-car may make it possible to do the group easily in one day. Shopkeepers in villages are often denied the privilege of buying from samples, and instead of the numerous sample-cases opened out before town buyers, a small hand-bag and a bulky catalogue serves for the village shopkeeper. The motor may be made a travelling sample-room, and the journey will cost less than it formerly did without samples.

Commercial Careers in the Colonies. This is a fitting place for a word to those who think about tempting fortune by embarking upon a commercial career in one of the Colonies or in a foreign country. Opportunity in a rapidly expanding country with a wide future before it is much more frequent, and the prospect of success much greater, than in this overcrowded competition-ridden homeland. At the moment, Canada and the Argentine Republic are the most promising oversea fields for commercial enterprise. The growth of both our great North American colony and of the South American republic is phenomenal, and is seldom appreciated by those who have no intimate knowledge gained by personal experience of the countries. Our other great colonies—South Africa, Australia, New Zealand, and the Indian Colonies—offer opportunities also, but the first named is at present under an eclipse of depression, the second is in the throes of evolution which do not encourage commercial ventures, and progress in New Zealand and India is of the slow order that is also in evidence in our own country. But Canada and the Argentine are undoubtedly the theatres where the agencies that bring success are to-day influencing events more than in any other parts of either hemisphere.

New countries are essentially the countries for young men. There is not the weary waiting for dead men's shoes; the stress of competition is not so keen as in the old land; and when opportunity comes, its hands are heavier with material gifts. Further, the fact that so many indifferent men—often wasters and incompetents—seek these far countries in search of riches or livelihood which they have been unable to find at home magnifies the chances of success to the really competent, energetic man who matches himself against them. The cry of the commercial employers in the Colonies is, "Send us good men. We are sick of your incompetents."

No one should set up business in the Colonies or in a foreign country without having had business experience in the country. He must find employment, gain experience, and then wait a favourable chance.

Cautions for Intending Emigrants. Sometimes positions abroad may be obtained before leaving home. More often they are obtainable only by the man on the spot, and he who would have them must go to the spot. When men are engaged in this country for such situations they are often required to enter into an agreement for a term of years—usually three—and have their passage paid. This practice is less common than it was, but it still prevails. It is not a good one. The new man usually finds that, although he has taken a seemingly lucrative position. viewed from the British wage standard, the remuneration which he has agreed to accept is less than that ruling in the market whither he has gone. He is tied up for the term of engagement, and cannot therefore improve his position should opportunity offer. He is also assisting to spoil the market in his new home. The two-pounds-a-week shop assistant in England is worth £25 a month in Johannesburg, and about as much in Winnipeg. And he need not think that he will be able to save the difference. The higher price of necessaries and luxuries makes that impossible.

It is always better for the shopman emigrant, if he is a good man, to pay his own fare and begin employment upon the understanding that he can leave at reasonable notice. If he is a man of inferior quality, he will be wise, however, to engage himself for a term of years if he can, otherwise he would find himself a member of the army of the unemployed, for Colonial business men do not keep poor servants long if there is a chance to replace them.

The Commercial Traveller Abroad. For the commercial traveller going abroad there are several things to be noted before going, or learned by bitter experience upon the field. Expenses are very much higher abroad than they are in England. In many colonial and foreign countries travellers must pay an annual tax, which is sometimes as high as £25 a year. The intending traveller must find out if he will have such a burden on him. Then the districts are usually thinly populated, and railway travelling is expensive, with business centres often far apart, so that the expense of a journey has no parallel to the cost of a commercial trip at home. In South Africa, for instance, few travellers representing home firms spend less than £600 a year in personal travelling and hotel expenses, making no count of salary. With this caution, commercial travellers intending to visit foreign countries may consider well the terms of employment offered them before they undertake a mission.

In countries where a foreign language is spoken, the traveller or the shop assistant ought to know that language. If he be ignorant of it, he need not go out on the chance of finding a position. Employers would not listen to him. If he go out to a position already secure, he will be of little use until he has obtained acquaintance with the vernacular, so that he will make himself proficient with all the speed possible. For instance, in the Argentine Republic, to which we have referred, Spanish is the language required, and no one need go there without a knowledge of that language.

SHOPKEEPING *concluded; followed by* BUSINESS MANAGEMENT

BUILDING REGULATIONS

The Public Health Act and Other Acts. Model Bylaws. Dictionary of Terms in the Finishing Trades

Continued from page 6028

By A. TAYLOR ALLEN

THE Public Health Act (1875) empowers sanitary authorities to make bylaws relating to new buildings.

(*a*) With respect to the structure of walls, foundations, roofs, and chimneys of new buildings, for securing stability and the prevention of fires, and for purposes of health;

(*b*) With respect to the sufficiency of the space about buildings to secure a free circulation of air, and with respect to the ventilation of buildings;

(*c*) With respect to the drainage of buildings, to water closets, earth closets, privies, ashpits, and cesspools in connection with buildings, and to the closing of buildings or parts of buildings unfit for human habitation, and to prohibition of their use for such habitation;

(*d*) As to the giving of notices, as to the deposit of plans and sections by person intending to construct buildings; as to inspection by the sanitary authority; and as to the power of such authority to remove, alter, or pull down any work begun or done in contravention of such bylaws

In 1877 the Local Government Board drew up a "model" series of bylaws for the guidance of local authorities. Series of annotated model bylaws are published by Messrs. Knight & Company.

It must be observed that bylaws made under the Public Health Act, 1875, cannot take effect until they have been submitted to and confirmed by the Local Government Board.

The following buildings are exempt from the operation of the bylaws relating to new buildings:

(*a*) Any building in his Majesty's possession, or employed or intended to be employed for his Majesty's use or service.

(*b*) Any county or borough lunatic asylum, and any building or part of a building belonging to the council of any county, city, or borough, and used, or intended to be used, for the detention of any prisoners.

(*c*) Any gaol, house of correction, bridewell, penitentiary, or other prison, and any building occupied or intended to be occupied by any prison officer for the use of such prison and contiguous thereto.

(*d*) Any building (not being a dwelling house) belonging to any person or body of persons authorised by virtue of any Act of Parliament to navigate on or use any river, canal, dock, harbour, or basin, or to demand any tolls or dues in respect of the navigation of such river or canal, or the use of such dock, harbour, or basin, and used, or intended to be used, exclusively under the provisions of such Act of Parliament for the purposes of such river, canal, dock, harbour, or basin.

(*e*) Any building (not being a dwelling house) erected or intended to be erected in connection with any mine, and used, or intended to be used, exclusively for the working of such mine.

(*f*) Any building erected, or to be erected, according to plans previously approved by the Land Commissioners for England of the Board of Agriculture under the Improvement of Land Act, 1864, or other Act or Acts for the improvement of land.

(*g*) Any building which may not be exempt by the operation of any of the preceding clauses of this bylaw and which may be erected, or may be intended to be erected, in accordance with such plan and in such manner as may be approved or directed in pursuance of any statutory provision in that behalf by one of his Majesty's principal Secretaries of State.

(*h*) Any building erected and used, or intended to be erected and used, exclusively for the purpose of a plant-house, orchard-house, summer-house, poultry-house, or aviary which shall be wholly detached, and at a distance of 10 ft. at the least from any other building, and which shall not be heated otherwise than by hot water, and in which the fireplace (if any) shall be detached with no flues of any kind within such plant-house, orchard-house, summer-house, poultry-house, or aviary

(*i*) Any building which shall not exceed in height thirty feet as measured from the footings of the walls, and shall not exceed in extent one hundred and twenty-five thousand cubic feet, and shall not be a public building, and shall not be constructed or adapted to be used either wholly or partly for human habitation, or as a place of habitual employment, for any person in any manufacture, trade, or business, and shall be distant at least eight feet from the nearest street, and at least thirty feet from the nearest building and from the boundary of any adjoining lands or premises.

(*j*) Any building which shall exceed in height thirty feet as measured from the footings of the walls, and shall exceed in extent one hundred and twenty five thousand cubic feet and shall not be a public building, and shall not be constructed or adapted to be used either wholly or partly for human habitation, or as a place of habitual employment for any person in any manufacture, trade or business, and shall be distant at least thirty feet from the nearest street, and at least sixty feet from the nearest building and from the boundary or any adjoining lands or premises.

(*k*) Any building erected, or intended to be erected, for use solely as a temporary hospital for the reception and treatment of persons suffering from any dangerous infectious disorder.

Thickness of Walls of Public and Warehouse Buildings. "Public building" means a building used or constructed, or adapted to be used, either ordinarily or occasionally, as a church, chapel, or other place of public worship; or as a hospital, workhouse, college, school (not being merely a dwelling-house so used), theatre, public hall, public concert-room, public ball-room, public lecture-room, or public exhibition-room, or as a public place of assembly for persons admitted thereto by tickets or otherwise, or used or constructed or adapted to be used, either ordinarily or occasionally, for any other public purpose.

"Building of the warehouse class" means a warehouse, factory, manufactory, brewery, or distillery:

Height not exceeding	Length.	Thickness of wall at its base.
Ft. 25	Any length	13½ in.
25 to 30	Not exceeding 45 ft.	13½ in.
,,	Exceeding 45 ft.	18 in.
30 to 40	Not exceeding 35 ft.	13½ in.
,,	Not exceeding 45 ft.	18 in.
,,	Exceeding 45 ft.	22 in.
40 to 50	Not exceeding 30 ft.	18 in.
,,	Not exceeding 45 ft.	22 in.
,,	Exceeding 45 ft.	26 in.
50 to 60	Not exceeding 45 ft.	22 in.
,,	Exceeding 45 ft.	26 in.
60 to 70	Not exceeding 45 ft.	22 in.
,,	Exceeding 45 ft.	4½ in. extra on thicknesses specified from base to within 16 ft. of top of wall
70 to 80	Not exceeding 45 ft.	22 in.
,,	Exceeding 45 ft.	4½ in. extra on thicknesses specified from base to within 16 ft. of top of wall
80 to 90	Not exceeding 45 ft.	26 in.
,,	Exceeding 45 ft.	4½ in. extra on thicknesses specified from base to within 16 ft. of top of wall
90 to 100	Not exceeding 45 ft.	26 in.
,,	Exceeding 45 ft.	4½ in. extra on thicknesses specified from base to within 16 ft. of top of wall

The Public Health Act (1875) provides no general power for a local authority to make a bylaw regulating the height of habitable rooms, but such a bylaw can be made by any local authority under Sec. 23 of the Public Health Acts Amendment Act, 1890 (an Adoptive Act). Recognising the sanitary value of such a bylaw, the following clauses, which have received their sanction, are given in extenso:

Every person who shall erect a new building, and shall construct any room therein so that it may be used for human habitation, shall comply with the following requirements:

If such room is not intended to be used as a sleeping room, he shall construct such room so that it shall be not less in any part thereof than eight feet in height.

If such room is intended to be used as a sleeping room, and is not an attic or a room wholly or partly in the roof of such building, he shall construct such room so that it shall be not less in any part than eight feet in height.

If such room is intended to be used as a sleeping room, and is an attic or a room wholly or partly in the roof of such building, he shall construct such room so that it shall be not less than eight feet in height on the average over the whole area of the room, and so that no part of such room shall be less than five feet in height.

Bylaws with respect to roofs and the structure of floors can also be made under the 1890 Act. New buildings in the metropolis are governed by the provisions contained in the London Building Act, 1894.

Building Line. As regards the question of building line, apart from the consideration either of street widening or air space, the only powers of urban authorities are those conferred by the following section of the Public Health (Buildings in Streets) Act, 1888. Without the written consent of the urban authority, no building (or part thereof) shall be erected or brought forward in any street, or any addition made thereto beyond the front main wall of the building on either side thereof in the same street. In considering what constitutes the front main wall of a house or building, all the circumstances of the case must be taken into consideration. The building must be looked at as a whole; its character, its position, its distance from the building which is being erected or brought forward on alleged contravention of the Act must be carefully considered. In the metropolis, the superintending architect of the County Council has power under the London Building Act (1894) to define the general line of buildings in a street.

Supervision of New Buildings by Local Authorities. Among the multifarious questions with which surveyors to local authorities have from time to time to deal in the course of their various duties not the least difficult are those connected with bylaws and that of exercising control over any new buildings that may be erected within the limit of their jurisdiction. This duty is in most towns largely determined by provisions contained in the Public Health Act (1875). To secure all the clauses of the bylaws being carried out, adequate inspection of buildings in course of erection is needed, and unless a staff of building inspectors is kept by a local authority, it is impossible to expect a town surveyor with his multitude of other duties to see that the bylaws are enforced. A question which naturally arises in the mind of the political economist is "How far is the local authority justified in controlling the individual action of a builder?" This has been answered in such a variety of ways as to bewilder the highest authority on the subject.

The following is a schedule of the thicknesses of external and party walls of domestic buildings as sanctioned by the Local Government Board:

Thickness of walls (domestic buildings).

"Domestic building" means a dwelling house or an office building, or other outbuilding appurtenant to a dwelling house, whether attached thereto or not, or a shop, or any other building not being a public building, or of the warehouse class:

Height not exceeding	Length.	Thickness of walls.
Ft. 25	Not exceeding 30 ft., and not comprising more than two storeys	9 in from base to top of wall
„	Exceeding 30 ft. or comprising more than two storeys	13½ in. below topmost storey 9 in. remainder
25 to 30	Any length	13½ in. below topmost storey 9 in. remainder
30 to 40	Not exceeding 35 ft.	13½ in. below topmost storey 9 in. remainder
„	Exceeding 35 ft.	18 in. lowest storey 13½ in. rest of wall below topmost storey 9 in. remainder
40 to 50	Not exceeding 30 ft.	18 in. lowest storey 13½ in. below topmost storey 9 in. remainder
„	Not exceeding 45 ft.	18 in. two lowest storeys 13½ in. remainder
„	Exceeding 45 ft.	22 in. lowest storey 18 in. next storey 13½ in. remainder
50 to 60	Not exceeding 45 ft.	18 in. two lowest storeys 13½ in. remainder
„	Exceeding 45 ft.	22 in. lowest storey 18 in. next two storeys 13½ in. remainder
60 to 70	Not exceeding 45 ft.	22 in. lowest storey 18 in. next two storeys 13½ in. remainder
„	Exceeding 45 ft.	4½ in. extra on thicknesses specified to all below the uppermost two storeys. Subject to the provisions respecting distribution in piers
70 to 80	Not exceeding 45 ft.	22 in. lowest storey 18 in. next three storeys 13½ in remainder
„	Exceeding 45 ft.	4½ in. extra on thicknesses specified to all below the uppermost two storeys
80 to 90	Not exceeding 45 ft.	26 in. lowest storey 22 in. next storey 18 in. next three storeys 13½ in. remainder
„	Exceeding 45 ft.	4½ in. extra on thicknesses specified to all below the uppermost two storeys
90 to 100	Not exceeding 45 ft.	26 in. lowest storey 22 in. next two storeys 18 in. next three storeys 13½ in. remainder
„	Exceeding 45 ft.	4½ in. extra on thicknesses specified to all below the uppermost two storeys

Continued

A SHORT DICTIONARY OF BUILDER'S FINISHING TERMS

AIR COCK—A tap to allow of the escape of air.
Anaglypta—A wall-covering modelled in relief.
Anchor Plate—A plate built into a wall to hold down some object.
Angus Smith's Solution—A preservative solution used for iron pipes.
Anti-syphon Pipe—An air pipe to counteract the tendency of traps to syphon out.
Apron—A strip of lead placed below a window, chimney, etc., and dressed on to the roof covering.
Arabesque Glass—A form of rolled glass with an ornamental pattern.
Axle Pulley—A pulley arranged in a vertical plate used in hanging sashes.
Automatic Flushing Cistern—A cistern arranged to discharge its contents as soon as it is filled.

BACK PUTTY—The putty placed between a pane of glass and the rebate of the sash.
Balance Weight—A weight used in sash frames to counterbalance the frame.
Barff's Process—A method of protecting iron by forming a coating of black oxide.
Bases—Those pigments which give opacity and body to paints.
Bastard Flatting—A flatting coat to which a little clarified oil or size has been added.
Bearing Plate—An iron plate used between a strap and a piece of timber.
Bell Board—A board on which a series of bells are attached.
Bib-cock—A form of cock which delivers water from the end of a pipe.
Blister—In painted work small parts of the paint that have become separated from the surface covered and raised.
Blown Joint—A soldered lead joint made with a blowpipe.
Bobbins—Boxwood balls used in bending lead pipes.
Bolt—A curved piece of wood used in bending lead pipes; a metal fastening for a door catching in a staple or thimble.
Boot Boiler—A form of boiler used at the back of a kitchen range.
Box Girder—A girder having two parallel webs.
Bracketing—Piece of wood to receive lathes for plaster cornices.
Brad—A small nail with a head on one side only.
Brazing—The joining two pieces of metal by means of brass solder.
Bringing Forward—Painting portions of work one or more extra coats before general painting.
British Plate—Plate glass cast and afterwards polished.
Brunswick Black—A material formed of asphaltum and turpentine and applied to iron.
Bulb Iron—Iron rolled with one flat and one cylindrical flange.
Bullet Latch—A latch formed with a spherical catch like a bullet.
Bullion—The centre of a sheet of crown glass.
Burlap—A woven material formed of jute.
Burning Off—Removing paint by applying heat to the surface.
Burning In—Melting solder to fit lead in a raglet.
Burnt Joint—A lead joint formed with lead in place of solder.

CABIN HOOK—A freely-moving hook attached to a staple or plate.
Calcothar—Red oxide of iron.
Cames—Strips of lead having an H section used in lead glazing.
Cantilever—A beam built into a wall and supported at one end only.
Casement Fastener—A metal fastener to secure a casement to the frame.
Cast Iron—Iron that has been melted and cast in a mould.
Cathedral Glass—Plain, tinted glass used in lead glazing.
Cat Ladder—Light iron ladders used for giving access to roofs.
Ceiling Block—A block of wood used for attaching a gas pendant to a ceiling.
Cesspool—A sunk outlet to a lead gutter.
Chimney Bar—A wrought-iron bar built in under the arch of a chimney opening.
Chequer Plate—An iron plate with a raised chequered surface.
Circulating Pipe—A pipe through which hot water from a boiler is circulated.
Cleaning Eye—An opening inserted in pipes and traps to facilitate cleaning.
Clearcolle—Thin liquid glue used on porous surfaces before whitewash.
Clips—Metal bands placed round a pipe to fix same to woodwork.
Clout Nails—Flat-headed nails.
Coach Screw—A long screw of uniform diameter and with a square head.
Coarse Stuff—A mixture of lime, sand and hair for first two coats in plastering.
Cobweb Grating—A form of grating used as outlet to lavatory basins.
Coburg Varnish—A pale oil varnish.
Cockle Furnace—A furnace of thick iron used for heating air.
Collar—A lead disc temporarily fixed round a pipe during wiping a joint to catch the superfluous solder.
Coil—A pipe bent to and fro to give a large heating surface at any desired point.
Compo—A general term given to cement used for coating brickwork.
Composition Nails—Nails made of various alloys to avoid corrosion.
Concrete Float—A thick, heavy float used in finishing concrete paving.
Copper Bit Joint—A soldered joint made with a copper bit.
Copper Nails—Nails made of copper, usually in the form of clout nails.
Core—A thick iron bar fitted under a handrail; the rough centre for a plaster moulding.
Cottar—Wedge-shaped keys.
Countersunk Joint—One finished with a splayed head flush with the plate.
Cover Flashing—A strip of lead fixed into a wall and covering the top of a flashing.
Creeping—The slow movement of lead downwards on a steep roof.
Cross-garnet Hinge—A hinge in the form of a ⊢.
Crown Glass—Glass blown in globular form and afterwards flattened.
Crystal Glass—A very pure white quality of sheet or plate glass.
Cup-and-ball Joint—A joint giving free rotary motion, used for chandeliers.
Cups—Small brass cones fitted into wood beads to receive the heads of screws.
Cutting Wheel—A circular knife used in trimming wallpapers.

DADO—A horizontal division at the base of a wall.
Darby—A two-handled plasterer's float.
Dead Lock—A lock having only one bolt operated by a key.
Dished—A slightly hollowed bottom formed in lead-lined sinks and cesspools.
Distemper—A material similar to whitewash, but mixed with colouring pigment.
Double-arm Pendant—A form of gas pendant having two arms.
Double Laths—Laths of extra thickness.
Double Size—Size of twice the usual strength.
Double-swing Bracket—A gas bracket having two arms, both with movable joints.
Dovetail Lathing—A sheet of metal bent into a series of dovetail grooves.
Draw-off—A tap by means of which water may be drawn from a pipe.
Drawn Pipes—Lead pipes produced by machinery without any joint.
Drip—An abrupt change in the level of a lead flat.
Drip Pipe—A pipe used in steam heating systems to get rid of condensation water.
Drop Handle—A handle which is hinged to lie close against a door when not in use.
Dryers—Substances added to paint to assist the absorption of oxygen.
D Trap—An old form of trap, shaped like a D.
Dubbing Out—The process of forming a core for plaster mouldings.
Dummy—A tool used by the plumber in pipe bending.

EARS—Flat projections cast on iron rain-water pipes for fixing them.
Eaves Gutter—A gutter to take rain-water fixed at the eaves.
Economiser—A metal shield to close the opening between a grate and the hearth.
Elbow—A socket joining two pipes at right angles.
Embossed Glass—Glass that has been ornamented by chemical process.
Escutcheon—A small shield placed round a keyhole opening.
Espagnolette Bolt—A long double-action bolt used to secure French windows.
Eye—A metal ring into which a bolt may be fitted.
Eye-plate—A plate by which an eye may be attached to woodwork.
Expanded Metal—Metal sheets perforated and drawn out to form a kind of netting.
Expansion Joint—A form of joint allowing of movement due to expansion.
Expansion Pipe—A pipe in a hot-water system to carry off or contain excess of water due to expansion.
Expansion Tank—A tank in a hot-water system to hold excess of water due to expansion.

FALL-DOWN STOP—A form of gate stop that is lowered when not in use.
Feather-edge Rule—A rule one edge of which is splayed off to a thin edge.
Feed Cistern—A small cistern to keep a boiler supplied with water.
Fine Stuff—A mixture of lime putty with a little sand and hair.
Finger Plate—A plate fixed to either face of a door above or below a lock.
Finial—An ornamental termination to a gable or hip.
Fining Float—Small float for working plaster mitres, etc.
Fire-bar—The horizontal bars which carry the fire in a grate, boiler, etc.
Fish-plate—An iron plate used in forming a fished joint.
Flake White—A form of pure white lead made in England.
Flange—The tension and compression members in an iron girder.
Flanged Joint—A lead joint formed with a flange below it to support the pipe on a floor.
Flashed Glass—White glass with a film of coloured glass overlaid.
Flashing—A strip of lead used to make watertight the joint between a sloping roof and a vertical face.
Flatting—A coat of paint that is finished without gloss.
Flitch—An iron plate placed vertically in a flitched beam.
Float—A flat wooden instrument for working the final coat in plastering.
Floating Rule—A long rule used in forming screeds and floating surfaces between screeds.
Floor Spring—A spring for automatically closing a door, fixed in the floor.

Flow Pipe—That portion of a circulating pipe from the boiler to the highest level.
Flush Bolt—A bolt let into a door or window so that the face is flush with the wood.
Flush Handle—A handle sunk into a door so as to be flush with its face.
Flushing Tank—A tank the whole contents of which are discharged at one time.
Fluted Sheet—Sheet glass rolled with ribbed rollers, producing flutes.
Foil—Thin leaves of copper and other metals, applied like gold leaf.
French Nails—Long thin wire nails with flat heads.
French Polish—A mixture of shellac and spirits of wine for polishing hard woods.

GALVANISED IRON—Iron covered with a coating of zinc.
Gasket—Strands of rope or cord driven into the joints of pipes.
Gas Tar—See *coal tar*.
Gauge—A measure of thickness of wire and metal; to mix materials in exact proportion with water.
Gauge Board—A board on which plasterers' materials are mixed.
Gauged Stuff—Coarse or fine stuff with which plaster of Paris is mixed.
Gauge Hook—A tool used by plumbers for shaving lead surfaces.
Gauge Rule—a rule used for forming sunk or raised plaster surfaces.
Gauging Trowel—A trowel used for gauging plasterers' stuff.
Gelatine Mould—Moulds formed of gelatine for casting plaster enrichments.
Gib—A bearing iron used in connection with cottars.
Gilding—A process of applying gold leaf to surfaces.
Glaziers' Putty—A mixture of whiting and linseed oil.
Gold Size—A material applied to surfaces to be gilded.
Governor—An automatic control to regulate the pressure of gas in buildings.
Grainers' Comb—A metal comb used to produce graining.
Graining—Finishing a painted surface to match the grain of wood.
Ground Brush—The brush used by painters for large surfaces.
Ground Glass—Glass the surface of which is rendered obscure by grinding.
Gudgeon—The term applied to the eye of a hinge.
Gutter Pipe—The pipe through which the contents of a gutter are discharged.

HACKING OFF—The process of removing old plaster.
Hacking Out—The process of removing broken glass and old putty.
Hair—In plastering, the long hair from the backs of oxen.
Hand Float—Small floats, usually of pine, used in plastering.
Hangers—The struts employed in trussing a timber beam.
Hasp—A hinged, slotted plate passed over a staple and secured with a pin or padlock.
Hawk—A small board with a handle used for gauging and holding plasterers' stuff.
Heel—In pipe bending, the outer side of the curve.
Hit-and-miss Grating—One of which the openings can be closed by sliding a perforated plate.
H-Iron—Iron rolled so as to have an H section.
Holding-down Bolt—A bolt used to secure any object to an anchor plate.
Hopper Closet—A closet in the form of a funnel.
Hydrant—A stand pipe to which a hose may be attached.

INGRAIN PAPER—Papers coloured throughout in their manufacture.

JAPAN—Lead paint mixed with varnish dried at a high temperature.
Japanese Gold Size—A preparation of gum anime and linseed oil.
Jhilmil—A form of metal lathing.

KEEN'S CEMENT—A preparation of plaster of Paris treated with alum.
Keying—The scoring of the surface of plaster to secure adhesion for the next coat.
Kicking Plate—A metal plate fixed to the bottom rail of a door.
Killed Spirit—Spirits of salts in which zinc has been dissolved.
King Bolt—An iron bolt taking the place of a king post in a compound truss.
Knotting—The process of killing or covering knots in woodwork before painting.
Knuckle—The projecting portion of a hinge through which the pin passes.

LAC—A resinous substance obtained from the East Indies.
Lacquer—A varnish made with methylated spirit.
Lapped Joint—In lead work a joint in which one sheet is covered by the edge of the next.
Larry—A rake used for mixing hair with coarse stuff.
Latch—A fastening which may be opened with a handle instead of a key.
Lath and a Half—A term applied to extra stout laths.
Laths—Thin strips of wood used as a groundwork for plastering.
Lattice Girder—A girder of which the web is formed of iron lattice work.
Laying—Another term for rendering in plaster work.
Laying Trowel—A large square trowel used in rendering.
Lead Lights—Lights formed of small panes connected by lead cames.
Lead Safe—A tray of lead formed to catch any overflow water.
Levelling Rule—A rule used by plasterers in levelling ceilings.
Lignomur—A wall-hanging formed of wood fibre.
Lime and Hair—Another term for coarse stuff.
Lime Plaster—A term signifying that plaster is formed with lime.
Lime Putty—Pure lime run with water and allowed to settle.
Lime White—Chalk lime mixed with an excess of water, used as a wash.
Lincrusta Walton—A wall decoration executed in relief.
Litharge—Another term for oxide of lead.
Luxfer Glass—A special glass formed with prismatic projections on one side.

MACK PARTITION—A patent partition formed of plaster and reeds.
Mandrels—Cylinders of soft wood varying in length.
Margin Trowel—A parallel-sided trowel for plaster margins.
Massicot—A superior kind of oxide of lead.
Mastic—A resinous gum obtained from the Mediterranean.
Metallo-ceramic Joint—A patent joint for uniting lead pipe to earthenware.
Middling Lead Pipe—A pipe intermediate in weight between light and heavy.
Milled Lead—Sheet lead that has been rolled out.
Minium—Another name for red lead.
Mortise Lock—A lock that is inserted into a mortise formed in the thickness of a door.
Muffled Glass—Glass formed with a wavy surface.
Muffling—Covering a running mould with plaster to reduce its section.
Muffling Plate—A metal plate used to reduce the section of a running mould.
Muller—A kind of pestle used in grinding paint.
Muranese—A form of obscured glass.

NIB—The upper edge of a plasterer's running mould.
Nipple—The screwed end of gas pipe to receive the fitting.
Norfolk Thumb Latch—A latch operated by a lever which can be depressed by the thumb.

OIL POLISH—A finish produced with linseed oil.
Overflow—An outlet allowing water to escape on reaching its level.
Over Graining—A thin additional coat over ordinary graining.
Overcast Joint—One on which a series of facets are formed after wiping.
Oxide of Iron Paint—Paint in which oxide of iron forms the base.

PACKING PIECE—Iron slabs of various thickness used in levelling girders on stanchions.
Palette—A thin wooden board to receive paints used in decorative work.
Palette Knife—A long, flexible blade used in mixing up colours.
Painter's Torch—An apparatus for producing a flame for burning-off.
Pan Closet—An old form of w.c. in which a pan was employed to receive the contents.
Panel Float—A small float used for laying and smoothing work in panels.
Panel Trowel—Resembles a laying trowel, but is smaller.
Parian Cement—A white cement prepared from plaster of Paris and borax.
Parliament Hinge—A hinge having the form of an H.
Patent Size—A preparation of gelatine.
Pebble Dash—Another name for rough coat.
Pedestal Closet—A modern form of w.c. with basin and trap exposed to view.
Pivot—A projecting pin working in a socket.
Plaster of Paris—A fine white plaster prepared from gypsum.
Plate Glass—Glass poured hot on to a table and rolled out.
Pneumatic Bell—A bell operated by the compression of air.
Polished Plate—Plate glass that has been polished.
Polishing Trowel—A trowel used in finishing the setting coat of plaster.
Pot Metal—Glass which is coloured throughout its substance.
Pouring Stick—A short, grooved piece of wood to convey melted solder to the back of a joint.
Picking Up—Applying coarse stuff to walls, partitions, or cubings.
Priming—Covering a wood surface with the first coat of paint.
P-Trap—A trap the general form of which resembles a ᑭ.
Pulp Paper—The commonest class of wallpaper.

QUADRANT STAY—A stay bar for openings and arches having a quadrant form.
Quarries—Glass cut into small pieces for lead glazing.

RADIATOR—A closed metal vessel having a large superficial area for radiation.
Raglet—A chase cut in stonework to receive lead flashings.
Rain-water Gutter—A channel to receive rain-water from the eaves of a building.
Rain-water Head—An open vessel above the pipe to receive the discharge from a gutter.
Rain-water Pipe—A metal pipe used to convey rain-water.
Red Lead—An oxide of lead, usually in the form of a red powder.
Reducing Pipe—One reduced from a larger to a smaller diameter.
Reflector—Reflecting surface used to alter the direction of rays of light.

Register Grate—One having a flap, or register, between the grate and the chimney.
Render—The process of laying coarse stuff or cement on solid walls or ceiling.
Return Pipe—That part of a circulating pipe between the highest level and the boiler.
Ribbon Joint—One in which a band of solder is formed round the joint.
R.I.J.—Abbreviation for rolled iron joist.
Rim Lock—A lock attached to the face of a door.
Rising Butts—Those that lift the door slightly as it opens.
Rising Main—The pipe taken up to supply a cistern.
Roll—The method of forming a longitudinal joint between two sheets of lead.
Rolled Plate—Plate glass that has been rolled to produce a fluted surface.
Rough Cast—A method of finishing external plaster with pebbles or shingle.
Rough Cast Plate—Cast plate rolled with a smooth roller.
R.S.J.—Abbreviation for rolled steel joist.
Rubber Cone—A union formed of rubber.
Rubbing Down—The process of rubbing each coat of painted work.
Rule—A strip of wood varying in size and form used in floating plaster.
Running Rule—Wood strips fixed as guides for running moulds.
Running Mould—Moulded profiles by means of which mouldings in plaster are formed.

SADDLE-BAR—A metal bar used to give support to lead lights.
Sanitary Paper—Wallpaper printed in oil colours and washable.
Sash Fastener—A metal catch to secure one sash to another.
Sash Lift—A metal hook or plate by which a sash is lifted.
Sash Tool—The brush used in painting sash-frames.
Sash Weight—Metal weights used to counterbalance the sash and its glass.
Satin Paper—Wallpaper having a polished, satin-like surface.
Scagliolер—A special form of coloured plaster used in imitation of marble.
Scouring—Working over plaster surfaces with a hand float.
Scratch—A tool used in scratching or scoring plaster surfaces to form a key.
Scratch Tools—Small tools of various shapes used in finishing plaster enrichments.
Screed—A strip of plaster laid as a guide for floating.
Seam Roller—A small roller used in smoothing the joints in paper-hanging.
Seamed Pipe—A lead pipe formed out of sheet lead with a soldered joint.
Setting—The process of laying and finishing the final plaster coat.
Setting Coat—The last coat in plastering, formed of fine stuff.
Service Pipe—A pipe conveying water from the supply to a fitting.
Sgraffito—Successive thin coats of coloured plaster incised and cut to give pictorial effects.
Shave Hook—A tool used in shaving lead-work.
Shaving—The process of removing a thin layer of lead to provide a bright surface.
Sheet Glass—Glass blown in the form of cylinders and afterwards flattened.
Shoe—The outlet of a rain-water pipe over a gulley.
Side-arm Roller—Resembles a seam roller, but will work close up to a projecting surface.
Silicate Cotton—A fibrous non-conducting material produced from iron slag.
Single-swing Bracket—A gas bracket having one movable arm.
Size—A liquid preparation of glue.
Size Kettle—A kettle with water jacket, in which size is melted.
Skimming Float—A large float used for laying setting stuff.
Slag Wool—See *silicate cotton.*
Slipper—The face of a running mould.
Slop Sink—A sink intended to receive bedroom slops.
Smoothing Roller—A broad roller used in paper-hanging.
Smudge—A preparation used by the plumber in soiling.
Snap Rivet—One formed with a spherical head.
Soakers—Sheets of lead inserted under slates or tiles, and turned up against a wall.
Soil—Another term for smudge.
Soiling—The process of covering with soil those parts of lead work to which solder is not required to adhere.
Soil Pipe—A pipe for conveying away the contents of w.c.'s.
Soldered Dot—A method of securing vertical lead sheets to woodwork or stone.
Soot Door—A small iron door and frame inserted in a smoke flue.
Sparge Pipe—A pipe arranged to distribute a discharge of water over a wide area.
Splash Stick—A small wood or iron stick used in upright soldered joints.
Sprig—A small metal brad. used by glaziers.
Sprigging—Temporarily securing panes of glass with sprigs.
Stanchion—A perpendicular support under a girder.
Standing Waste—A waste pipe standing up within a cistern.
Stand Pipe—A vertical pipe fitted with a tap for drawing off water.
Stay Pipe—A metal bar used to secure a window when open.
Stencil—A pierced plate for painting designs that repeat.
Stepped Flashing—One cut to allow of the upper edge being turned into successive brick joints.
Step Setter—A tool used in forming stepped flashings.
Stiffeners—In built girders pieces of angle iron used to stiffen the web and flanges.
Stippling—Finishing a painted surface with the end of a paint-brush.
Stock—The backing for the profile plate in a running mould.
Stopcock—A valve used to shut off a supply.
Stopped End—A closed end to a rain-water pipe.
Stopping—The process of filling up small holes in woodwork or plaster.
S-trap—A trap the outlet of which is in the form of an S.
Strap—A narrow plate used in securing timber joints.
Strap Hinge—A hinge for heavy gates, fixed to them with iron straps.
Striking Plate—The metal plate into which the bolt of a lock is inserted.
Stucco—A somewhat vague term applied to several plastic mixtures.
Swan-neck—A bent pipe connecting a rain-water gutter and pipe.
Syphon Box—An apparatus used to collect water from gas supply.
Syphon Closet—One in which the contents are removed by syphonic action.

TACKY—The condition of paint or varnish which fails to dry properly.
Taft Joint—A wiped lead joint resembling in form a copper bit joint.
Tar Paint—A paint for iron formed with tar, lime and naphtha.
Tension Rod—An iron rod used in trussing timber beams.
Throat—In pipe-bending, the inner side of the lead.
Tie-rod—A metal rod replacing a tie-beam in a compound roof.
Tingle—A broad strip of stout lead used to hold down the edges of lead sheets.
Tinning—The process of covering a copper bit with solder.
T-iron—Iron rolled in the section of a T.
Toe—The lower end of the stock of a running mould.
Touch—A piece of tallow candle is used to touch lead surfaces after shaving.
T-piece—A form of union between two horizontal and one vertical tubes.
Traversing Rule—A rule used for forming screeds in gauged or setting stuff.
Trimming Knife—A knife used for trimming wallpapers.
Trowelled Face—A plaster face highly finished with a trowel.
Trumpet-mouth Waste—A waste pipe the mouth of which is enlarged like a trumpet.
Turnbuckle—A fastening of iron or brass turning on a pivot.
Turn Pin—Wood cones used for enlarging ends of lead pipes..
Tynecastle Canvas—A material moulded in relief on canvas for covering walls.

UNDERHAND JOINT—A wiped joint on a horizontal pipe.
Union—A screw joint to unite a pipe to a cistern or a lead and iron pipe.
Universal Joint—A ball-and-socket joint.
Upright Joint—A wiped joint on a vertical pipe.

VALLEY GUTTER—A gutter formed in the angle between two roofs.
Valve Closet—One in which the outlet of the basin is closed by a valve.
Vehicles—The liquid with which pigments are mixed to form paint.
Ventilating Stove—A stove provided with a hot-air chamber and air inlet.

WALL HOOK—An iron spike with a curved end that will grip a pipe.
Warning Pipe—One that gives notice by dripping when a cistern is full.
Washable Distemper—Material resembling distemper, but which may be washed.
Wash-down Closet—One in which the bottom of the pan is continued into the trap.
Wash-out Closet—One in which the contents of the pan are washed out into the trap.
Water Stain—A material used for altering the colour of woodwork.
Water Waste Preventer—A cistern using only a limited amount of water at each discharge.
Wax Moulds—Used by plasterers for casting enrichments.
Wax Polish—A glossy surface produced on wood with the aid of wax.
Web—The vertical member of an iron girder.
Weeping Pipe—A pipe which allows water to drip slowly.
Welted Joint—One in which two metal sheets are folded together to form a joint.
White Lead—A carbonate of lead, the base of many paints.
Whitewash—A mixture of whiting, water and double size.
Wired Glass—Glass in which wire netting is embedded.
Wiped Joint—A joint formed with solder by means of a cloth pad.

ZINC PAINT—A paint of which the base is zinc white.
Zinc White—An oxide of zinc.

HARBOURS AND DOCKS

The Action of Waves and Tides, and their Consideration in Harbour Construction. Different Classes of Harbours

By A. T. WALMISLEY

SCARCELY any branch of engineering presents so many difficulties as that which deals with marine structures, and in the prosecution of this study the student cannot do better than peruse carefully the various papers dealing with marine work which are published in the volumes forming the Minutes of Transactions of the Institution of Civil Engineers, and which furnish accounts of the most recent improvements.

The consideration of the action of the waves is of primary importance in the design of works exposed to the action of an open sea. Waves near a coast do not attain the dimensions of those in the open sea, and the reference to waves as "mountain high" is a popular error. Waves have to be considered by the harbour engineer in connection with harbours, docks, and coast protection, and may be classified as: (1) tidal waves, (2) wind waves, (3) ground swells, (4) breaking waves.

Tidal Waves. The great tidal wave of the ocean, which causes the rise and fall of the water on a coast, is an element that must be taken into consideration. The maximum effect due to a tidal wave occurs at the time of high spring tides when accompanied by heavy on-shore gales. The height to which the water rises above the beach is increased during gales, and varies from 3 ft. to 4 ft. according to locality. The effect of gales is greatest when the wind, after blowing along the coast in the same direction as the main stream of the flood tide, changes about the time of high water to an on-shore direction. When a tide is rising the water for some distance from the coast is flowing towards the shore, and when falling, is flowing from it. A tidal wave moves along the deep water of the open sea at a greater velocity than in shallow water near the coast. The crest of a wave in the open sea is therefore in advance of that near the shore, resulting in an oblique lateral movement along the shore. The tidal wave becomes a wave of translation when it encounters the obstruction caused by the shoaling of the shore, and is reflected back, setting up a series of small oscillations or waves, which break on reaching the low-water level.

VELOCITY AND PRESSURE OF THE WIND

Feet per minute.	Miles per hour.	Force in lb. on sq. ft.	Description.
88	1	·005	Hardly perceptible
352	4	·079	Gentle wind and breezes
440	5	·123	
880	10	·492	Good breeze
1,320	15	1·107	
1,760	20	1·970	Brisk gale
2,640	30	4·429	High winds
3,080	35	6·027	
3,520	40	7·870	Very high
3,960	45	9·960	
4,400	50	12·300	Storm
5,280	60	16·710	Great storm
7,040	80	31·490	Hurricane
8,800	100	49·200	

The rise and fall of tide, irrespective of wind, is effected not merely by a vertical swelling and depression or rising and fall of water, but by a series of small waves, which vary in height according to the conditions of tide and beach, and which are absent from the shore only when absorbed by larger waves during gales.

Influence and Prevalence of Wind. Although the wind is the primary cause of the attacks to which all shores are exposed, its influence is excited through the waves raised by it. It is necessary to consider the direction of the prevailing winds, at what seasons they generally blow, and the distance that the wind travels unimpeded, so that the entrance to the harbour may be made to face the proper direction for vessels entering and leaving.

Wind Waves. Wind waves are produced by wind blowing on the surface of the sea and are pure undulations. The form of wave transmitted towards the shore has no forward progressive movement until the margin of a shore is reached. The common form of wind waves in open sea is cycloidal, but shore waves assume more the form of an ellipse.

Ground Swell or Rollers. By ground swell or rollers is implied a product of wind waves which are generated at some distant part of the ocean, and which travel across the ocean shorewards, and form long, low undulations. Their effects extend to a greater depth than that of ordinary waves, and they exert greater power of transmission nearer the bottom than shorter waves in the same depth. The long waves formed by ground swell on approaching shallow water, where depth is constantly diminishing, are increased in height and velocity, and exert more powerful and a greater percussive effect on a sea-wall or cliff than ordinary wind waves, and the back-wash proves more destructive to a beach.

Breaking Waves. Breaking waves are produced owing to the water becoming shallow, and being no longer able to complete the undulation under ordinary conditions. A wave breaks when it reaches water of a depth approximately equal to its height from trough to crest. A wave on breaking assumes a progressive accelerated horizontal motion, and is capable of carrying forward with it any material with which it comes into contact, and on receding down the slope has a strong erosive and transporting power. The mean level of the sea at the place where a wave breaks on the shore is raised by the action of an on-shore wind, and is further increased by the impetus of the waves, hence the surface of the water forms a slope upwards towards the shore, causing an undercurrent towards the sea. An off-shore wind produces an off-shore current.

The height, length, and velocity of waves are governed by the depth of the water. The force and percussive effect of a breaking wave on a cliff or sea wall are in proportion to the cube of the depth of the water in which it breaks.

The percussive force is diminished in proportion to the angle at which the wave strikes the object with which it comes into contact, either horizontally

or vertically. The force of waves on a beach varies with the slope, the higher the beach and shallower the water, the less the eroding and transporting force.

The length of a wave is the distance measured from the top of the crest of one wave to that of the next. The height is the vertical distance from the bottom of the trough to the top of the crest.

As regards the velocity of waves—short waves whose lengths are not greater than the depth of the water have a velocity depending sensibly only on their length and proportional to the spread of their length. Long waves whose lengths are greater than the depth of the water have velocity depending sensibly only on their depth, and are proportional to the square root of the depth. The velocity of a wave ceases to increase with the depth beyond a depth equal to the length of the wave. Long waves in deep water have the greatest velocity, irrespective of their height.

The question of the movement of material at great depth has given rise to much discussion. The movement of sand, stones, etc., in water of considerable depth is generally due to tidal currents, aided by wave action. There occurs a movement at the bottom of the deep-water channels that intersect the sands lying off the shore, but the sand is drifted backward and forward only with the flood and ebb tide.

The late Sir John Coode stated (Minutes of Evidence, Select Committee on Harbours of Refuge, 1851) that he "found the shingle of the Chesil Bank disturbed by wave action, during the heaviest gales, at a depth of eight fathoms, the shingle thus disturbed being of large size."

Movement of the Particles Forming Waves. Passing waves give an observer the impression that they are advancing towards the shore, but instead of passing onward, each wave oscillates between certain points, the distance between which bears a fixed relation to the length of the wave between crest and crest. Only the form and energy of the wave are transmitted and not the water, except to a certain extent in the case of waves of translation.

The dynamical effect of waves striking a plain surface is not easy to estimate; but when a gale is subsiding more damage is often done to sea walls, etc., during that period than when at its height, owing to the waves becoming more regular and in a way steadying themselves as the force of wind decreases, and thus throwing their full weight against any opposing structure.

Fetch is the distance in any direction which is freely traversed by waves driven by the wind.

Crests on waves are formed in the open ocean by the wind urging the top of the wave forward at a greater velocity than the body of the wave, and causing that portion of the wave to break by pushing it over. Waves sometimes carry their crests for a long distance, and become dangerous to vessels of small size. These waves do not disperse, and cannot be regarded as ordinary breakers. There is no reliable formula for calculating the height of waves during strong gales. The height of spray on broken water is often shaken about instead of the actual wave. The greatest height may be taken as between 40 and 50 ft.

Tides. Tides are due to the combined attraction of the sun and moon. They exert their greatest attractive effect upon that part of the water which is immediately opposite to, and therefore nearest, to them.

Tides are mainly governed by the moon, in spite of the much greater force exerted by the sun at the earth's surface, and are influenced by the moon and follow her apparent passage round the earth, due to the earth's rotation. Two lunar tides are experienced in the course of a day. Morning and evening tides, ordinary and equinoctial tides, and summer and winter tides, are affected by variations in distance of the sun, moon, and earth from each other, and also by declination.

During each lunar month, the sun, moon, and earth are in line, and effective lunar and solar attractions are combined, raising the water on the two opposite sides of the earth, and this increased rise creates what is known as a *spring tide*.

Equinoctial Spring Tides. These occur in March and September, when the sun is vertical over the equator, and its attractive power is then greatest. When the lunar tides at new and full moon coincide with the solar tides about this time, which they do more closely now than at other times, these abnormally high and low tides occur. During each lunar month also the sun is once in a position at right angles to the moon as regards the earth, the lunar tide is reduced by the opposing action of the sun, by the extent of the solar tide, and the result is called a *neap tide*.

Considerable influence is exerted by the wind upon the tides by raising or depressing the sea-level along coasts. A strong on-shore wind increases the normal rise of the tide and prevents it from falling to its full extent. An off-shore wind produces the opposite result. Furthermore, it is found that changes in atmospheric pressure affect the tidal rise by altering the local pressure upon the sea. The weight of the atmosphere at the earth's surface equals a pressure of 15 lb. per square inch, and is equivalent to nearly $8\frac{3}{4}$ tons per superficial yard.

Barometers record atmospheric pressure by comparing it with the height of a column of mercury, which it is capable to balance. The weight of mercury is approximately thirteen times that of sea water; therefore, a fall or rise of 1 in. would represent an elevation or depression to the extent of 13 in. According to Lord Avebury, a rise of 1 in. in the barometer causes a depression of the tide at London of about 7 in., and of 11 in. at Liverpool.

Double tides are caused by portions of the tidal wave reaching a locality by different routes, such as takes place at Southampton. The portion of the tidal wave which passes up the western channel, being deeper and more direct, reaches Southampton earlier than the portion of the tidal wave passing up the eastern channel, thus forming a double tide.

Currents. No general rules regarding currents can be laid down, as each place has its own peculiarities. For information as regards the flow and velocity of currents it is usual to refer to the Admiralty charts. Ocean currents are produced by the difference of the temperature at the equator and near the Poles. The density of the heated water being reduced, it flows towards the Pole, and becomes replaced by an undercurrent of cold water travelling towards the tropics.

Tides occur twice in every 24 hours and $50\frac{1}{2}$ minutes. When a place is on the same side of the equator as the moon, the tide which is produced while the moon is *above* the horizon, as already explained, is greater than while the moon is under the horizon of the place; but when a place is upon the opposite side of the equator to the moon the effect is reversed. In midsummer, the afternoon tides are higher than the morning tides. In the winter, the morning tides are usually the highest.

Beardmore gives the following table for finding the height of the tide at any period after high water.

HEIGHT OF TIDE AFTER HIGH WATER					
Time from high water.		Multiplier.	Time from high water.		Multiplier.
Hours.	Minutes.		Hours.	Minutes.	
0	00	1·000	3	00	·500
0	30	·975	3	30	·375
1	00	·916	4	00	·258
1	30	·841	4	30	·158
2	00	.741	5	00	·083
2	30	·625	5	30	·025

The rule is to multiply the range of tide for the day by the factor opposite the hour at which the height is required. Suppose, as our example, that the total rise of tide at Dover on the 12th April was 20·4 ft., high water made at 3 p.m. What was the height of tide at 4 p.m.? $20{\cdot}4 \times {\cdot}916 = 18{\cdot}68$ ft.

Harbour Regulations. Parliament has from time to time authorised a considerable expenditure of national funds for harbours and breakwaters useful for the Navy, and they are therefore deemed, very properly, to be of national rather than of local importance—as, for example, at Portland, Plymouth, Dover, Holyhead, and Chatham.

A General Act, called the "Public Works Loan Act," authorises advances to be made to such undertakings. Acts of Parliament are necessary for harbour works of large magnitude. Small undertakings, where it is not proposed to acquire land for the purposes of the works, are carried out without the expense and trouble of a special Act, under Provisional Orders of the Board of Trade. All such legal documents are cheaper than engineering works, and are not always executed within the prescribed limits of time. Harbour improvements, or the construction of a dock required for the special interests of a mercantile port, may be sometimes constructed and paid for by local or municipal capitalists, or, in addition, outside aid may be obtained.

Harbour Revenues. Works are generally made directly remunerative by subjecting vessels, merchandise and passengers, to a tax or toll for the use of the improved accommodation. The revenue from harbours and docks is generally levied in the shape of dues on vessels, calculated according to weight, bulk, or value, and sometimes as a poll tax on passengers. The necessary money may be provided through the ordinary means of a joint stock company, or by means of a harbour trust. In the former case, the net revenue will be applied to the payment of a dividend to shareholders, who will naturally endeavour, by keeping down expenditure and maintaining high rates, to obtain as much profit as possible. In the latter case, the money is raised on bonds bearing a fixed rate of interest for the payment of which the revenue of the undertaking is pledged, the profits beyond what is necessary for this fixed rate being applied to the extension or improvement of the works, also to a sinking fund for the redemption of the bonds and then to the reduction of the tolls. As examples of the first system, joint stock companies own the docks of London, Southampton, Hull, and Plymouth. The Clyde Trust, the Mersey Docks and Harbour Board, the Dublin Board, the Belfast Board, and the Dover Harbour Board, are examples of the second system.

Different Classes of Harbours. We have (1) harbours of refuge and anchorage breakwaters, which consist of one or more breakwaters, arranged so as to form a safe roadstead, easily accessible in all states of weather and tide to the largest vessels; (2) deep water and tidal harbours for commercial purposes, in which an arrangement of piers or breakwaters, or of both, enclose and tranquillise a water area enabling vessels to be moored at the quay walls or wharves, forming the inner sides of the piers; and (3) canted or curved piers, where vessels lie under the lee of the cant and the sheltered side of the pier is finished as a quay. Where the coast lies open to a heavy sea it is found necessary to make a double harbour, the entrance to the inner basin being protected by the outer works.

The shore between high water and low water belongs to the Crown, unless alienated by special rent to the lord of the manor or frontages, and no groynes or erections of any kind for coast protection may be constructed below high water without their consent. The influence of the protection of one portion of a foreshore by such artificial means should be considered in its effect upon adjoining foreshores which may not be as well protected. The terms of reference to the Royal Commission on Coast Erosion, which is now sitting, are:

To inquire and report:

(*a*) As to the encroachment of the sea on various parts of the coast of the United Kingdom, and the damage which has been, or is likely to be, caused thereby; and what measures are desirable for the prevention of such damage.

(*b*) Whether any further powers should be conferred upon local authorities and owners of property with a view to the adoption of effective and systematic schemes for the protection of the coast and the banks of tidal rivers.

(*c*) Whether any alteration of the law is desirable as regards the management and control of the foreshore.

(*d*) Whether further facilities should be given for the reclamation of tidal lands.

Depth of Water. It has been found in actual experience that harbour entrances formed by converging jetties have, in general, attained a better depth of water than those where parallel jetties have been adopted. The force of a scouring current makes itself felt against the shallowest point of the channel, while shoals formed in the wider sheltered area inside are easily removed by dredging. The harbour engineer must anticipate vessels 1,000 ft. in length and drawing 40 ft. of water, and in all modern harbours must dredge accordingly.

The system of producing scour by a single jetty can be resorted to only in very exceptional circumstances. At the same time, trumpet-shaped entrances cannot be recommended. The superiority of converging jetties, kept low in places to ensure the filling of the estuary at every tide, consists in the small interference with littoral currents. They tend to produce scour round the projecting point formed by the piers, and they concentrate the current at the most critical point of the channel. Uniform width in a channel tends to produce uniform scour and to improve the discharge of flood waters. Hence, the advantage of a pier upon both the sides of a harbour entrance.

STRENGTH & SPEED OF SHIPS

The Strength of Material and Attachments. Distribution of Structural Material. Speed and Resistance of Sailing and Steam Ships. Steering

By Dr. J. BRUHN

When the designer has ensured that his ship will float at the required draft, and that she will float in the upright position, then he has to make sure that she will possess the third essential quality—namely, such structural strength as will admit of her being exposed to all the ordinary forces met with in her trade. The designer is, however, in most instances to a large extent relieved of the trouble and responsibility of himself ascertaining if his ship will have the required strength. The classification societies, such as Lloyd's Register, Bureau Veritas, British Corporation, and others exist with a view to ensuring, in the interest of owners and underwriters, that their ships possess ample structural strength, and the standard of efficiency which they provide is usually so high that the ship designer or builder practically leaves this question entirely to them. These societies provide definite dimensions (scantlings) for the various structural items according to the size, type, and arrangement of the ship. Their wider experience with regard to this particular point enables them to determine what the dimensions of the material ought to be more readily than it would usually be possible for the individual designer to do; but the latter must, on the other hand, sometimes investigate the question of strength independently. In doing so he uses the same broad principles upon which the tabulated rules of classification societies have been based.

Strength of Material. The strength of a ship depends, in the first instance, on the strength of the material employed. At the present moment there is for practical purposes only one material used in shipbuilding—namely, mild steel. Chemically, this consists almost solely of iron with a very small quantity of carbon and traces of silicon, sulphur and phosphorus. Its strength is usually supposed to be measured by the number of tons required to pull asunder a bar with a section of one square inch. For ordinary shipbuilding steel, this, the tensile strength, varies from 26 to 32 tons per square inch. This figure is, however, in itself no criterion as to the suitability for its intended purpose. It is only when the material is otherwise satisfactory, when it is elastic, ductile, flexible, etc., that the tensile strength may be taken as a guide to its efficiency. In fact, it is often undesirable to have a very high tensile strength, as that is not usually associated with good qualities in other directions. To such an extent is this the case that practically all specifications for steel contain an upper as well as a lower limit for the tensile strength of the material. The steel is nearly always tested at the maker's works with a view to its quality being guaranteed before it is forwarded to the shipyards. Strips are cut off the rolled plates, and some are pulled asunder in a machine with a view to ascertaining the tensile strength, which is the breaking load divided by the sectional area of the test piece. Other pieces are subjected to bend tests which afford a fair criterion as to the elasticity and ductility of the material. Good steel is an excellent material for shipbuilding purposes, but, at the same time, a lighter material with the same ductility would be still better even if the tensile strength were somewhat less.

Strength of Attachments. The structure of a large steel ship is necessarily made up of a great number of individual plates and angles, which have to be attached to one another by rivets. The strength of a ship does not, therefore, depend solely on the strength of the building material, but also on the strength of the means whereby the individual pieces of material are joined together. Excellent steel is comparatively easy to obtain, but it is of little use if the attachments are of inferior quality. It is therefore the designer's duty to arrange the riveting of his structure in such a way that it shall be as nearly as possible equal in strength to the plating.

There is a variety of ways in which plates and angles have to be joined in a ship. Figure 150 shows the simplest. It is here merely a question of attaching the ends of two plates which may be subjected to tensile stresses. The pull across the entire width of the one plate must be transmitted through the rivets to the other plate. The strength of the plate is represented by its sectional area or by the product of its width (b) and thickness (t), together with the tensile strength of the material (q). The strength of the rivets is represented by the aggregate sectional area of the rivets and the strength of their material per square inch (q_1). It would be of no use to have the strength of the riveting greater than that of the weakest point of the plate, which is where it is injured by the rivet holes. Let the diameter of the rivets be d, their number n, and their distance apart, centre to centre, p. If the strength of the riveting is equal to that of the perforated plate, then

$$\cdot 785 d^2 \times n \times q_1 = (b - nd) \times t \times q,$$

or, as $$n = \frac{b}{p},$$

$$\cdot 785 d^2 \times \frac{b}{p} q_1 = \left(b - \frac{b}{p} d\right) t \times q;$$

or $$\cdot 785 d^2 q_1 = (p - d) \times t \times q.$$

The plates were supposed to be subjected to pull, in which case q, the tensile strength of the material, is a proper factor of the right-hand term. The rivets, it will be observed, are not subjected to a pull in this case, but to a shearing action; q_1 does therefore not represent the tensile strength of the rivet material, but the shearing strength, which may be taken as 80 per cent. of q. The above equation may then be written

$$\frac{\cdot 628 d^2}{(p - d)} = t.$$

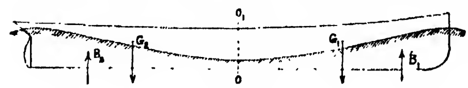
Spacing of Rivets in Practice. From this it will be seen that the diameter of the rivets and their spacing should depend on the

thickness of the plates to be attached. Larger rivets may be adopted with wider spacing, or smaller ones with closer spacing. In practice, it is found desirable to use relatively much larger rivets in thinner than thicker plates, because in the former case the actual size of rivet is such that it can be knocked up with ease by manual power, whereas the rivets for the thicker plates would be so large that it is better, where hand riveting is adopted, to have more and smaller individual rivets. Roughly, the diameters of the rivets in steel plates of the thickness t are equal to $\frac{1}{2} + \frac{10}{16}t$ in., which shows that they are relatively small for the greater thicknesses, and the necessary strength of the attachments has, in those instances, to be provided by means of additional rows of rivets. One row may be enough for the thicknesses up to $\frac{1}{4}$ in; two may be needed when the thickness is $\frac{1}{2}$ in.; three when $\frac{3}{4}$ in.; and four when 1 in. There are other points except the mere consideration of strength that govern in practice the sizes of rivets, such as the necessity to have a spacing of the rivets that will admit of the edges of the plates being caulked and made efficiently watertight. In a ship the edges of the plates as well as the butts have to be riveted together, but the attachment need not usually be so strong in the former as in the latter case. There are a number of other forms of riveted attachments—as, for instance, those between the frames and shell plating, and between the beams and the deck plating—which must also be strong enough to resist the stresses brought to bear upon them. In a general way, it may be said that it is the riveted attachments that are the weak points in a ship's structure, and when any straining does occur at sea, the result is nearly always slack and leaky rivets, and very rarely actually fractured plates.

Distribution of Structural Material. The question of the strength of ships is not merely one of sound material and effective attachments: it is also one of sufficient material and efficient distribution. It will be self-evident that the strength of the ship depends in some measure on the amount of the structural material; but it will also depend largely on the arrangement of the steel plates and angles. The most efficient distribution is that which admits of the greatest strength being obtained with the minimum weight of material. In order to determine this distribution, it is necessary to deal with the forces that act on a ship. These are, of course, of a very variable character. Some forces are at a maximum when the vessel is in dry dock, others when she is in the light condition, and others again when she is loaded. It should be the maximum probable forces in each instance that should govern the amount of strength to be provided at any particular place in the structure.

A ship cannot be made strong enough to resist any forces, any more than a bridge can be made strong enough to bear any load that may be placed upon it. It may be possible to make a vessel of moderate size strong enough to rest on a soft river bottom; but it is quite impracticable to make a large ship strong enough to bump on a rocky shore. Except in the case of a few small vessels, specially designed to rest on the bottom of harbours and such places, it ought to be the conditions at sea that should govern all questions of strength. The waves of the ocean cannot apply the local pressure to a ship which it is possible for a ragged ledge of rocks to do; but they can at the same time cause very heavy distributed pressures to act on the structure. Just as the problem of the stability of ships and land structures was seen to be in reality the same, so the question of the strength of ships will be found, when closely examined, to be very much the same as the problems the civil engineer has to solve on land. To the superficial observer the question of the structural strength may appear a more intricate one at sea than on terra firma; but in many respects it is really a less difficult one, although in itself an exceedingly complex one.

Forces Acting on a Ship. The forces that act on a ship's structure and tend to strain it, are gravity, inertia, and the pressure of the supporting medium. A loaded ship will usually have the weight of her structure and cargo more or less uniformly distributed throughout her length. The support or buoyancy is also distributed in much the same manner. This means that the weight is at each point practically directly balanced by the supporting upward pressure of the water. When the vessel is placed among large ocean waves, the conditions change considerably. The weight of the structure and cargo remains always the same, but the supporting pressure will increase in way of the

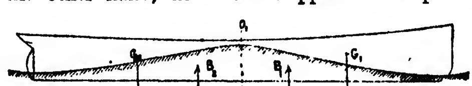


151

crests of the waves, where the water is piled up, and it will decrease at the hollow of the waves, where the draft is diminished.

Figure 151 shows a vessel as she may float for a moment when waves of her own length are passing by. It will easily be realised that the support of the buoyancy is, in this instance, chiefly confined to the ends of the vessel, and the ship will have a tendency to sag down in the middle, just as a loaded bridge, supported at its ends, would do. The centre of gravity of the whole ship must still be over the centre of buoyancy, and both of these points may be taken to be in the line OO_1. The tendency for the vessel to sag down causes a bending moment to be set up at OO_1. Looking at the forward half of the vessel, it will be apparent that there is an upward moment about OO_1 equal to the product of the forward buoyancy multiplied by the distance of its centre B_1 from OO_1. There will, likewise, be a downward moment equal to the weight of the forward half of the vessel multiplied by the distance of its centre of gravity from OO_1. If these moments balanced, then there would be no moment at OO_1, but if one is greater than the other, then there will be a moment at OO_1, which must be borne by the structure, and must be balanced by a similar but opposite moment caused by the weight and buoyancy of the after end of the vessel.

Sagging and Hogging Moments. In the illustration shown the upward moment of the buoyancy is clearly greater than the downward moment of the weight, with the result that the end of the vessel is lifted relatively to the middle, or inversely the middle is sagging down in relation to the ends. Such moments are called sagging moments. If, on the other hand, the vessel happens to be poised



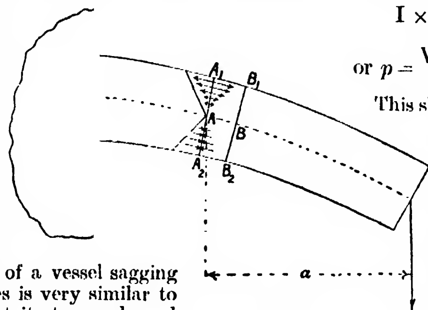
152

instantaneously on the crest of a wave, as shown by 152, then it will be understood that there is an unnecessarily large amount of support amidships,

and very little at the ends of the vessel. While the moment of the weight of the forward half of the vessel remains the same as before, the moment of the buoyancy is reduced, owing to its centre B_1 moving closer to OO_1.

In these circumstances the weight moment will be the greater of the two, and the result will be a downward moment about OO_1 equal to the difference between the moments of weight and buoyancy, or equal to half the weight of the ship multiplied by the horizontal distance between the points B_1 and G_1. As before, this bending moment must be borne by the structure at OO_1, and be balanced by that of the other end of the vessel. In this case the middle of the vessel tends to rise and the ends to droop, which would cause the outlines of the vessel to assume the form of a hog's back, hence the name of *hogging* moment for the resulting bending tendency. The case of a vessel sagging with its two ends on waves is very similar to that of a bridge supported at its two ends and that of a vessel hogging to a bridge of the cantilever type supported at the middle only. All that is needed to determine the sagging and hogging moments at OO_1 is an estimate of the weight and centre of gravity of the forward portion of the vessel, and of the forward displacement and its centre of buoyancy. A ship may meet with a variety of waves, but those of its own length produce the most severe straining actions. For the purpose of calculation it is usual to assume the wave to be of a trochoidal profile and of a height equal to one-twentieth its length. As the waves are getting longer, they become relatively lower, and it would be more correct to assume a proportionally lower wave for the larger ships.

Bending of Girders. A ship is simply a hollow girder, and will bend as such a structure does when loaded. In the bending of a beam, as shown by **153**, the top fibres of the material are stretched and the bottom ones compressed, while midway between the two there will be some which neither stretch nor contract. The two cross sections, as A_1A_2 and B_1B_2, originally parallel, will, therefore, when the beam is bent, be slightly angled, and A_1 B_1 will be longer than A B, while A_2B_2 will be shorter. The bending action is therefore made up of simple tension and compression. The tension in the upper half of the beam, say from A to A_1, will produce a moment about A, and similarly the compression on the lower half will also produce a moment about A tending to turn in the same direction—namely, that which is opposite to the motion of the hands of a watch. The greater the tension and compression the greater the moments will be. Together they must be equal to that of the weight W multiplied by the distance from the section considered. It will therefore be seen, as might be expected, that the larger the bending moment the larger the tension and compression will be. A tensile or compressive stress is the tension or compression respectively per square inch of material measured, say, in tons.



153

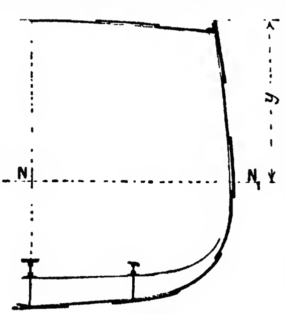
The straining moment at A_1A_2 depends on the moment of the section and on the stress on the material. If the stresses were of equal magnitude over the whole section, then the moment would simply be the moment of the area multiplied by the stress, but as the stress is increased uniformly towards the edges of the beam the moment is the product of the moment of inertia I of the section of the beam at A_1A_2 and the maximum stress p divided by its distance y from the point of no stress, A. We therefore have the following:

$$I \times \frac{p}{y} = W \times a,$$

$$\text{or } p = W \times \quad \times y$$

This shows that the maximum stress on a girder is equal to the bending moment (W × a) at the point considered multiplied by the distance which the highest stressed fibres are from the point of no stress, the whole being divided by the moment of inertia of the cross section of the material. Exactly the same formula holds good in the case of a ship. The bending moment may be estimated as described above.

Moments of Inertia of Sections. The moment of inertia of the material section is estimated as follows. Let **154** represent a half cross section of a ship. A horizontal line NN_1 is drawn at about one-third the vessel's depth above the top of keel. The sectional area of each of the individual plates is then determined and tabulated. Each of these sectional areas is then multiplied by the distance of its centre of gravity from NN_1, and also by the square of this distance. All the sectional areas of the plates and angles both above and below NN_1 are then added together, while the products of the areas and their distances from NN_1 are added up separately for the parts above and below NN_1. The difference between the two sums of these products represents the moment of the section with reference to NN_1, and if this be divided by the total sectional area the result is the distance of the centre of gravity from NN_1. It so happens that the horizontal line of no extension or compression passes through the centre of gravity of the section, and this line xx_1, called the *neutral axis* of the section, may therefore be drawn parallel to NN_1. The moment of inertia I of the section is the sum of all the products of the areas and the squares of their distances from NN_1 with a deduction of the product of the total area and the square of the distance between xx_1 and NN_1. The point of maximum stress is the one farthest removed from xx_1, which in nearly all vessels will be at the deck, either at the middle or at the side. Its distance from the neutral axis is usually designated y, and the maximum stress is therefore, M being the bending moment:



154

$$p = \frac{M}{I} y$$

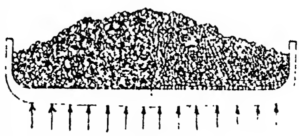
Effect of Depth of Girder. This is a frequently occurring expression in all strength

calculations. It will be observed that the stress at any place will vary as the bending moment and inversely as the moment of inertia of the section. Furthermore, it will vary as the distance from the neutral axis. For a given amount of material the moment of inertia will be larger the deeper the section is. The deeper vessel is therefore, other things being equal, the stronger. From the fact that the strength depends on the moment of inertia it will further be evident that it will be advantageous to place as much as possible of the material at the top and bottom of the structure, leaving only a sufficient amount of plating at the side of the vessel to resist the other forces acting there. The stress estimated by the above formula is that on an uninjured section of material, and if the stress in way of the rivet-holes is desired, it is necessary to multiply p by the ratio $\frac{s}{s-d}$ where s is the spacing of the rivets centre to centre and d their diameter.

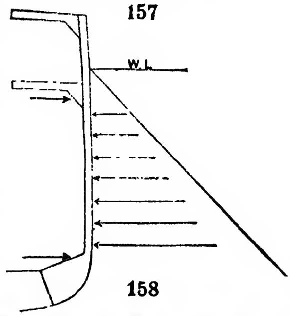
155

156

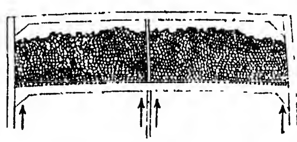
Floors, Beams, and Girders. Just as the ship is, as a whole, a large girder, so all its parts are dependent for their strength on smaller girders. At the bottom of the vessel the floors form girders across the ship to carry the cargo and resist the pressure of the water. At the sides of the vessel the frames form girders from bottom to deck, and at the top the beams form girders supporting the loads on the deck. Each floor may be looked upon as a girder in conjunction with part of the shell plating, as shown by **155** for a single-bottom vessel and by **156** for a ship with an inner bottom. It will act as a beam supported at its ends, in this instance the sides of the ship, and it will be loaded with the weight of cargo on the top and with the pressure of the water below, as shown by **157.** If these forces are equally distributed and of equal magnitudes there will be no bending tendency. On the other hand, if the weights carried are in excess of the upward pressure, or if the latter is in excess of the weights, then there will be bending moments, which must be resisted by the floors. The strength of these is represented by the moment of inertia of the sections shown in **155** and **156,** and what was said with regard to the moment of inertia of the midship section of the ship applies equally here—the deeper the girder the stronger it will be for the same amount of material, because the greater the moment of inertia will be. The water pressing against the side of a vessel tends to bend the frames inwards, and there is usually no inside pressure tending to counterbalance the outside effort. The frames will therefore act more or less as a girder fixed at the bottom and at the decks and loaded with a pressure gradually becoming greater as the draft is increased [**158**]. The beams support the loads they carry between the pillars and the frames, as indicated by **159.** The beams of the uppermost deck carry a load only momentarily when a wave may be breaking upon them, but they have to be of considerable strength to resist the effect of such bodies of loose water. Water-tight bulkheads are stiffened in the same manner as the side of the vessel to resist the pressure of water that may accidentally have got into one of the holds.



157



158



159

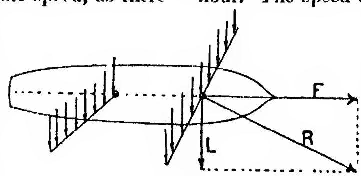
Value of Experience. From the above a rough idea may be gathered as to the nature of the strength required in a ship, but it will be readily understood that a great many other complicated straining tendencies are at work in a ship when she is at sea, rolling and pitching among waves. The effect of these may be more or less acurately estimated, but it is in any case usual to allow a fair margin for strength for unforeseen eventualities. The experience gained by existing vessels is of the greatest value in forming a reasonable judgment as to the amount of margin necessary to prevent straining under exceptional circumstances. It should always be the aim of the designer to ensure the necessary strength with the minimum amount of material; because every ton of weight saved in the structure of a vessel means a ton more carrying ability.

The ratio between the dead-weight carried by a vessel and the weight of the ship complete is a measure of the efficiency of the distribution of the structural material. At the present time it is 2 to 3, but it is a figure which has been steadily increased, and will continue to be increased, as there are still ample opportunities of improving the structural designs of ships.

Speed of Ships. Speed is not a primary necessity for a ship like stability and strength. At the same time, some measure of it is absolutely essential in any efficient ship. It would always be in the owner's interest to have a vessel as fast as possible, provided the weight of machinery and coal remained the same. As the speed increases, so does, however, also the weight of the machinery and coal necessary to drive her, which means that the dead-weight is reduced. It is a problem for the owner and designer to solve to what extent the cargo-carrying capacity of a vessel for a particular trade should be sacrificed for the sake of gaining speedier transit. Where passengers only are carried, the dead-weight is not so important, and higher speed is therefore the rule in such cases, although even here the cost of the coal burnt and the upkeep of the more powerful engines and boilers place a limit to the economical speed.

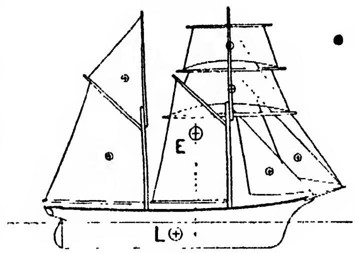
Speed of Sailing Vessels. The speed of sailing vessels is an indeterminable quantity, in so far as it depends on the strength of the wind. For the same velocity of wind, the speed will vary with the amount of sails provided. This must, however, be largely governed by considerations of the size and stability of the vessel. All sailing ships are very much alike, and a certain amount of sail area is provided in proportion to their size, and they then sail with what speed they may attain. The form of the vessel has some influence on the speed, but here, again, the cargo-carrying necessity governs this element to a large extent. In most sailing vessels the full-bodied model which will carry a good dead-weight is more profitable than the sharper-formed one conducive

to a greater speed. The direction of the wind need not necessarily be the direction in which the ship moves. In fact, it is unusual for a vessel to encounter a steady stern wind, and a skilful navigator knows how to utilise a wind coming from any direction. A side wind is, as a rule, the one that suits him best. Figure **160** explains how it is that such a beam wind may make the vessel go ahead. The wind is represented by the arrows, and as it strikes the sails it is deflected, and a normal pressure, R, is the result. This pressure may be resolved into two forces, one, L, tending to move the vessel sideways, and another, F, tending to move it forward. The former causes but little motion, as it is difficult to move the long ship sideways through the water. F, on the other hand, will move the vessel forward with considerable speed, as there is comparatively little resistance to motion in this direction. Most fine and swift vessels will sail quicker with a beam wind than with a stern wind, chiefly because their sail arrangement admits of a larger area being utilised in the former instance. When the wind is right aft, the sails on the various masts more or less shelter those immediately in front of them.

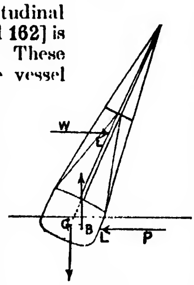


160

Wind Pressure on Sails. The side pressure of the wind on the sails is balanced by a corresponding pressure of the water on the opposite side of the vessel. The former acts as a force applied at the centre of gravity of the entire sail area, called the *centre of effort* [E, **161** and **162**], the latter as a similar force applied at the centre of gravity of the immersed longitudinal middle-line plane. This point [L, **161** and **162**] is called the *centre of lateral resistance*. These two forces, W and P [**162**] tend to heel the vessel until the righting moment of stability has become large enough to resist such action. The ship will then remain in this inclined position while being driven forward. The heeling moment will be equal to the resisting moment when the product of the total wind pressure, W, and the vertical distance between the centres of effort and lateral resistance is equal to the product of the displacement D and the horizontal distance between the centres of gravity, G, and buoyancy, B. A vessel with a lofty rig or with a large sail area will therefore require a greater amount of stability than one with low masts or with a small sail area. As a wind increases gradually from a calm, the speed of a vessel will increase, but when a certain force is reached, she will be heeled over to too great an angle, or the masts and rigging will be strained too much, and the sail area has to be reduced by reefing or by the removal of some of the individual sails, and this process will be going on as the force of the wind increases, until the vessel may be practically without sails. As the wind increases, so the effect of the waves, which tend to impede the progress of the vessel, will increase, with the result that the speed is very much reduced. It is, therefore, only within narrow limits that the speed of a ship is augmented with a higher wind velocity. The highest speed that sailing vessels attain for any length of time is 12 to 14 knots an hour with favourable winds.



161



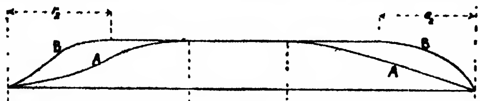
162

The Speed of Steamers. The speed of a steamer is a more definite quantity than that of a sailing vessel, as mechanical propulsive power of a given magnitude is provided. The earliest steamers were, however, provided simply with a set of engines, and they obtained such speed as they could, as it was then quite impossible to calculate the power required to propel a vessel through the water at a given velocity. As time went on, and experience was gained, it was possible to estimate fairly accurately from the results obtained with a certain vessel and a certain power what the speed would be for a similar vessel with a smaller or larger horse-power. At the present time an owner having a steamer built expects to get not only the speed and horse-power guaranteed, but also the amount of coal burnt per hour. The speed of an object being forced through the water will naturally depend, in the first instance, on the driving power, and, in the second instance, on the resistance the object offers to the motion. It is the marine engineer's business to provide the engine-power, and the naval architect has to design the ship so that the resistance to motion is a minimum. It might be imagined that as water is an easily divided fluid, it would offer but little resistance to the passage of a body through it, but the contrary is the case. The resistance of a ship is of two kinds. The sides and the bottom must, in the first instance, be rubbed against the water the vessel is moving past, much in the same way as an object being dragged along on land rubs against the ground, and thereby offers resistance to motion. This is called the *frictional resistance* of the ship. It will depend on the size and character of the outside surface of the ship, and on the speed. With rough bottoms covered with marine growths, the friction is very large, but with ordinary clean and well-painted bottoms, there is little variation in the frictional resistance. The amount of surface and the speed are, therefore, the chief elements to be considered. It is found that the resistance varies directly as the wetted surface of the vessel and directly as the square of the speed. Let F be the total resistance due to friction when the vessel is moving at a speed of S knots per hour, C the resistance of 1 sq. ft. of surface when moving at a speed of 1 knot per hour, and A the wetted surface of the vessel. The resistance due to friction is then:

$$F = C \times A \times S_2.$$

Wave-making Resistance. In passing through the water a ship causes a momentary channel to be made. At the bow the water is parted, and at the stern it again closes in upon the vessel. The result of this forcible parting is a piling up of the water or the creation of the familiar wave at the bow of every vessel going at a fair speed. The production of such a wave or series of waves requires a force of considerable magnitude, and it is, therefore, another element of resistance to the progress of the vessel. The amount of water piled up or the magnitude of the wave-making resistance depends largely on the size and form of the vessel and on the speed, but is independent of

the amount of wetted surface. This part of the resistance is a much more difficult one to deal with than the part due to friction. It is quite impossible to estimate mathematically what the wave-making resistance of a ship of given form will be. Generally speaking, it will, however, be augmented with an increase in the fulness of the form. Let 163 represent two water-lines of different ships. The degree



163

of fineness may be measured by the lengths of entrance and run or the lengths of the wedge-shaped parts forward and aft respectively. The relative wave-making resistance of the vessels A and B will thus depend largely on the relative lengths of their entrances e and e_2, and of their runs r and r_2. B will thus have a much greater resistance than A. The length and draught of the vessel, as well as the form of the cross-sections, will also have some influence on the wave-making resistance. It was seen that the frictional resistance depended upon the square of the speed. The wave-making resistance increases, on the other hand, more rapidly with an increased speed. For moderate speeds up to about 12 knots per hour the resistance is thus chiefly due to friction, but when very high speeds are reached, the wave-making resistance becomes the most important. For each ship form there is usually a limit to the economical speed at which it can be driven. It would thus be very expensive to drive a very bluff-shaped vessel through the water at a very high rate of speed.

Experimental Tanks. The resistance of ships is now often estimated by experiments on models. When the resistance of one vessel is known, it is possible to estimate pretty accurately what the resistance of another of identical form but different dimensions will be. Some of the large shipyards have, therefore, long tanks, where they can determine the resistance of models by towing them through the waters at certain speeds. From the results thus obtained it is possible to estimate what the resistance of the full-sized ship would be. The models are made of paraffin wax to the exact form given by the drawings, hollowed out, and trimmed by small weights to float at the required draught. They are then fixed to a trolley travelling over the tank and towing the model, while the exact speed and resistance are being simultaneously and automatically recorded. Such experimental tanks are very valuable for the determination of the horse-power necessary to give a vessel the required speed, but they are very expensive to construct and to operate. It is, therefore, only few designers who have such means available to assist them in their estimates, and those who have not must resort to calculations based upon the results of existing vessels, with the particulars of which they are familiar.

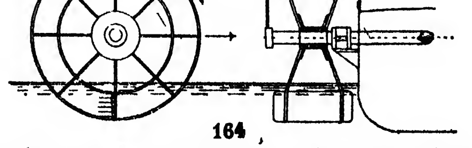
Approximate Methods of Determining Horse-power. It was seen that the frictional resistance varies as the square of the speed and, also, that it constitutes nearly the entire resistance of a ship at the lower velocities, and the greater part even at the somewhat higher speeds. As, moreover, the wave-making resistance also varies, more or less, as the square of the speed, the whole of the resistance may be assumed to vary as the square of the speed, S, of the vessel, particularly where the comparison is only applied to cases with small variations in the speed. Further, the frictional resistance varies as the amount of the vessel's wetted surface. For similar models the area of the surface will vary as the square of the linear dimensions, or as the two-third power of a cubical expression (say, the volume or weight of the displacement D). Comparing nearly similar ships, this expression $D^{\frac{2}{3}}$ may also be taken to be a rough measure of the wave-making resistance. The entire resistance may, therefore, be taken to be approximately represented by the product $D^{\frac{2}{3}} \times S^2$. When the resistance of a ship is known, the force to overcome it is known, and the required horse-power can be determined, as it will be the product of the resistance and the speed. If I.H.P. is the indicated horse-power and C a constant, then:

$$\text{I.H.P.} = C \times D^{\frac{2}{3}} \times S^3.$$

When the displacement, D, the speed, S, and indicated horse-power, I.H.P., are known, then C can be determined for that particular ship, and as long as the variations in size, form, and speed are not great, there will be little variation in the value of C. The horse-power required to drive a vessel of a slightly different displacement and slightly different speed is then determined by extracting the cube root of the number representing the tons of displacement, squaring the result, and multiplying it by the speed cubed and by the constant, C, as determined from the results of previous ships.

Effect of Size, Speed, and Propellers. The above expression for the horse-power shows the relative effect of the size and the speed of the vessel. For every per cent. increase in the size of the vessel as represented by the displacement, only $\frac{2}{3}$ of 1 per cent. increase in horse-power will be required to maintain the original speed, whereas for every 1 per cent increase in the speed of a vessel, the power will have to be increased 3 per cent., the displacement remaining the same. The enormous effect of the speed or the power required may also be seen from the fact that if the displacement is doubled it is only necessary to add about 60 per cent. to the horse-power to maintain the speed, but if the speed is doubled, 700 per cent. of an increase is required in the power, assuming the displacement to remain constant.

The horse-power determined by model tank experiments is that required to drive the vessel at the desired speed, and considerable addition must be made to this to obtain the number of indicated horse-powers it may be necessary for the engines and boilers to develop. The reason for this is that a great amount of power is lost between the pressure of the steam in the cylinders and the pressure of the propeller blades on the water. This



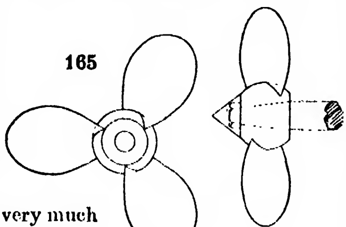
164

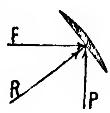
waste of power is chiefly due to the friction of the machinery in the cylinders, bearings, thrust blocks, etc.; but a large amount of power is also lost in more or less inefficient churning of the water by the propeller. In many cases as much as double the amount of power required to overcome the resistance

of the vessel must be developed by the engines. It will thus be seen that model experiments do not solve the entire problem of determining the dimensions of engines necessary to give the desired speed. The horse-power given by the above approximate formula is usually that indicated by the engines; so that, although this method is rougher than the experimental one, it is more direct.

Paddle and Screw Propellers. A very important factor in the problem of propulsion is the propeller. The first type of these to be used and the simplest to understand is the paddle-wheel. As 164 shows, it consists of a wheel fitted with floats very much like those of a water-wheel. One wheel is fitted on each side of the vessel, and as they are being turned round by the engines, the floats will exert a pressure on the water they drive backwards. It is the return pressure of this water that sends the vessel ahead. The vessel will, however, not move forward a distance equal to the periphery of the wheel for each revolution, as in the case of a wheeled vehicle on land. The water will, to a certain extent, slip. The speed of the vessel will thus be the number of revolutions multiplied by the periphery of the wheel less a certain percentage called the *slip*, which will vary according to the design of both ship and propeller.

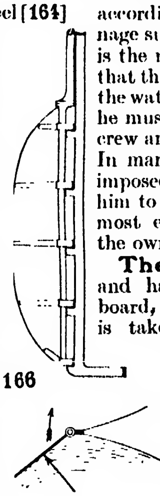
165





It will be observed that the floats of the wheel [164] strike the water rather obliquely at the first touch, and thus cause an unprofitable downward pressure in the water. To obviate this, all paddle-wheels are now constructed with feathering floats, which cant slightly, and are nearly vertical during the whole of their passage through the water. As already explained in an earlier article, paddle-wheels are now used only for river or channel vessels.

For all sea-going steamers, screw propellers are now invariably used, as they are of handier dimensions, and can be fitted deep down in the water, where they are not so likely to be damaged by being struck by waves. A ship's screw consists of a more or less spherical part, called the *boss*, which is hollow and fixed on to the shaft. On this boss there are two, three, or four warped blades very much like the wings of a windmill. Figure 165 shows a propeller with three blades. The after sides of these are parts of screw surfaces. The pitch of any screw is the distance it moves either forward or back during one complete turn. In the same way the pitch of a propeller is the distance it would travel for one revolution if it were moving in a solid. As water is not a solid, there is usually some slip with this form of propeller, as in the case of the paddle-wheel. The speed of the vessel will therefore again be the pitch of the screw multiplied by the number of revolutions, diminished by a greater or smaller percentage. To ensure a high degree of efficiency it is essential that the size, form, and pitch of the propeller should be properly adjusted to the revolutions and power of the engines.



166

Steering. All vessels, whether propelled by sail or steam, are steered by a rudder, which has been of practically the same design through many centuries. It consists of a blade, which is straight on the fore edge, where it is hinged on to the sternpost and rounded on the free after edge, as shown by 166. It is free to be turned through an angle of some 30°. to 40°. on either side of the middle-line plane. When the rudder blade is thus turned to one side, as shown by the plan view [166], it will press on the water it comes in contact with as the vessel moves ahead. The stream of water which impinges on the blade causes, of course, an equal opposite pressure to be applied to the rudder, as indicated by the arrow, which has the effect of sending the stern of the vessel in the same direction, and thus tends to turn the ship. Rudder blades are now nearly always made of a single steel plate stiffened by either wrought iron or cast steel ribs or arms.

Difficulties of a Designer. A designer has to see that his ship is floatable, stable, strong, speedy, steerable, etc. He must provide the owner with a vessel that will carry a large amount of cargo on a small draught, and be propelled with a minimum of coal consumption; but in addition to all these primary and unavoidable difficulties, he has got to bear all the various Government regulations in mind, and design his ship so as to be as profitable as possible under the more or less arbitrary legal requirements of the country where she is to be owned. He has to arrange his structural details in such a way that the tonnage of the vessel is either large or small, according to whether the earning of a heavy tonnage subsidy or the payment of a small harbour due is the more profitable. He must further make sure that the vessel has the legal amount of volume above the water to act as safeguard against foundering, and he must provide sufficient life-saving appliances for crew and passengers in case the vessel does founder. In many other ways the designer is hampered by imposed regulations and conditions, and it is for him to effect such compromises as will result in the most efficient and all-round satisfactory ship to the owner.

The Trial Trip. When a steamer is built, and has got her engines, boilers, and outfit on board, and is in complete working order, she is taken on what is termed her *trial trip*. In large passenger vessels with a high guaranteed speed this is an important point in her completion; but if she is a cargo tramp it usually consists in her making a little pleasure trip with her builders and owners and their friends on board. During the trip the speed is, as a rule, tried by her steaming parallel to a measured mile marked by posts on the shore. From the time she takes to accomplish this distance her speed in knots is easily calculated. At the end of the trial trip the ship is formally handed over to her owners, and it remains for the experience of the next few years to show to what extent her designer has succeeded in producing a staunch and good vessel that will add to his fame and will earn a profit for the owners.

continued from page 6059

THE PROCESSES OF BREWING

Malting. Hops and Yeast. Producing, Boiling, and Hopping the Wort. Gravity of Beers. Fermenting the Wort. Racking and Fining

THE importance of malt in brewing is amply recognised, and the brewer cannot take too great pains to obtain, or make, malt of the highest grade. Malt is the result of checking the natural process of germination of any cereal at a particular moment. In the brewery, barley provides the only first-class malt, and malt barley must form the principal ingredient in any mash. In some breweries a small proportion of prepared maize or rice or sugar is used. This substitution cannot be regarded as an adulteration but is rather employed to produce a particular type of beer.

In a few large breweries only is the malt actually made on the premises, most brewers purchasing their malt ready made from maltsters.

Malting. Malting may be divided into four stages: *steeping*, *couching*, *flooring*, and *kilning*, which follow one another in the order given.

The grain is shot into a cistern and covered to a depth of about 5 in. with water. All husks that float are skimmed off, for they are bad and would eventually contaminate the malt. The grain is kept under water for from 40 hours to 60 hours until it has swollen up and the process of germination been thereby started. If a corn when crushed between the finger and thumb breaks up into a flour or meal fairly readily, the steeping is complete. If a paste results, the grain is over steeped.

The next step is couching. The wet grain is removed from the steeping tanks and piled up in heaps called *couches*. There it remains for from 20 hours to 48 hours, the object being to enable it to generate sufficient heat to germinate evenly and well. Then the grain is spread out on the floors of the flooring-rooms and there germination progresses rapidly, the plumule growing up the back of the grain, and little rootlets being put forth. The maltster continually examines his grain, watching to see how far the acrospire or plumule has progressed. When it is between half way and three-quarters up the back of the grain, according to the fancy of the maltster, germination is stopped by the fourth process—namely, kilning. The malt is run on to the floors of the kilns, and there it is gradually heated, the operation commencing at about 90° F. When the moisture is nearly all driven off the temperature is gradually raised, the exact point reached being determined by the character of the malt desired.

Black and brown malts for black beer brewing are literally caramelised on the kilns, while pale malts are only heated to 185° F. During the process of kilning a good many of the rootlets come off and the remainder will be removed by the screening which the malt undergoes.

A First-class Malt. Undoubtedly experience is the great factor in malt buying, and only after long years can the brewer feel sure that his opinion is sound. In the first place the malt must be evenly grown. That is to say, that in a sample, the length to which the acrospire has grown must be about the same in every individual grain. In very few corns should the husk be pierced, and in very few cases should the growth not have reached half way up the back of the grain. The rootlets should be uniform in colour, and not be a mixture of colours. The total number of bad corns should not be above 3 per cent. and of these black sheep only a very few should be mouldy corns, for these would ruin the beer. The extract from the malt should exceed 90 lb. per quarter for best English malts.

Hops and Yeast. The third essential in brewing is the hop. The brewer buys hops in the open market, and on the judgment of his buyer a good deal of the success of the brewery depends. For the finest pale ales the new hops, mixed with a small proportion of the previous year's crop for the first few weeks of the season, should alone be used. For "dry hopping" also, the very best of the new hops should be used, and best Goldings and Worcesters are the classes recommended for this purpose by experts.

Yeast is a microscopic plant which grows very rapidly and, at the same time, converts the sugar in the beer into alcohol and carbonic acid. Under the microscope the plant should appear to consist of a number of round, well-nourished cells. The cells should be filled with a clear fluid, and should show no signs of granulation. Granulated cells are old ones which are dying. If there are many to be seen in a sample the yeast should be rejected. The micrographs (by the courtesy of the British Pure Yeast Co.) show ordinary Burton yeast [**5**] and yeast with elongated cells taken from beer in process of fermentation [**6**]. In Burton yeasts it is usual to find a number of oval cells, and as long as these seem fat and well-nourished the yeast is good. If, under the microscope, any rods are seen the yeast will decompose the beer, for those rods are bacilli giving rise to other forms of fermentation which are not wanted by the brewer. The age of the yeast is important, and it may be held that no yeast should be used for high-class brewing which is more than a week old.

Process of Brewing. We shall now make a trial brew to supplement the information which the reader will have gathered from the preceding pages. The first thing necessary is to warm the mash tun. This is done by running steam or hot water into it, and keeping the covers on. While the vessels are being heated the malt is weighed out, and after being carefully screened is passed through the grist mill.

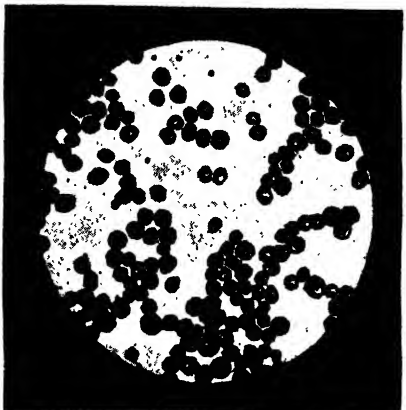
Now comes the question of the stiffness of the mash. The brewer's object is to get all the available extract out of the malt, and to do this it will generally be found that from two to two and a quarter barrels of water to each quarter of English malt weighing 336 lb. will give a good workable mash. More water makes the mash too thin, and less would make it so stiff as to greatly increase the difficulty of working.

Our malt is now ground and in the grist case, the mash-tun is warm, and everything is ready. Hot liquor, just under boiling point, is run into the tun, and the taps are opened. As soon as the temperature at the outfall pipes is the same as at the inlet, the taps are shut, and the calculated quantity of water to be used for the mash is run in.

The lids are put on, and the whole allowed to stand for about half an hour to thoroughly steam the interior of the tun. Then the covers are opened, and the liquor soon falls to the temperature at which mashing is to be effected, which should be between 140° F. and 152° F. for pale ales, and for black beers between 144° F. and 150° F.

Mashing and Sparging. The moment the liquor is ready the slides of the grist case are opened, and the grist run into the mash-tun as quickly as possible, while the rakes are set going at such a speed that they will revolve once in a minute. As soon as all the grist is in the covers are shut, and the rakes kept going for a quarter of an hour to ensure the mash being well mixed. The temperature of the mash is now taken, and after another fifteen minutes a small quantity of water at a higher temperature than the mashing heat is run into the tun through the underlet pipes at the bottom of the tun. This is to bring the total heat up a little. The rakes are now run three times round the tun, and then the mashing part of the process is completed.

The mash now stands in the tun for two hours, when "the taps are set," which means that the under taps are opened and the hot liquor, which now becomes *wort*, is run off to the under-back, where it must be kept at an even temperature, or is run straight to the copper. The spargers are now set going, and the brewer watches the heat of the sparging water very carefully, his object being to get all the extract out of the goods, but to get none of the soluble starch therefrom. Accordingly, he tries to make the sparging maintain the heat of the goods at about 156° to 158°, but never to permit it to rise to 160° nor to fall below 152°. The temperatures of sparge waters necessary to effect this vary according to the brewery and its construction, but it is as well always to sparge on a certain quantity of really hot water (say, about 170° to 175° first of all), to restore the heat to the upper strata of the goods which have got cooled during the two hours mashing. Then, when the temperature begins to rise, the heat of the sparges must be lowered gradually, or the goods will get heated above 160°, and the wort will contain free starch.



5. PHOTO-MICROGRAPH OF BURTON YEAST

Difficulties in Mashing and Sparging. Taken all round, about four hours' sparging will secure the proper cleansing of the goods, if the apparatus is all that can be desired, and the sparges should be graduated carefully, much less being run off in the first hour than in those succeeding. Mr. Southby advises that in the first hour three-quarters of a barrel per quarter of malt used is ample to run off, and twice that should be run off in the last hour.

There are two great sources of annoyance to the brewer at this stage of work. The first is called *flooding of the goods*, which always brings about imperfect drainage of the wort, and the second is the production of a cloudy wort. Excessive stirring will cause flooded goods, and the remedy is obvious. If, however, it is found that less stirring in that particular tun tends to the formation of balls in the goods, then the plant is defective, and either rakes with an increased speed must be fitted, or an outside masher added to the brewery. Flooded goods may result from the presence of an excess of floury matter in the grist. To obviate this, the malt must not be ground so finely in the grist mill, and where pure malt only is used this always cures the trouble.

Cloudiness of the wort may be caused by particles of the goods being forced through the false bottom of the tun. When this is the case on the first setting of the taps, and if, later, the wort runs clear, the cloud is of little importance, for the cloudy wort can be returned to the top of the goods, and the clear wort run off to the under-back. If the cloudiness continues, the plant, again, is defective, and will have to be seen to. A cloudiness which sometimes makes its appearance at this stage of brewing, and is much more serious, may be due to the use of unsound malt, or may be brought about by heating the mash too much. In either of these cases the wort is practically useless.

Boiling and Hopping. The brewer has now obtained his wort by the recognised English method of infusion, and it has either been run direct to a steam-heated copper, or has been collected in the under-back.

The wort at this stage is liable to undergo change, and the general principle is to try and get it all into the coppers as quickly as possible. The change, however, is sometimes advisable, especially when the malts are deficient in diastatic power, and then the brewer allows his wort to "stew" a little at a temperature of 150° to 165°. This can be effected either in the under-back or in the copper. As soon as the wort reaches 165° it must be raised to the boiling point as quickly as possible to stop any further stewing. While the wort is boiling in the copper the hops are added, the practice in different breweries varying. Some add all the hops at once; others add only a portion, and keep a quantity of the finest hops to be added just before the contents of the copper are turned out. This last method preserves the aroma of the hop very well.

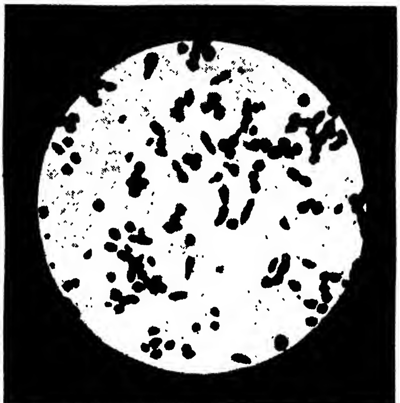
At whatever period of the boiling the hops are added, they must be well pressed down into the seething wort so as to ensure that they are all well wetted. Any hops that float dry on the surface lose their aroma in the steam and do not benefit the wort. For at least an hour, and preferably for two to two and a half hours, the wort is kept in active ebullition, second wort requiring a little longer than first wort where the coppering is done in two stages. Then the contents of the copper are run as quickly as possible into the hop back. For a quarter of an hour the wort stands in the hop-back to allow the sediment to settle, and then it is run off bright to the coolers, the hops remaining behind.

Cooling and Refrigerating. Besides reducing the temperature of the wort to the right point for fermentation to take place, the coolers and refrigerators [4] are essential to complete the aeration of the wort. Whatever forms of these are used, the wort must be reduced to 60° F. in less than six hours from the time it leaves the copper, or else dangerous changes may take place in the wort, and bad beer result. From the coolers

the wort runs either to the fermenting vats at once, or is drawn off into the collecting vessel, there to await the advent of the Excise officers, who at this stage come to determine how much duty has to be paid by the brewer on the beer he is now about to make.

Specific Gravity of Beer. There are two methods of calculating the value of any particular beer. One states the beer in terms of pounds per barrel, and is based on the following facts. It is known that a barrel of pure water weighs 360 lb. avoirdupois, and consists of 36 gallons. Now take a barrel of water, remove one gallon, and the weight will be 350 lb. Fill up the vacant space with a gallon of sugar solution weighing 16 lb., and the total weight of the full barrel will be 366 lb. This, being 6 lb. in excess of the normal weight of a barrel, would be spoken of as a liquor of 6 lb. gravity. This strength is determined by means of a saccharometer, an instrument which is immersed in the beer or wort, and sinks more or less according to the gravity of the fluid. The point to which the instrument sinks is read off and that gives at once the gravity of the beer in pounds.

This is not the method adopted by the Excise officers. They use a more accurate instrument, known as *Bates' Saccharometer*, which is really a modified hydrometer adjusted for beers and worts. It is graduated on the basis of distilled water being of the specific gravity 1·000 at normal temperature. The reading is taken as well as the temperature of the liquid. If the temperature is above or below 60° F., the operator refers to the tables provided and makes the correction necessary. The depth of the fluid in the main collecting vessel or tun is taken, and the area of the floor of the vessel is known, so a simple calculation will tell at once how many barrels of wort or of beer are in the tun.



6. GROWING YEAST CELLS IN FERMENTING BEER

The Customs make this experiment before fermentation takes place, and they have adopted a gravity of 1·055 as a standard, charging the brewer 7s. 9d. for each 36 gallons of beer or stout at that gravity which could be made from the wort present, after making an allowance of 6 per cent. for wastage during later stages.

Fermentation. The temperature at which the process is started depends on the original gravity of the wort. For strong beers 58° is a good heat, for ordinaries 60° is the best, while for beers which are expected to be consumed immediately, as high a temperature as 63° may be used.

As the wort is run into the tuns the yeast is mixed with it, the process being known as *pitching*. The amount of yeast again depends on the strength of the worts, the quality of the water, and the amount of hops used, but varies from 1 lb. per barrel for mild ales to 4 lb. for very strong stingoes.

When the wort, mixed with yeast, is all in the tuns, fermentation commences. Gradually a white foam rises to the top, and as the process continues this foam grows into mountains of froth, which eventually break down into an ordinary, thick, creamy yeast head, which tells the brewer that fermentation is nearly at an end. But he does not depend on his eye to know when to stop fermentation, or *cleanse* the beer, as it is called. At least three times a day while fermentation is going on samples are drawn from the tun and tested with the saccharometer. At the end of the first day it will be found that the gravity of the beer goes down about 1 lb. every three or four hours, while the temperature in the tun rises 1° or 2° in the same period. If this speed is not attained, then the beer must be roused, or stirred up, or warm water run through the attemperators. On the other hand, if the beer is getting on too fast, the temperature may be reduced by running cold water through the attemperators.

Cleansing and Racking. When the beer has reached the gravity which the brewer desires, he cleanses the beer of yeast either by skimming all the yeast off the top of the tun and returning it to the yeast backs, or he runs the beer and yeast into large barrels and lets the yeast work out of the bungholes, care being taken to keep the vessels perfectly full. This is the process used at Burton. When the beer is cleansed it is run into the racking squares and allowed to settle for a short time, so as to permit the yeast in the beer itself to settle, for yeast in the cask may cause trouble later on. This part of the process often takes place in the fermenting vat.

For first-class ales, and for export ales, and even for the best Dublin stouts, brewers often have recourse to "dry hopping"—that is to say, that a certain quantity of the very finest new hops is introduced into each barrel through the bunghole before the beer is run in from the racking squares and the casks closed with shives. For beers which are to stand for long, porous spiles must be fitted at first or else the head of the cask may be blown out.

Fining. Fining beers is often done in the brewery just before the trade casks are sent out; but frequently the publican fines his own ales. The finings are made of isinglass, and are either white or brown. They are generally prepared by working up about 4 lb. of isinglass in about a hogshead of weak acid or sour beer; of either class of finings from one pint to two pints to the barrel will suffice unless the beer be very stubborn indeed. The brewer must discover by experiment what is the smallest quantity of finings that will render his ales bright, and must not exceed that.

The prospective brewer should attend a good brewery as a pupil for some time so that his eye may get trained to perceive the tiny indications which tell him that all is going well. If he wish to enter into the chemistry of the art he will find the "Laboratory Text Book for Brewers," by Lawrence Briant, an excellent elementary work, and for the variations in the processes of brewing, as well as for the higher science of his calling, the "Handbook of Practical Brewing," by E. R. Southby, published by the "Brewing Trade Review," of Little Trinity Lane, E.C., a most useful work. To enable the brewer to keep abreast of the times, the "Brewing Trade Review" is one of several useful papers.

BREWING *concluded; followed by* WINES AND CIDERS.

TRIGONOMETRICAL RATIOS

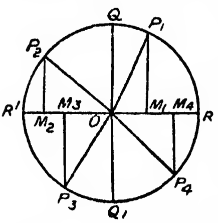
Definitions of the Ratios. Relations Between Ratios of the Same Angle. Changes in Magnitude of the Ratios

continued from page 6086

By HERBERT J. ALLPORT, M.A.

8. The Trigonometrical Ratios. Suppose an angle of any magnitude A [see note, Art. 4] to be traced by the revolution of OP from the initial position OR. Draw QOQ′ at right angles to ROR′. Unless the angle A is an exact number of right angles, the revolving line must take up some position in one of the four *quadrants* ROQ, QOR′, R′OQ′, Q′OR. In the figure, four different values of A are shown, corresponding to the four positions P_1, P_2, P_3, P_4 of P.

Draw PM ⊥ to OR. Then OM is the projection of OP on the initial line, and MP is equal to the projection of OP on OQ (which makes + 90° with the initial line). From the three quantities, OP and its projections, we can form *six* ratios. These ratios are of great importance in treating of the angle A, and each has a separate name.



(1) The ratio of MP to OP is called the *sine* of the angle A.

(2) The ratio of OM to OP is called the *cosine* of the angle A.

(3) The ratio of MP to OM is called the *tangent* of the angle A.

The remaining three ratios are formed by inverting the first three Thus,

(4) The ratio of OP to MP is called the *cosecant* of the angle A.

(5) The ratio of OP to OM is called the *secant* of the angle A.

(6) The ratio of OM to MP is called the *cotangent* of the angle A.

The *order of the letters* in the above ratios must be carefully noted, since OM and MP stand for the projections of OP on OR and OQ respectively, and *these projections vary in sign according to the quadrant in which* OP *lies*. For example, if A is an angle lying between + 5 right angles and + 6 right angles, the revolving line will be in the second quadrant, such as OP_2, and its projection OM_2 is then *negative* [Art. 7]. The cosine of the angle A is then $\frac{OM}{OP}$, *i.e.*, a *negative* quantity, by the algebraic rule of signs.

The six ratios thus defined are called the trigonometrical ratios of the angle A. They depend only on the magnitude of A, and not on the length of OP. For if OP were taken of a different length, the new triangle, OPM, would be similar to the old one, and therefore (*Prop.* 56) the ratios of the sides would be the same as before.

9. Instead of "sine of the angle A," etc, we speak of sine A, cosine A, and so on; while, in writing them, we abbreviate them into sin A, cos A, tan A, cosec A, sec A, and cot A respectively.

10. From the above we see that to obtain the ratios of any given angle we take any point in either of the arms containing the angle, and draw a perpendicular from that point to the other arm, produced if necessary. The beginner will do well always to try and imagine that the arm to which he draws the perpendicular is in the position OR of the figure to Art. **8**; he will then have no difficulty in seeing in which quadrant the other arm must lie, and, consequently, whether OM and MP are positive or negative.

11. Note that the ratios of an angle are mere *numbers*, or *fractions*. We may therefore have any *power* of a ratio. For example, the third power of sin A would be $(\sin A)^3$. This is always, for convenience, written $\sin^3 A$. Again, such an expression as cos A . tan B means the *product* of the cosine of angle A and the tangent of angle B.

12. Relations between the Ratios of the same Angle. From the definitions of Art. **8** it is evident that

(1) $\sin A = \frac{1}{\operatorname{cosec} A}$.

Similarly,

(2) $\cos A = \frac{1}{\sec A}$,

and

(3) $\tan A = \frac{1}{\cot A}$.

Also,

(4) $\tan A = \frac{MP}{OM} = \frac{\frac{MP}{OP}}{\frac{OM}{OP}} = \frac{\sin A}{\cos A}$;

and, therefore,

$$\cot A = \frac{\cos A}{\sin A}.$$

By referring to the figure of Art. **8** we have, from *Prop.* 34,

$$OM^2 + MP^2 = OP^2.$$

Hence, $\frac{OM^2}{OP^2} + \frac{MP^2}{OP^2} = 1$;

or, $\cos^2 A + \sin^2 A = 1.$

Dividing both sides of this equation by $\cos^2 A$, and using (2) and (4) we get

$$1 + \tan^2 A = \sec^2 A.$$

Similarly, dividing by $\sin^2 A$, we get

$$\cot^2 A + 1 = \operatorname{cosec}^2 A.$$

13. The five results just proved must be committed to memory—namely,

(1) $\sin A = \dfrac{1}{\operatorname{cosec} A}$.

(2) $\cos A = \dfrac{1}{\sec A}$.

(3) $\tan A = \dfrac{1}{\cot A}$.

(4) $\tan A = \dfrac{\sin A}{\cos A}$

$\cot A = \dfrac{\cos A}{\sin A}$.

(5) $\sin^2 A + \cos^2 A = 1$

$1 + \tan^2 A = \sec^2 A$

$1 + \cot^2 A = \operatorname{cosec}^2 A$.

It is generally convenient, in proving an identity, to express the other ratios in terms of the sine and cosine, by means of these relations.

EXAMPLE. Prove that

$$\frac{\cot A + \tan B}{\tan A + \cot B} = \cot A \,.\, \tan B.$$

The expression on the left

$$= \frac{\dfrac{\cos A}{\sin A} + \dfrac{\sin B}{\cos B}}{\dfrac{\sin A}{\cos A} + \dfrac{\cos B}{\sin B}} = \frac{\dfrac{\cos A \cos B + \sin A \sin B}{\sin A \cos B}}{\dfrac{\sin A \sin B + \cos A \cos B}{\cos A \sin B}}$$

$$= \frac{\cos A \sin B}{\sin A \cos B} = \frac{\cos A}{\sin A} \times \frac{\sin B}{\cos B} = \cot A \,.\, \tan B.$$

The working of such examples should cause no difficulty if the five formulæ are well known, and if it is remembered that sin A, etc., are *numbers—i.e.*, that the example is simple *arithmetic*.

14. The five relations between the six trigonometrical ratios proved in Art. **12** enable us to express any five of the ratios in terms of the sixth.

EXAMPLE. Express the other trigonometrical ratios in terms of the tangent.

From (5) we have

$$\sec A = \sqrt{1 + \tan^2 A}$$

$$\therefore \cos A = \frac{1}{\sqrt{1 + \tan^2 A}}.$$

Hence,

$$\sin A = \sqrt{1 - \cos^2 A}$$

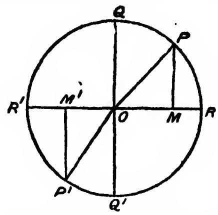
$$= \sqrt{1 - \frac{1}{1 + \tan^2 A}} = \frac{\tan A}{\sqrt{1 + \tan^2 A}};$$

$$\therefore \operatorname{cosec} A = \frac{1}{\sin A} = \frac{\sqrt{1 + \tan^2 A}}{\tan A}.$$

Also, from (3) $\cot A = \dfrac{1}{\tan A}$, so that the other five ratios are now expressed in terms of tan A.

15. Changes in the Magnitude of sin A. As A increases from 0° to 360° the magnitude of sin A changes. Let OR be the initial line, and let OP trace out the angle A. Suppose ROP is one value of A. Draw PM $\perp$ to OR. Then $\sin A = \dfrac{MP}{OP}$.

Now, when A = 0°, OP coincides with OR, so that MP is zero. Thus, when A is 0°, sin A is 0. Again, when A = 90°, OP and MP both coincide with OQ, which is equal to OR. Hence, when A is 90°, sin A $= \dfrac{OQ}{OQ} = 1$. Also, as A *continuously* increases from 0° to 90°, *i.e.*, passes through *every* possible value between 0° and 90°, the length of MP continuously increases from zero to OP; so that $\dfrac{MP}{OP}$, *i.e.*, sin A, continuously increases from 0 to 1.



In exactly the same way we see that as A continuously increases from 90° to 180°, sin A continuously decreases from 1 to 0.

Next, as A increases between 180° and 270°, the revolving line passes through such positions as OP'. Evidently M'P' is now negative, and since OP is always positive we have $\dfrac{M'P'}{OP'}$ negative; *i.e.*, as A increases continuously between 180° and 270°, sin A continuously decreases from 0 to −1.

Similarly, as A continuously increases from 270° to 360°, sin A continuously increases from −1 to 0.

Hence, *the sine of an angle can never be greater than + 1 and never less than − 1.*

16. Changes in the Value of cos A. The student can now verify for himself that as A increases from 0° to 90°, cos A decreases from 1 to 0. As A increases from 90° to 180°, cos A decreases from 0 to − 1. As A increases from 180° to 270° cos A increases from − 1 to 0. As A increases from 270° to 360° cos A increases from 0 to 1.

Hence, *the cosine of an angle can never be greater than + 1 and never less than − 1.*

17. Changes in the Value of tan A. Referring to the figure of Art. **15**, when A is 0°, MP is zero, and OM is equal to OP. Therefore tan A, or $\dfrac{MP}{OM}$ is zero. As A increases between 0° and 90°, MP continuously increases, while OM continuously decreases, hence, $\dfrac{MP}{OM}$ continuously increases. When A approaches 90°, OM becomes infinitely small, until, when A is 90°, $\dfrac{MP}{OM}$ becomes OP divided by an infinitely small quantity, *i.e.*, tan A is an infinitely great quantity. Thus, between 0° and 90°, tan A increases continuously from 0 to ∞.

Similarly, between 90° and 180°, tan A decreases from ∞ to 0. Between 180 and 270°, tan A decreases from 0 to $-\infty$. Between 270° and 360° tan A increases from $-\infty$ to 0.

IRREGULAR VERBS

Third Conjugation—continued

Past Definite in **si**

Aprire, to open

Ind. Pres.—Apro, apri, apre, etc.

Past Def.—Aprii (apersi), aprì (aperse), aprìrono (apèrsero).

Past Part.—Aperto.

Assalire, to assault

Ind. Pres.—Assalgo, assalisci and *assali, assale, assaliamo, assalite, assalìscono* and *assàlgono.*

Past Def.—Assalii (assalsi), assalì (assalse), assalìrono (assàlsero).

Subj. Pres.—Assalisca and *assalga*; third person plural, *assalìscano* and *assàlgano.*

Past Part.—Assalito.

Benedire, to bless

Ind. Pres.—Benedico, benedici, etc.

Imperf.—Benedicevo and *benedivo,* etc.

Past Def.—Benedissi, benedicesti, benedisse, benedicemmo, benediceste, benedissero; and *benedii, benedisti, benedì, benedimmo, benediste, benedirono.*

Subj. Pres.—Benedica, etc.

Past Part.—Benedetto.

Gerund—Benedicendo.

Coprire, to cover

Past Part.—Coperto [see *aprire*].

Costruire, to construct

Ind. Pres.—Costruisco, etc.

Past Def.—Costruii, etc. (regular) (*costrussi, costrusse, costrùssero*).

Past Part.—Costruito (*costrutto*).

Dire (Dicere), to say, to tell

Ind. Pres.—Dico, dici, dice, diciamo, dite, dìcono.

Imperf.—Dicevo, dicevi, diceva, dicevamo, dicevate, dicèvano.

Past Def.—Dissi, dicesti, disse, dicemmo, diceste, dìssero.

Future—Dirò, dirai, dirà, etc.

Imperat.—Di', dica, diciamo, dite, dìcano.

Subj. Pres.—Dica, dica, dica, diciamo, diciate, dìcano.

Imperf.—Dicessi, dicessi, dicesse, dicèssimo, diceste, dicèssero.

Condit.—Direi, diresti, direbbe, etc.

Past Part.—Detto.

Pres. Part.—(Dicente).

Gerund—Dicendo.

Istruire, to instruct [see *costruire*].

Maledire, to curse [see *benedire* and *dire*].

Offrire (Offerire), to offer

Ind. Pres.—Offro, offri, etc.; (*offerisco, offerisci,* etc.).

Past Def.—Offrii, offristi, etc.; (*offersi, offerse, offèrsero*).

Past Part.—Offerto.

Profferire, to offer

Past Part.—Profferito and *profferto* [see *offerire*].

Salire, to ascend, to go up

Ind. Pres.—Salgo, sali, sale, saliamo, salite, sàlgono (salisco, salisci, etc.).

Past Def.—Salii, salisti, salì, etc. (*salsi, salse, sàlsero*).

Subj. Pres.—Salga, salga, salga, saliamo, saliate, sàlgano.

Imperat.—Sali, salga, saliamo, salite, sàlgano.

Past Part.—Salito.

Scolpire, to engrave

Ind. Pres.—Scolpisco, etc.

Past Def.—Scolpii, scolpisti, etc. (*sculsi, sculse, scùlsero*).

Past Part.—Scolpito (*sculto, scólto*).

Soffrire, to suffer [see *offrire*].

Exercise LV.

1. Intesi picchiare, aprii, ma non vidi nessuno. 2. "Che Iddio vi benedica," disse la pòvera madre. 3. Quando il signor N. ritornerà in ufficio, gli dirò che siete venuto. 4. Se mi aveste detto la verità, vi avrei perdonato. 5. Gli offrimmo cinquecento lire, ma non volle accettare. 6. Se non le dispiace di salire fino al quarto piano (floor), le mostrerò il violino di cui le parlai l'altro giorno. 7. Di' a tuo cugino che venga domani da me, perchè ho da parlargli. 8. Voi non potete crèdere quanto àbbia sofferto quell' infelice! 9. Questo ponte fu costruito quattrocento anni fa (ago).

Esercizio di Lettura—continued

Don Rodrigo era fin allora rimasto tra la ràbbia e la maravìglia, attònito, non trovando parole; ma, quando sentì intonare una predizione, s'aggiunse alla ràbbia un lontano e misterioso spavento.

Afferrò rapidamente per ària quella mano minacciosa, e, alzando la voce, per troncàr quella dell' infàusto profeta, gridò: "èscimi di tra' piedi[1], villano temeràrio, poltrone incappucciato[2]."

Queste parole così chiare acquietàrono in un momento il padre Cristòforo. All' idea di strapazzo e di villanìa era, nella sua mente, così bene, e da tanto tempo, associata l'idea di sofferenza e di silènzio, che, a quel complimento, gli cadde ogni spìrito d'ira e d'entusiasmo, e non gli restò altra risoluzione che quella d' udir tranquillamente ciò che a don Rodrigo piacesse d' aggiùngere. Onde, ritirata placidamente la mano dagli artigli del gentiluomo, abbassò il capo, e rimase immòbile, come, al cadèr del vento, nel forte della burrasca, un àlbero agitato ricompone naturalmente i suoi rami, e riceve la gràndine come il ciel la manda.

"Villano rincivilito[3]!" proseguì don Rodrigo, "tu tratti da par tuo[4]. Ma ringràzia il sàio[5] che ti copre codeste spalle[6] di mascalzone[7], e ti salva dalle carezze che si fanno ai tuoi pari, per insegnàr loro a parlare. Esci con le tue gambe, per questa volta[8] e la vedremo."

Così dicendo, additò[9], con impero sprezzante, un ùscio[10] in fàccia a quello per cui èrano entrati; il padre Cristòforo chinò il capo, e se n' andò[11], lasciando don Rodrigo a misurare, a passi infuriati, il campo di battàglia.

NOTES. 1. get out of my way; 2. you dolt of a friar; 3. tamed boor; 4. you are acting your natural part; 5. habit; 6. your shoulders; 7. scoundrel; 8. you may go away on your own legs this time; 9. pointed; 10. door; 11. went away.

PROPOSITIONS

Subjective Propositions. Subjective propositions are generally constructed with the conjunction *che*, and the verb may either be in the indicative or the subjunctive mood. Examples:

Delle volte avviene che gli uòmini più pacìfici pròvocano (or *pròvochino*) *discòrdie*, It happens sometimes that the most peaceful men provoke dissensions; *È chiaro che avete* (or *abbiate*) *ragione voi*, It is clear that you are right.

But it is a rule to use the subjunctive:

1. In dependence upon verbs indicating a sentiment or an opinion, as: *Mi dispiace*, I am sorry; *Mi duole*, I regret; *Mi pare*, It seems to me; *È meglio*, It is better, etc. Examples: *Mi pare che non ci sia niente altro da fare*, It seems to me that there is nothing else to do; *È meglio che abbiate parlato così*, It is better that you have spoken so; *Mi dispiace che abbiate dovuto aspettare*, I am sorry that you have been obliged to wait.

2. In dependence upon a negative proposition, or a proposition having a negative meaning, as: *Non è vero che io t'àbbia detto questo*, It is not true that I have told you this; *Raramente avviene che il delitto resti impunito*, It seldom happens that crime remains unpunished.

3. When a fact is represented, not as real or present, but only as possible or future, as: *Bisogna che ognuno lavori*, It is necessary that everyone should work; *È giusto che gli scolari diligenti sìano premiati*, It is just that diligent pupils should be rewarded.

Subjective propositions may also be constructed with the infinitive, as: *Molto spesso accade di restare* (*che si resti*) *disillusi*, It very often happens that one is disappointed; *È vietato fumare* (*che si fumi*), Smoking is prohibited; *È necessàrio pensare* (*che si pensi*) *all'avvenire*, It is necessary to think of the future.

Objective Propositions. Objective propositions, like the subjective, are constructed with the conjunction *che*. We use the indicative when a fact is mentioned with certitude or conviction, as:

Sono convinto che la cosa è così, I am convinced that the thing is so; *Dico che il tutto è uguale alla somma delle sue parti*, I say that the whole is equal to the sum of its parts.

But when a fact is mentioned as only possible—*i.e.*, as an opinion, a doubt, a wish, etc.—the subjunctive or the future of the indicative must be used. Examples: *Spero che suo padre sia completamente guarito*, I hope that your father is completely cured; *Mi àuguro che tutto vada* (or *andrà*) *bene*, I wish that everthing may go well; *Credo che questa volta àbbia detto il vero*, I think that this time he has spoken the truth; *Credo che pioverà*, I think it will rain.

The subjunctive must also be used when an objective proposition depends upon a negative or interrogative proposition, as: *Non son sicuro che egli esegua i miei òrdini*, I am not sure that he executes my orders; *Chi crederebbe che vi fòssero al mondo delle persone sìmili?* Who would believe that there are such persons in the world? *Io non credo che gli abbiate parlato*, I do not believe that you have spoken to him.

NOTE. After the verbs *temère*, to fear; *sospettare*, to suspect; *badare*, to take care; *dubitare*, to doubt, it was a rule to use the conjunction *che* followed by *non* (*che non*), but modern usage prefers to omit the *non*, in order to avoid ambiguity. Examples: *Dùbito che egli* (*non*) *arrivi in tempo*, I doubt about his arriving in time; *Sospettammo che* (*non*) *ci volessero ingannare*, We suspected that they wished to cheat us.

But it is common to use *che non* in the expressions: *Poco mancò che non restassi bruciato*, I came within very little of being burned; *Poco mancò che non mi tagliassi un dito*, I very nearly cut my finger.

Objective propositions are also constructed with the infinitive preceded by the preposition *di*, as: *Vi prego di continuare*, I beg you to continue; *Ho paura di prender freddo*, I am afraid of catching cold.

NOTE. After the verbs *volère*, *potère*, *sapère*, *dovère*, *fare*, *lasciare*, *vedère*, *udire*, *sentire*, the infinitive is used without preposition, as: *Voglio dire tutto quello che so*, I wish to say all I know; *Non so parlare tedesco*, I cannot speak German; *Fècero arrestare il ladro*, They had the thief arrested.

After some verbs, as *tornare*, *cominciare*, *aiutare*, *mèttersi*, *aspirare*, etc, the objective infinitive is governed by the preposition *a*, as: *Torna a scrivere*, He resumes writing; *Aiutàtemi a portare questo tàvolo*, Help me to carry this table; *Comìncio a capir meglio*, I begin to understand better; *Li invitammo a passare una settimana con noi*, We invited them to spend a week with us.

When the object is expressed by a noun or pronoun it is often repeated by a pronominal particle, which gives more strength to the expression, as:

Questo lo so, I know this; *Lo sbàglio l'ho fatto io*, I have made the mistake; *La farò io la giustizia*, I will do justice.

The partitive object preceding the verb is repeated by *ne*, as: *Danari non te ne posso dare*, I cannot give you any money; *Di codesti consigli io non ne ho bisogno*, I have no need of these counsels of yours.

Note here the meaning of the following expressions, in which *la* is used as an indefinite object: *Egli se la gode*, He passes his life in enjoying himself; *Se l'è svignata*, He has succeeded in getting out of it; *Non la vuo'e intèndere*, He does not want to understand the reason; *Chi la dura, la vince*, Perseverance always gains its end; *Me la pagherà*, He shall pay for the trick he has played me.

The verbs *èssere* and *stare*, followed by the infinitive preceded by the preposition *per*, indicate a near future, as: *Egli sta per morire*, He is at the point of death; *Egli è per uscire*, He is on the point of going out; *Sta per venire*, He is just now coming.

CONVERSAZIONE

Il suo amico ha parlato con l'avvocato?

Lui dice di sì, ma io non credo che gli àbbia parlato.

Se è così, gli scriverò io direttamente.

Bisogna che gli scriva sùbito, perchè la causa è fissata per giovedì pròssimo.

Quanto crede che gli debba offrire?

Non saprei (I do not know), tutto dipende dall'importanza dell'affare.

Si tratta di ben poco, ma quando si ha da fare con gli avvocati non si sa mai dove si va a finire.

Questo è vero; e se vuole un consiglio da amico, cerchi di venire a un accordo.

KEY TO EXERCISE LIV.

1. They appeared dressed in so strange a manner that we all began to laugh. 2. We have bought a new sewing-machine. 3. The impression that he received from seeing the man who had died for him, and the man killed by him, was new and unspeakable. 4. Give me something to eat, because I am dying of hunger. 5. Your servant must be a good man; I have always heard him praised by everyone. 6. I have not succeeded in understanding a word of what he has said. 7. If it does not rain we will go out too. 8. I never heard such a thing! 9. The buttons of my shirts have all come off; I beg you to sew them better next time. 10. I cannot understand why he has not yet come.

Commercial Letters—continued

London.

Messrs. ———
Malaga.

Dear Sirs,

I am in receipt of your esteemed favour of ——, and of the samples of iron ore which you were good enough to send me.

I have taken good note of what you say, and am quite prepared to be of service to you on the recommendation of our mutual friends Messrs. A.B.C., of Seville.

I have had the samples of iron ore analysed, and, as you will see from the enclosed certificate of analysis, the result is the same as that obtained on your side. It is good mineral, and of a kind well suited to the requirements of the Welsh ironfounders.

The cost of the analysis is £1 1s., which I have debited to your account. I readily accept the conditions you mention for the sale of the consignments of ore, and, as I am in constant touch with the principal founders of this country, as soon as you advise me that you are in a position to make consignments, I will attend to the necessary contracts and chartering.

Awaiting your reply,
I remain,
Yours faithfully,
JOHN BROWN.

Londres.

Sres ———
Malaga.

Muy Sres mios,

He tenido el gusto de recibir su apb^le^ del —— asi como tambien las muestras de mineral de hierro que han tenido Vds á bien mandarme.

Enterado de cuanto se sirven Vds decirme estoy pronto à servir à Vds dada la recomendacion que se nos ha hecho de esa respetable casa por los mutuos amigos los Sres A.B.C., de Sevilla.

He hecho analizar las muestras del mineral de hierro cuyo resultado como verán Vds por el certificado de analisis adjunto, concuerda con el practicado en esa. Es un mineral bueno y su clase muy á proposita para estos fundidores de Gales.

El costo del analisis asciende á £1 1s. que le dejo cargado en cuenta. Son conformes las condiciones que Vd señala para la venta de cargamentos de su mineral y como estoy en continuo contacto con los principales fundidores de este pais, tan pronto me avise Vd que está en disposicion de hacer embarques, me ocuparé de efectuar los contratos y fletamentos necesarios.

En la espera de sus noticias, tengo el gusto de ofrecerme de Vds ato. S.S. q.s.m.b.

JOHN BROWN.

Barcelona.

Don John Brown,
London.

Dear Sir,

We enclose a letter of introduction from our friends Messrs. T. P. & Co., of this city, with whom we have had friendly business relations for many years. Our object in writing to you under the auspices of our said friends is to ask if you would be willing to open a credit for our account to the extent of £5,000 for bills at 60 days in favour of Messrs. A. T. & Co., of New Orleans, for consignments of cotton sent to us here.

If you are willing, as we hope you will be, to undertake this transaction, will you kindly let us know your conditions.

We have the pleasure to remain,
Yours faithfully,

Barcelona.

Don John Brown,
Londres.

Muy Señor ntro,

Acompañamos una carta de presentacion de nuestros amigos los Sres T. P. y Cia de esta plaza con quienes nos unen buenas relaciones comerciales y amistosas desde hace muchos años. Nuestro objeto al dirigirnos hoy á Vd bajo los auspicios de dichos amigos es para suplicarle tenga à bien decirnos si estaria Vd dispuesto á abrirnos un crèdito hasta la suma de £5,000 y á favor de los Sres A. T. y Cia de Nueva Orleans, mediante giros á 60 dias vista, contra embarques de algodon à esta, à nuestra consignacion.

Si como esperamos, esta Vd dispuesto à admitir esta operacion, le agradecerémos se sirva decirnos que condiciones habrian de regir.

Con este motivo nos es grato suscribirnos de Vd. atcs S.S. q.s.m.b.

London.

Messrs. ———,
Barcelona.

Gentlemen,

I beg to acknowledge receipt of your esteemed favour of the —, which I have duly considered.

Although this firm does not usually undertake business of this kind, which, from its nature, is more suited to a banking firm, yet Messrs. T. P. & Co.'s recommendation of your esteemed firm is of such a nature that I have no objection to opening a credit for your account to the extent of £5,000, in favour of Messrs. A. T. & Co. of New Orleans, upon the following conditions:

Messrs. A. T. & Co. will draw on me at 60 days' sight to the extent of the sum mentioned, sending me the bills of lading for each consignment of cotton on the same day as they negotiate the bills.

This firm will attend to the marine insurance for your account, and

Londres.

Sres ———
Barcelona.

Muy Sres mios,

Correspondo á su apb^le^ del—de cuyo contenido he quedado bien impuesto.

Aunque esta su casa no se ocupa de esa clase de negocios, que por su indole son mas propios de casas bancarias, es tal la recomendacion que nuestros amigos los Sres T. P. y Cia me han hecho de su respetable casa, que no tengo inconveniente en abrir un crédito por cuenta de Vds hasta £5,000, à favor de los Sres A. T. y Cia de Nueva Orleans, en las condiciones siguientes.

Los Sres A. T. y Cia giraran á mi cargo á 60 dias vista hasta dicha suma, remitiendoseme los conocimientos de embarque de cada partida de algodon en la misma fecha en que se negocien los giros.

El seguro maritimo lo cubrirá esta su casa por cuenta de Vds y 8 dias

eight days before Messrs. A. T. & Co.'s bills fall due I will draw on you at three months at the current rate of exchange for the amount, plus the insurance premium and my commission of 1% (one per cent.). I have no doubt that these conditions will meet with your approval, and that our business relations will be lasting and profitable.	antes del vencimiento de los giros, de los Sres A. T. y Cia de Nueva Orleans, giraré á cargo de Vds y á 3 meses fecha, al cambio corriente, por su valor más la prima del seguro y mi comision de 1% (uno por ciento). No dudo que estas condiciones le serán aceptables y confiando que nuestras relaciones comerciales serán duraderas y de mucho provecho me reitero con este motivo á sus ordenes ato S.S. q.s.m.b.
I remain, Yours faithfully, JOHN BROWN.	JOHN BROWN.

IDIOMATIC PHRASES

Abrir la mano, to take bribes
Alegrar las luces, to snuff the candles
Amontarse el juicio, to lose presence of mind
Andando el tiempo, in the course of time
Andar en coplas, to be the talk of the town
Andar en dimes y diretes, to wrangle
Aporrearse en la jaula, to strive in vain
A puño cerrado, with might and main
Armar caballero, to dub a knight
Armar un lazo, to set a trap
Arrimar el hombro, to lend a hand
A sus anchas, to be at one's ease
Bailar el pelado, to have no money
Bailar sin són, to be very eager
Buscar á tientas, to grope
Buscar cinco pies al gato, to pick a quarrel
Cantar de plano, to make full confession
Cebar un anzuelo, to bait a fish-hook
Cenar á oscuras, to be stingy
Coger la calle, to run away
Coger una liebre, to fall in the mud
Comer con gana, to eat with a good appetite
Contados sus alfileres, to be dressed in one's best
Contar paparruchas, to tell incredible tales; to draw the long bow
Costar un ojo, to be very expensive
Dar á conocer, to introduce people to each other
Dar el pésame, to condole
Dar el traste, to let go to rack and ruin
Dar en blando, to succeed easily
Dar fin, to end
Dar los dias, to wish "many happy returns"
Dar mal rato, to cause uneasiness
Dar una carcajada, to burst out laughing
Dar voces, to cry out
De cuando acá? since when?
De socapa, secretly, under protest
Dejar entre renglones, to forget to say something
Dejar el siglo, to become a monk or nun
Descabezar el sueño, to take a nap; "forty winks"
Echar coche, to set up a carriage
Echar el cuerpo fuera, to abscond
Echar la casa por la ventana, to be wild with delight
El me ha puesto un hierro, he has put me under a deep obligation
En seco, without cause
Es cuanto cabe, it is the last straw
Eso ni me va ni me viene, it is not my business
Estar con cuidado, to be anxious
Estar de ver, to be worth seeing
Estar mascando tierra, to be dead and buried
Estar sin habla, to be speechless
Hacer cuerpo presente, to put in an appearance

Participial Adjectives
(ACTIVE VOICE)

From all Esperanto verbs, whether transitive or intransitive, compound tenses may be formed by means of the various forms of the auxiliary *esti*, and the participles.

The auxiliary remains the same for each person, the participle alone agreeing with the subject in number.

The present participle (active voice) is *anta* (sing.), *antaj* (plural).

The past participle (active voice) is *inta* (sing.), *intaj* (plural).

The future participle (active voice) is *onta* (sing.), *ontaj* (plural).

In order to simplify the explanation of the participles, both active and passive, one pronoun (*mi*) and one verb (*lavi*) will be used throughout. Nine compound tenses can be formed by combination of the three active participles with the three tenses of the auxiliary verb. (These participles may also be combined with *esti*, *estus* and *estu*.)

Mi estas lavanta, I am washing; ***Mi estas lavinta***, I have washed (lit. I am having washed); ***Mi estas lavonta***, I am about to wash.

Mi estis lavanta, I was washing; ***Mi estis lavinta***, I had washed (lit. I was having washed); ***Mi estis lavonta***, I was about to wash.

Mi estos lavanta, I shall be washing; ***Mi estos lavinta***, I shall have washed (lit. I shall be having washed); ***Mi estos lavonta***, I shall be about to wash.

Mi estus lavanta, I should be washing; ***Mi estus lavinta***, I should have washed (lit. I should be having washed); ***Mi estus lavonta***, I should be about to wash.

The present, past and future infinitives are expressed by *esti lavanta*, to be washing; *esti lavinta*, having washed; *esti lavonta*, to be about to wash.

The participles are in reality adjectives, and when predicated of a plural noun or pronoun must take the final "j": ***Ni estas lavantaj***, We are washing. The participles may also be used to qualify directly a noun or pronoun, in which case they accord with such noun or pronoun both in number and case.

Example: *La tempo pasinta neniam revenos; la tempon venontan neniu aŭkoraŭ konas* (Zamenhof), The time passed never will return; the time to come nobody yet knows.

Careful thought must be used in constructing these compound tenses, and the exact meaning of the participle in reference to the auxiliary must be fully understood.

When *anta* is used it indicates that the action is still in progress at the time indicated by the auxiliary.

When *inta* is used it indicates that the action was completed at the time indicated by the auxiliary.

When *onta* is used it indicates that the action is about to take place at the time indicated by the auxiliary.

The student should compare these remarks with the foregoing table of the compound tenses, and at the same time note that the English auxiliary "to have" is always rendered by *esti*, the sole auxiliary verb in Esperanto.

The compound tenses, though perhaps appearing a little complex to beginners who have so far remarked the extreme simplicity of the language, give a precise shade to the meaning which one wishes to render. In practice, nevertheless, whenever the compound forms can be dispensed with, the simple tenses are used if they adequately fulfil the requirements of the sense to be conveyed. Thus the simple *mi lavos* may be used to signify I wash, I do wash, and I am washing.

Impersonal Verbs

Those Esperanto verbs which by their nature are impersonal do not require the use of the indefinite pronoun as in English.

Examples: *Pluvos*, It will rain; *Estas tondre*, It is thundery; *Mi pensas, ke neĝos morgaŭ*, I think it will snow to-morrow.

The words "it" and "there" in "it is," "there is," "there are," "there was," "there will be," etc., when used indefinitely, are never translated.

Examples: *Estas necese*, It is necessary; *Estos sufiĉe da tempo poste*, There will be enough time later; *Estis multe da homoj tie*, There were many people there.

Other examples of similar usage are: *Ŝajnas al mi, ke . . .* It seems to me that . . . .; *Okazos kunsido*, There will be a meeting (a meeting will be held); *Se plaĉas al vi*, If you please (if it please you).

Suffixes

AĴ denotes something made from, or having the quality contained in the root word.

Examples: *Bona*, good; *bonaĵo*, a good thing; *grava*, important; *gravaĵo*, an important thing; *bovo*, ox; *bovaĵo*, beef.

EBL denotes possibility (to *be*, not to *do*).

Examples: *Kredi*, to believe; *kredebla*, credible; *legi*, to read; *legebla*, legible.

IND denotes worthiness.

Example: *Laŭdi*, to praise; *laŭdinda*, praiseworthy; *legi*, to read; *leginda*, readable.

EC denotes an abstract quality.

Examples: *Varma*, warm; *varmeco*, warmness, warmth; *frato*, brother, *frateco*, brotherliness.

Vocabulary

bros', brush
brust', chest, breast
brut', brute, cattle
ĉagren', disappoint, vex
ĉen', chain
defend', defend
degel', thaw
dron', drown (v. i.)
except', except
faktur', invoice
fold', fold
flam', flame
fortik', strong, robust
frost', frost
fulm', lightning
gren', corn,
hajl', hail (subst.)
klin', bend, incline
konsist', consist

konstant', constant
lan', wool
melk', milk (v.)
merit', merit, deserve
ofend', offend
ombrel', umbrella
ordon', order, command
plac', public square
pluv', rain
polic', police
polv', dust
postul', require, demand
pretend', claim
pump', pump (v.t.)
regn', realm, kingdom
regul', rule (s.)
rezultat', result
ripoz', repose, rest
ruĝ', red
ruz', trick, ruse
sabl', sand
salut', greet, salute
sam', same
sav', save, rescue
sent', feel, perceive
soif', thirst
sol', only, alone
spir', breathe
ŝang', change
trem', tremble

EXERCISE XVI.

(NOTE. Translate the compound tenses as they appear in English.)

It blows strongly outside. When he had folded (was having folded) the invoice and written his address on the envelope, he gave both to me. What strange weather it is to-day! Sometimes it snows, sometimes hails, sometimes lightens and thunders. One can never be certain about it. This chain has 37 links, each one of (out of) gold. He does not like frosty weather, and is always happy when it commences to thaw. He was defending. They are about to milk. I shall have changed (shall be having changed). We are not claiming. You will have saved. He was about to defend. I had offended. They will have rested. I have ordered. She is breathing. Those who are about to die salute you. They have offended me. They were just going to save her. The villager had milked her cows. The policeman is peacefully sleeping. I feel as though I am about to die. If I had had an umbrella, I could have visited you in spite of the rain. A grain of dust had fallen into her eye. She was trembling, and could hardly breathe. If they had known the rules, they would not have made the same error twice. The blind man was about to fall into the flames, when that courageous person saved him.

KEY TO EXERCISE XV.

Permesu, mi petas, ke mi pasu! Kia domaĝo ke vi ne kaptis la krimulon! Ĉiuj bonaj urbanoj renkontu min ĉi tie morgaŭ por ke ni kune portu nian peton al la reĝo. Akveregoj ekfalis de la plafono. Iru rekte ĝis kiam vi atingos la arbaron, kaj zorgu por eviti ĉiujn vojojn kiuj kondukas maldekstren kaj dekstren. La penso pri tiu mizera avarulo kaŭzas al mi multan doloron. Ricevu, sinjoro, miajn plej korajn dankojn. Rigardu tiun insektaron. Estu paco en la mondo kaj senfina konvolo en la koroj de homoj. Ĝi estu tiel. Antaŭ dek du jaroj mi fondis tiun ĉi grupon, kaj nun la membraro nombras tricent dek kvin. Bone, amiko mia, mi vin gratulas. Vi ĉiam sukcesu kiel antaŭe! Kiel dolĉe odoras tiuj floroj! Fajrero povas kaŭzi brulegon. Kvankam mi ne efektive konas ion malbonan pri tiu persono, mi tamen malkonfidas al li, sed preferas konservi mian propran opinion pri li nuntempe. Jen estas klubano, kiu kolektas monerojn. Estas necese ke vi lernu parkere la tutan radikaron en ĉi tiuj vortaretoj. La muŝo rampis sur la korpo de la kapro. Kolektu (vi) la pinglojn kaj enpaku ilin en la skatoleton.

SECTION I. VERBS

Contracted Verbs. Verbs in *αω*, *εω*, and *οω* are contracted in the present and imperfect tenses. The following are the contracted tenses of *τιμάω*, I honour; *φιλέω*, I love; and *δηλόω*, I manifest.

ACTIVE VOICE

Present Indicative

τιμῶ (for τιμάω)	φιλῶ	δηλῶ
τιμᾷς (for τιμάεις)	φιλεῖς	δηλοῖς
τιμᾷ (for τιμάει)	φιλεῖ	δηλοῖ
τιμᾶτον, etc.	φιλεῖτον	δηλοῦτον
τιμᾶτον	φιλεῖτον	δηλοῦτον
τιμῶμεν	φιλοῦμεν	δηλοῦμεν
τιμᾶτε	φιλεῖτε	δηλοῦτε
τιμῶσι (ν)	φιλοῦσι (ν)	δηλοῦσι (ν)

Imperfect Indicative

ἐτίμων (ἐτίμαον)	ἐφίλουν	ἐδήλουν
ἐτίμας	ἐφίλεις	ἐδήλους
ἐτίμα	ἐφίλει	ἐδήλου
ἐτιμᾶτον	ἐφιλεῖτον	ἐδηλοῦτο
ἐτιμάτην	ἐφιλείτην	ἐδηλούτην
ἐτιμῶμεν	ἐφιλοῦμεν	ἐδηλοῦμεν
ἐτιμᾶτε	ἐφιλεῖτε	ἐδηλοῦτε
ἐτίμων	ἐφίλουν	ἐδήλουν

Present Subjunctive

Same as Present Indicative	φιλῶ	δηλῶ
	φιλῇς	δηλοῖς
	φιλῇ	δηλοῖ
	φιλῆτον	δηλῶτον
	φιλῆτον	δηλῶτον
	φιλῶμεν	δηλῶμεν
	φιλῆτε	δηλῶτε
	φιλῶσι	δηλῶσι

Present Optative

τιμῷμι (τιμάοιμι)	φιλοῖμι	δηλοῖμι
τιμῷς	φιλοῖς	δηλοῖς
τιμῷ	φιλοῖ	δηλοῖ
τιμῷτον	φιλοῖτον	δηλοῖτον
τιμῴτην	φιλοίτην	δηλοίτην
τιμῷμεν	φιλοῖμεν	δηλοῖμεν
τιμῷτε	φιλοῖτε	δηλοῖτε
τιμῷεν	φιλοῖεν	δηλοῖεν
or	*or*	*or*
τιμῴην (τιμαοίην)	φιλοίην	δηλοίην
τιμῴης	φιλοίης	δηλοίης
τιμῴη	φιλοίη	δηλοίη
τιμῴητον	φιλοίητον	δηλοίητον
τιμῳήτην	φιλοιήτην	δηλοιήτην
τιμῴημεν	φιλοίημεν	δηλοίημεν
τιμῴητε	φιλοίητε	δηλοίητε
τιμῴησαν	φιλοίησαν	δηλοίησαν

Present Imperative

τίμα	φίλει	δήλου
τιμάτω	φιλείτω	δηλούτω
τιμᾶτον	φιλεῖτον	δηλοῦτον
τιμάτων	φιλείτων	δηλούτων
τιμᾶτε	φιλεῖτε	δηλοῦτε
τιμάτωσαν or τιμώντων	φιλείτωσαν or φιλούντων	δηλούτωσαν or δηλούντων

Present Infinitive

τιμᾶν (τιμάειν)	φιλεῖν	δηλοῦν

Present Participle

τιμῶν, ῶσα, ῶν	φιλῶν, οῦσα, οῦν	δηλῶν, οῦσα, οῦν

Passive and Middle

Present Indicative

τιμῶμαι	φιλοῦμαι	δηλοῦμαι
τιμᾷ	φιλεῖ	δηλοῖ
τιμᾶται	φιλεῖται	δηλοῦται
τιμᾶσθον	φιλεῖσθον	δηλοῦσθον
τιμᾶσθον	φιλεῖσθον	δηλοῦσθον
τιμώμεθα	φιλούμεθα	δηλούμεθα
τιμᾶσθε	φιλεῖσθε	δηλοῦσθε
τιμῶνται	φιλοῦνται	δηλοῦνται

Imperfect Indicative

ἐτιμώμην	ἐφιλούμην	ἐδηλούμην
ἐτιμῶ	ἐφιλοῦ	ἐδηλοῦ
ἐτιμᾶτο	ἐφιλεῖτο	ἐδηλοῦτο
ἐτιμᾶσθον	ἐφιλεῖσθον	ἐδηλοῦσθον
ἐτιμάσθην	ἐφιλείσθην	ἐδηλούσθην
ἐτιμώμεθα	ἐφιλούμεθα	ἐδηλούμεθα
ἐτιμᾶσθε	ἐφιλεῖσθε	ἐδηλοῦσθε
ἐτιμῶντο	ἐφιλοῦντο	ἐδηλοῦντο

Present Subjunctive

Same as Present Indicative	φιλῶμαι	δηλῶμαι
	φιλῇ	δηλοῖ
	φιλῆται	δηλῶται
	φιλῆσθον	δηλῶσθον
	φιλῆσθον	δηλῶσθον
	φιλώμεθα	δηλώμεθα
	φιλῆσθε	δηλῶσθε
	φιλῶνται	δηλῶνται

Present Optative

τιμῴμην	φιλοίμην	δηλοίμην
τιμῷο	φιλοῖο	δηλοῖο
τιμῷτο	φιλοῖτο	δηλοῖτο
τιμῷσθον	φιλοῖσθον	δηλοῖσθον
τιμῴσθην	φιλοίσθην	δηλοίσθην
τιμῴμεθα	φιλοίμεθα	δηλοίμεθα
τιμῷσθε	φιλοῖσθε	δηλοῖσθε
τιμῷντο	φιλοῖντο	δηλοῖντο

Present Imperative

τιμῶ (τιμάου)	φιλοῦ	δηλοῦ
τιμάσθω	φιλείσθω	δηλούσθω
τιμᾶσθον	φιλεῖσθον	δηλοῦσθον
τιμάσθων	φιλείσθων	δηλούσθων
τιμᾶσθε	φιλεῖσθε	δηλοῦσθε
τιμάσθωσαν or τιμάσθων	φιλείσθωσαν or φιλείσθων	δηλούσθωσαν or δηλούσθων

Present Infinitive

τιμᾶσθαι	φιλεῖσθαι	δηλοῦσθαι

Present Participle

τιμώμενος, η, ον	φιλούμενος, η, ον	δηλούμενος, η, ον

Note. A few verbs in αω take η for α in their contracted forms; of these the commonest are: ζάω, live; διψάω, thirst; πεινάω, hunger; κνάω, scrape; ψάω, rub; χράω, give oracles; and χράομαι, use. Thus, ζῆν, to live; διψῇς, thou thirstest; χρῆσθαι, to use.

SECTION II. SYNTAX

The Accusative Case

The accusative always depends on a verb, or on a verbal notion in a noun. It may denote:

1. External object; 2. Internal object (including the accusative of result and the cognate accusative; 3. Aim; 4. Extent; 5. Relation (including the accusative of the part affected, and the limiting accusative).

1. External Object. This is the ordinary use of the accusative, to limit or direct the action of the verb—as: τοῦτο ποιοῦμεν, We do this; ἡ πίστις σου σέσωκέ σε, Thy faith hath saved thee.

An intransitive verb—*i.e.*, one whose meaning is complete in itself, may be used transitively by an extension of its meaning—*e.g.*, λανθάνω, I lie hid; φεύγω, I flee; φθάνω, I am first. Thus, λανθάνουσι τοὺς φύλακας, They escape the notice of the guards; φεύγει τὸν πατέρα, He flees from (shuns) his father; ἔφθησαν (from φθάνω) τὸν χειμῶνα, They anticipated the storm; ὄμνυμι τοὺς θεούς, I swear by the gods.

This accusative is frequent in expressions of emotion, a verb being understood—as: νὴ τὸν Δία, Yes, by Zeus; μὰ τὸν Δία, No, by Zeus; οὐ τὸν ἥλιον, No, by the sun (I swear).

2. Internal Object. The accusative repeats with more or less modification of meaning the idea given by the verb. Under this we have:

(*a*) Accusative of Result—as: πημονὰς ἐρεῖς, You will give pain by speaking (lit. you will speak pains); βοθρὸν ὤρυξε, He dug a hole. With this may be reckoned the accusative in apposition to the whole sentence, denoting the result of the action of the verb—as: Ἑλένην κτάνωμεν, Μενελέῳ λύπην πικράν, Let us kill Helen, (which will be) bitter grief to Menelaus.

(*b*) The Cognate Accusative, noun and verb having a common stem—as: βουλὰς βουλεύειν, to plan plans; ἀποστήσεσθαι διπλῆν ἀπόστασιν, to revolt a double revolt. Under this heading comes what is often called the adverbial accusative, where a noun, pronoun, or adjective is used in the accusative case with an adverbial meaning—as: προφάσιν, ostensibly; καιρόν, opportunely; πᾶσαν ἰδέαν, in every way; δίκην, like; χάριν, for the sake of; τοῦτον τὸν τρόπον, in this way; τέλος, finally; τί, in what respect; πρῶτον, at first; τὸ λοιπόν, for the rest; οὐδέν, not at all.

Under the head of Internal Object must be placed the *Accusative Absolute*, usual with the participles of certain impersonal verbs—as: δέον, it being a duty; ἐξόν, it being allowed; προσῆκον, it being fitting; δόξαν, it having been decided; μετόν, παρόν, ὑπαρχόν, τυχόν, δεδογμένον, εἰρημένον (though it had been stated). κ. τ. λ. Example: οὐδεὶς (ἐξὸν εἰρήνην ἄγειν) πόλεμον αἱρήσεται, No one (when it is possible to have peace) will choose war.

3. Accusative of Aim, or "Terminus ad quem," after verbs of motion. In prose this is preceded by a preposition, such as πρός, εἰς, ἐπί, to, towards, against, etc. But in poetry it is found without a preposition—as: ἔβης Θήβας,

Thou didst go to Thebes (Sophocles); χρεία τίς σε Θεσσαλῶν χθόνα πέμπει, Some necessity sends thee to the land of the Thessalians.

4. Accusative of Extent. (*a*) Extent of space—as: ἀπέχει δ' ἡ Πλάταια τῶν Θηβῶν σταδίους ἑβδομήκοντα, Platæa is distant from Thebes 70 stades. (*b*) Duration of time—as: ἡμέρας ἔχουν (= ἔχεον, from χέω) ἑβδομήκοντα, They worked at the mound for 70 days.

5. Accusative of Relation, Respect, Reference, or Definition. (*a*) Of the part affected—as: ἀλγεῖ τοὺς ὀδόντας, He has a pain in his teeth; πόδας ὠκύς, swift of foot (lit. swift as to his feet). (*b*) Accusative of Limitation, used in certain common words, as: μέγεθος (in size), ὄνομα (by name), γένος, φύσιν—*e.g.*, διαφέρει τὴν φύσιν, He differs in nature; Ἕλληνές εἰσι τὸ γένος, They are Greeks by race.

Double Accusative: 1. After verbs of making, thinking, finding, naming, appointing, etc.—as: στρατηγὸν αὐτὸν ἀπέδειξε (ἀποδείκνυμι), He appointed him general.

2. After verbs of asking, teaching, concealing, taking away, clothing, unclothing, reminding, depriving, etc.—as: Θηβαίους χρήματα ᾔτησαν (from αἰτέω), They asked the Thebans for money; μή με κρύψῃς ταῦτα, Do not hide this from me; ἀναμιμνήσκειν τοὺς Ἀθηναίους τὴν συμμαχίαν, to remind the Athenians of the alliance.

3. After verbs of doing anything to, or saying anything of a person—as: δρᾶν τινά τι, to do something to someone; εὖ ποιεῖν τινά, to benefit someone; πλεῖστα κακὰ τὴν πόλιν ποιοῦσιν, They do the most evils to the state. [Note. εὖ πράσσω means: I fare well, *not* I do good to someone].

SECTION III. TRANSLATION.

The student has now reached a stage when he may profitably begin to read some of the Greek authors. For his guidance a list of the most commonly read authors is here given. One or two books of a prose writer should be read before any works of the poets are attempted.

Prose Writers. 1. Xenophon (B.C. 430–354), historian, wrote "Anabasis," "Hellenica," "Cyropædia," etc.

2. Thucydides (B.C. 471–400), historian, wrote "History of the War between Athens and Sparta," in eight books.

3. Herodotus, "the father of history" (B.C. 484–420), wrote a history of early Greece.

4. Demosthenes (B.C. 384–322), orator, was the author of several magnificent speeches.

5. Plato (B.C. 429–347), philosopher, disciple of Socrates, wrote "The Republic," "The Apologia of Socrates," and several philosophical treatises.

Poets. 1. "The Works of Homer," the great epic poem of Greece (compiled B.C. 940–850), including the "Iliad" and the "Odyssey."

2. Æschylus (B.C. 525–456),
3. Sophocles (,, 495–405),
4. Euripides (,, 480–406), } the great tragedians of Greece.

Æschylus wrote "The Seven against Thebes," "The Agamemnon," "The Persæ," "Prometheus Bound," "The Eumenides," "The Choephoræ," "The Suppliants," etc. Sophocles wrote "Œdipus Rex," "Antigone," "Ajax," "Philoctetes," "Œdipus Coloneus," etc. Euripides wrote "Medea," "Bacchæ," "Hippolytus," "Hercules Furens," "Iphigenia in Tauris," "Alcestis," "Electra," "Andromache," "The Cyclops," "Hecuba," "Ion," etc.

5. Aristophanes, comic poet, (B.C. 448–380), wrote "The Clouds," "The Frogs," "The Knights," "Plutus," "The Wasps," "The Acharnians," "The Birds," "The Ecclesiazusæ" ("Women in Parliament"), etc.

Xenophon's "Anabasis" is a good book to begin on, and after reading some of it the student might try a book of Thucydides. He will find Thucydides much harder than Xenophon. Not until he has read something of these authors should he try poetry. The best of the poets to begin on is Euripides (say, "The Medea").

Herodotus and Homer should be left till a little later, as they are earlier than the classical period, and their Greek is not "classical." Æschylus is perhaps the most difficult of the poets, and to appreciate the works of Plato (except the "Apologia Socratis") the student needs some acquaintance with philosophy. A rough working knowledge of Greek history is essential, and Abbott's "History of Greece" (Rivington), in two volumes, is recommended. Also the late Prof. Jebb's "Greek Literature" (Macmillan, 1/-) should be procured.

Students desirous of studying the New Testament in Greek are advised to procure one of the Gospels in "White's Grammar School Texts," published by Longmans, 1s. each.

With regard to English translations of Greek authors, among the finest are Jowett's "Republic of Plato" and "Thucydides," Jebb's "Sophocles," Campbell's "Sophocles" and "Æschylus" (World's Classics Series), Butcher & Lang's "Odyssey," and Lang, Myers, & Leaf's "Iliad." The translations in Bohn's series are literal, but hardly inspiring.

Key to Translation (page 6096)

Indian Rivers

And at that time all the Indian rivers* were flowing both great and turbid and with a swift current: for it was the season of the year. And at this season the waters from heaven are carried down in heaps to the Indian land,* and the snows of the Caucasus (whence are the sources of many of the rivers) increase their water. But in winter they become small and clear to see and all passable, except, at least, the Indus and the Ganges.

* For "the Indian rivers" Greek says either οἱ Ἰνδοὶ ποταμοί (the simple and natural order), or οἱ ποταμοὶ οἱ Ἰνδοί (as here), or even ποταμοὶ οἱ Ἰνδοί; but *not* οἱ ποταμοὶ Ἰνδοί, for that would mean "the rivers (are) Indian." This latter is the *predicative* use of the adjective, the former being the attributive.

Continued from page 6121

By W. E. GARRETT FISHER

BEFORE considering the solar system in detail, we must glance at the methods by which the successors of Copernicus ascertained its real movements and relations. Even after Copernicus had persuaded men—not without much opposition—that the earth moved round the sun like the other planets, nearly two centuries passed before the actual laws governing planetary motion were clearly understood.

The First Astronomers. Tycho Brahé (1546—1601), who was the first of the great practical astronomers of modern times, made a series of wonderful and accurate observations of the stars. When we think that he had not the advantage of using a telescope, these observations were remarkably exact, and they provided the material on which the genius of John Kepler worked. Kepler (1571—1630), who was a pupil of Tycho Brahé, undertook to calculate from these observations how the planets ought to move round the sun in order, at all times, to hold the positions in which they were actually found. We can hardly realise the many difficulties of this task, which Kepler carried out by what is known as the Method of Trial and Error. That is to say, he had the unwearied patience to work out the consequence of every possible law of motion which his fertile imagination could suggest. All that he knew for certain was that at certain times the various planets occupied such and such places in the sky. Ultimately, by the aid of the perseverance which amounts to genius, he was successful in discovering the true orbits and laws under which the planets move in them. These laws, known for all time by the name of Kepler, are three in number.

Kepler's Laws of Planetary Motion.
1. The orbit of each planet is an ellipse, having the sun in one focus.
2. As the planet moves round the sun its radius vector describes equal areas in equal times.
3. The square of the time in which each planet completes its orbit is proportional to the cube of its mean distance from the sun.

These laws cannot be fully understood without some acquaintance with mathematics, which, of course, is a necessary prelude to all but the most elementary astronomical work. They may, however, be briefly explained for the comprehension of the non-mathematical reader. The figure in the diagram [7] is an ellipse—what is known in popular language as an oval—which is symmetrical about the line AB, known as its major axis. It has two foci, S and S_1. The fundamental law of the ellipse is that if we take any point P on it, and join this point by a straight line to the two foci, then the sum of these two lines SP and S_1P is always the same—$SP + S_1P = C$. This enables us to draw an ellipse in practice by fastening a piece of string to S and S_1 with drawing pins, placing a pencil in the angle SPS_1, and running it round, so as to keep the string taut. Kepler's first law means that a planet always moves in an orbit of this shape, each planet describing a different ellipse.

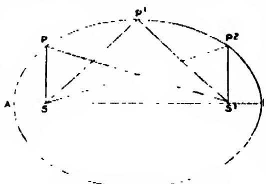
The second law is rather less easy to understand. The *radius vector* is the line joining the sun to the planet at any moment; if we suppose the sun to be at the focus S, and P to be the planet, the radius vector at various positions of the planet will be represented by the lines SP, SP_1, SP_2, etc. If the positions P, P_1, P_2, etc., represent those which the planet occupies after equal periods of time—say, once a month—then the sectors of the ellipse bounded by each pair of lines, SP and SP_1, SP_1 and SP_2, will be equal. If a planet were to move in a circle round the sun, it is obvious that this law would imply that it moved with a uniform speed, but since the curvature of the ellipse varies in every part of its course, so must the speed of the planet in order that its radius vector may describe equal areas in equal times. The planet will, in fact, be moving faster when it is near the sun, as at P, than when it is far off from the sun, as at P_2.

Kepler's third law shows that there is a definite numerical relation between the motions of all the planets, and that the time which each of them takes to complete its orbit depends upon its distance from the sun. We cannot explain in an elementary course why this relation should assume the particular form given to it in Kepler's law, but the reader must take it for granted that this is a necessary consequence of the physical laws under which the planets move.

The Discovery of the Telescope. The next great step in the history of astronomy was taken when the Italian Galileo (1564—1642) discovered the telescope about the year 1609. There is some dispute as to how far the discovery of the fact that two lenses placed in a certain relation to one another [see PHYSICS, page 2901] would magnify distant objects, or bring them apparently nearer to the observer, was Galileo's, but there is no doubt that Galileo was the first to apply this discovery to the study of the stars. His first telescope [8], which was about equal in power to the instrument which can nowadays be bought at a toy shop for two or three shillings, showed him that the moon was another world like our own, with mountains and valleys, rocks and volcanoes, plains, and apparently seas and rivers—though we now know that this was a mistake. Galileo's next discovery with a more powerful telescope was the existence of countless stars which were invisible to the naked eye. The Milky Way, for instance, proved to be no mere luminous haze, but an assemblage of myriads of small stars. The next fruit of the telescope was the discovery that the planet Jupiter had satellites—four little moons, which were to become important as being the first addition made since history began to the numbers of the solar system. Lastly, Galileo discovered the wonderful rings which girdle the planet Saturn, and the existence of spots on the sun. The truth of these discoveries was fiercely assailed, and every schoolboy is familiar with the story of how Galileo was imprisoned by the Inquisition, and forced to recant his belief in the new

science of astronomy. But the progress of truth has never been seriously checked by obstacles of this kind, and Galileo's work served as the solid foundation of the vast and splendid fabric which has been reared by the labours of his followers. In addition to his purely astronomical work, he did a vital service to science by the discovery of the laws of motion, for which the student must consult the course on PHYSICS [pages 35 and 422].

Newton and the Law of Gravitation. The discovery of the telescope, in spite of the theologians, who wanted mankind to put it to their blind eye, like Nelson at Copenhagen, soon eliminated the objections which were still urged to the theories of Copernicus and his successors. The bounds of the solar system had been enlarged, the other planets had been discovered to be worlds like our own in miniature, their motions had been clearly established, and astronomy had now got the length of forming a conception of the whole solar system, much as we see it to-day, with the earth taking its place as a minor planet and sharing the motions of its fellows. But there was still no apparent reason in Nature for all these wonderful and complex movements. Kepler had determined the *how* of the planetary motions, and it remained for Sir Isaac Newton (1642-1727), one of the greatest names in modern science, to ferret out the *why*.



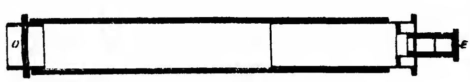
7. KEPLER'S LAWS

Newton, who was born in 1642 in a Lincolnshire village, showed an early genius for mathematics, and was sent to Cambridge, where he devoted his life to this study. Much of his work, which practically resulted in the foundation of modern mathematics, will be found described elsewhere. We have here to deal only with the great service that he did to astronomy. The problem of what should make the planets move, as Kepler had shown that they did, in elliptical orbits round the sun, and hold their steady motion without variableness or shadow of turning, soon presented itself to his wonderful mind as worthy of deep thought. In his own words, he "intended his mind upon this problem for many years," and at last he hit upon the solution. The common story is that it was the sudden fall of an apple from one of the trees in the orchard where he was sitting one summer day, revolving this great problem in his mind, that led the truth to flash upon Newton, and it is quite possible that this may be so. It is often a seemingly trivial accident that leads to a great discovery, just as a solid fragment dropped into a saturated solution makes it suddenly flash into crystals throughout.

The Action of Gravity. It had long been known, of course, that the falling of bodies was due to their weight or *gravity*, and that this simply meant that they were attracted by the earth. Newton did not discover the existence of gravitation, as is sometimes erroneously said. What he did was to apply the well-known force of gravitation to the work of keeping the planets in their orbits. The first law of motion, which Galileo discovered and Newton enunciated as the basis of physical science, asserts that a body continues to move always in the same *straight line unless it is deflected* by some external force. All bodies which, like the planets, move in closed orbits must be continually deflected from a straight line by some constantly acting force, competent to keep them moving obediently round the centre, or they would fly away for ever into the remote abysses of space. Newton was the first to perceive that the familiar force of gravitation, which brings a stone back to the earth after we have flung it away into the air, was also adequate to keep the planets from travelling on in straight lines.

The rate at which a body falls towards the earth is always the same at the same part of the earth's surface, though it varies slightly as we go towards the poles from the equator. Consequently we can calculate the distance which a projectile, starting with a given velocity from the earth's surface, will travel before it falls to the ground [see PHYSICS]. Such a projectile will reach the earth from the highest point of its flight in exactly the same time as if it were allowed to fall from that point. But we know that the earth is a sphere, and its surface is everywhere curved downwards from the straight line which is drawn tangentially to it. Suppose, now, that our projectile is fired along this straight line with such a velocity that by the time it has fallen down 10 ft. towards the earth it has reached a point where the earth's surface is curved 10 ft. downward from the direction from which the projectile was started. Clearly, although it has fallen freely under the attraction of gravitation, it will be no nearer the earth's surface than when it started. By the time it has fallen another 10 ft. the earth's surface will still have curved as far away from it, since the curvature of the sphere increases exactly at the same rate as the speed with which the body falls to the ground.

Thus our imaginary projectile, preserving its initial velocity, as it would do if there were no atmospheric resistance to check it, will also preserve its original distance from the earth, and will ultimately come back to the same place from which it started, after completing the circuit of the earth. If it is fired with a velocity less than we have supposed, it will reach the earth sooner or later; if with a velocity somewhat greater, it will travel away from the earth in a gradually widening spiral. But if the velocity is rightly chosen, our projectile will become a satellite perpetually circling the earth at the same distance. It is, of course, impossible to try such an experiment, even if we could impress the necessary velocity upon our projectile—as, indeed, in days of modern artillery is not outside the range of possibility. The resistance of the air would entirely upset the whole experiment. But the planets, and even our satellite, the moon, are far outside the reach of such a minor consideration; they move through the void of space, which is practically an absolute vacuum and presents no resistance whatever to their movement. Newton was led by some such train of thought to ask himself whether the fact that the moon was constantly falling towards the earth and at the same time moving always forward with a definite velocity, might not suffice to account for its continuance in its orbit.



8. GALILEO'S TELESCOPE
E. Eyepiece *O* Objective

The Law of the Inverse Square. By mathematically working out the consequences of Kepler's laws of planetary motion Newton discovered that these laws implied that the force which held all the planets moving round the sun

must be a force emanating from the sun and varying inversely with the square of the planet's distance from that body. Having made this discovery, he looked round for a force which acted under these conditions, and was capable of producing the observed results. It struck him, as we have seen, that the well-known force of gravitation might be the force required, and he saw that this force would be quite able to keep a projectile circling the earth if it started with the proper velocity, and the resistance of the atmosphere could be removed. He then proceeded to extend this calculation to the moon.

Why the Moon Circles the Earth. The moon is roughly distant from the earth by sixty radii of our planet. Therefore, if the law of gravitation is subject to the condition of varying as the inverse square of the distance, its intensity at the moon would be $\frac{1}{3600}$ of its intensity at the surface of the earth. Now experiment has shown that a body falling freely on the surface of the earth falls about 16 ft. in the first second. Therefore the moon ought to fall towards the earth at the rate of $\frac{16}{3600}$ ft. per second. Newton then calculated whether, if the moon fell constantly towards the earth at this rate, its known velocity would keep it in movement, and always at the same distance from the earth, like the projectile which we have been considering. His calculation apparently came out wrong, and he laid the whole question aside for sixteen years.

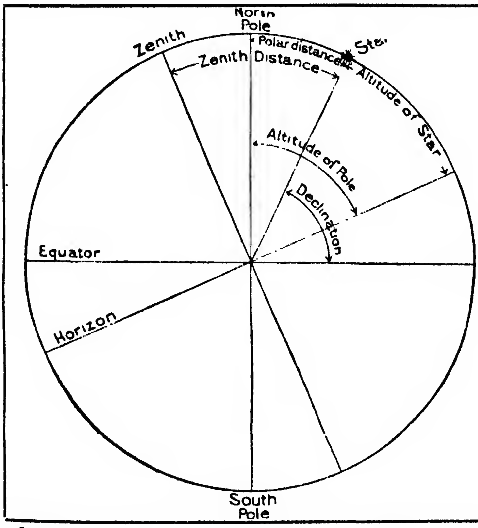
At the end of that time he discovered that his calculation had been based on an under-estimate of the size of the earth. He worked it out again with the improved data which were supplied by a new French measurement of the earth's circumference, and he thus found that the great question was solved. The fall of the moon towards the earth under the influence of gravitation was exactly sufficient, when compounded with its own velocity, to keep it moving for ever in its orbit. Newton at once devoted himself to this investigation, and finally produced the first coherent explanation of the planetary motions. They are all subject to the law of gravitation, which is thus enunciated:

Every particle of matter in the universe attracts every other particle of matter with a force proportional directly to the mass of each and inversely to the square of the distance between them.

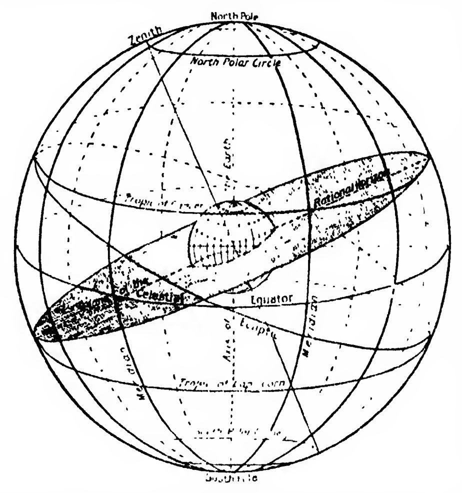
Universal Gravitation. So far as astronomers have been able to observe the behaviour of matter in the laboratory, in our own solar system, or in stellar systems situated so incredibly far away that the most powerful telescope is unable to show their components and light itself takes many years to bridge the abyss by which they are divided from the earth, this law has always been found to dominate material motions, and it is now the fundamental law of mathematical astronomy. It enables us to calculate the motions of all the bodies in the heavens, with the aid of a few observations of their positions at different times. In this manner tables of the movements of the moon and planets can be prepared for any length of time in advance. The "Nautical Almanac," which is indispensable to the navigator, contains such a set of tables for the whole year, and the chief business of Greenwich Observatory is to prepare this almanac for publication years in advance. We shall see elsewhere how these tables enable the sailor to find his way across the seas [see NAVIGATION]. The method by which they are calculated is very much more complicated than any we can explain here, since none of the planets moves under the simple influence of the sun's gravitation and its own velocity, but they are all *perturbed* by their mutual attraction, and complicated elements are thus introduced into the calculation of their future places.

Celestial Measurements. The determination of the places held at any particular time by the planets and the calculation of their orbit fall within the scope of mathematical astronomy. This it is quite impossible to teach in a brief course like the present, which merely aims at giving the student a rational idea of the mechanism of the heavens. But without any but the most elementary mathematics it is quite possible to give an outline of the principles which are involved in celestial measurements and computations.

In the first place it must be understood that the astronomer begins by dealing, not with real places of the planets and stars, but with their apparent projections on the celestial sphere. We are accustomed to talk in popular language of the "vault" of the heavens, the "arch" of



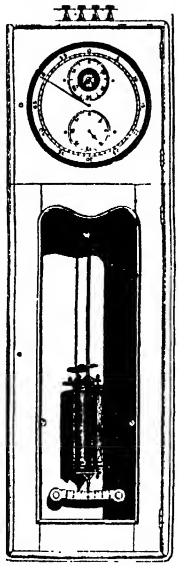
9. HOW CELESTIAL MEASUREMENTS ARE MADE



10. THE IMAGINARY CELESTIAL SPHERE

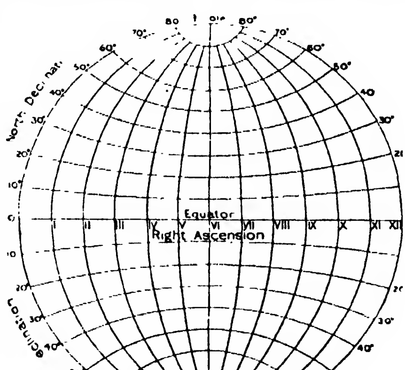
the sky, and so forth. From the earliest times man has had a notion that the earth was surrounded by a vast sphere on which the stars were fixed for his delight. The crystalline spheres of the early astronomers were but the development of this notion, which seems to come naturally to us as we look at the night sky.

As a matter of fact, we know nowadays that the stars are very far from being symmetrically arranged on the surface of a sphere which has the earth, or even the sun, in its centre. Instead of being equidistant from us, as that hypothesis would involve, some of them are hundreds of times farther away than others, and they are arranged in what, so far as we know at present, is an entirely irregular order. But ever since the dawn of astronomy it has been the custom to fix the places of both stars and planets with reference to this imaginary sphere. A little thought will make it clear that, if we ignore the question of the distances of the planets and stars from the earth, we can fix their places and trace their motions just as well if we deal with their projections on a vast imaginary sphere as if we dealt with the actual bodies themselves. This imaginary sphere is supposed to have the earth in its centre, and the regions into which it is mapped out for convenience of reference correspond with the divisions of terrestrial geography [10].



11. SIDEREAL CLOCK

Measurements on the Celestial Sphere. The pair of globes which used to form part of the furniture of every girls' boarding school have unfortunately gone out of use, and it is very rarely that an astronomical globe is nowadays seen. Yet a great deal of this part of astronomy can be learnt in five minutes by studying such a globe, which otherwise takes a long while to describe. The student may, however, take the ordinary geographical globe and apply to it all that we are saying about the imaginary sphere of the heavens. It is well known that the position of any place on the earth can be fixed absolutely by means of two, and only two, measurements. These are called in geography *latitude* and *longitude*. The former gives the angular distance of a town from the equator, and the latter its distance from a fixed meridian, which in English geography is that of the Royal Observatory at Greenwich. A moment's thought will make it clear that there can only be one place corresponding to any given latitude and longitude. Measurements of the apparent place of a star or planet are made in exactly the same way.



12. STELLAR MEASUREMENTS

The imaginary celestial sphere [10] is divided, like the geographical globe, by *great circles* or *meridians*, each of which passes through its two *poles*. These poles are situated where the axis of the earth, if indefinitely prolonged in both directions, would intersect the cele tial sphere, and so they occupy the *zenith* of the terrestrial poles—"zenith" being the astronomical term for the point vertically above the observer's standpoint. Every circle drawn on the celestial sphere which passes through its poles must be a great circle [see MATHEMATICS], which is the largest circle that can possibly be drawn on the surface of such a sphere; and all great circles are equal to one another. The celestial *equator* is a great circle drawn round the imaginary sphere midway between the poles, and it, of course, is situated where the plane of the earth's equator, if indefinitely prolonged, would intersect the celestial sphere [9].

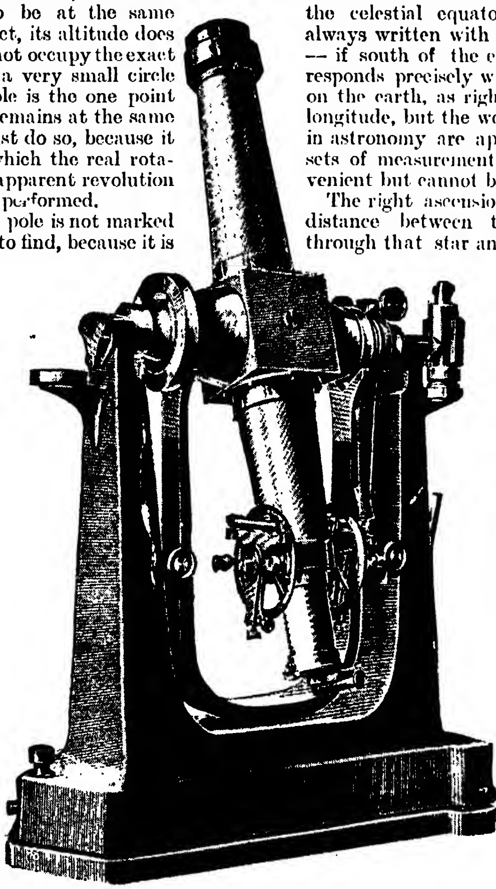
The Meridian. All these imaginary points and lines are definitely fixed in the sky with relation to the earth. But every place on the surface of the earth has its own celestial meridian, which is a great circle drawn on the celestial sphere through the poles and the horizontal points which lie due north and south of the observing station. The rotation of the earth causes this meridian to make a complete revolution of the sky in twenty-four hours. In the course of this revolution it passes over every visible star; but for convenience we usually speak of these stars as crossing the meridian, which we consider to be fixed as it appears to our senses, though, of course, this is only a way of speaking, and no astronomer forgets for a moment that the reality is just the reverse of the apparent fact. If we are going to set up an astronomical observatory, the first thing that we have to do is to determine the exact position of its proper meridian—or, in other words, to mark the point due south of it. The next thing is to determine its terrestrial latitude.

The latitude of a place on the earth is measured by the number of degrees between it and the equator. As the *quadrant*, or quarter of the great circle or meridian intercepted between the poles and the equator, measures 90°, we can, if we like, express the position of our station with equal accuracy by measuring its *polar distance*, which is obtained by subtracting the latitude from 90°; it is merely a question of convenience which measurement we use [9]. Bearing in mind that the celestial sphere is simply a reproduction of the terrestrial sphere on a larger scale, we shall see that the point on the celestial sphere which is the zenith of our standpoint has the same relation to the celestial pole and equator as the observing station has to the terrestrial ones. Talking of the zenith introduces us to another very important great circle on the celestial sphere—that of the *horizon*. The horizon, in popular language, is the limit of our vision at any particular place. But the astronomical horizon is more exactly defined as a great circle distant 90° from the zenith. If we are at sea, or on one of the flats of the Fen district, or a similar plain, the apparent

horizon and the astronomical horizon practically coincide.

Determining Celestial Altitudes. A glance at the diagram [9] will now bring out some interesting relations between these various points and circles on the celestial sphere. The *altitude* of any point in the heavens is measured by its distance in degrees from the horizon, and its *zenith distance* by the number of degrees between it and the zenith; the altitude, of course, can always be obtained by subtracting the zenith distance from 90°. When we are observing the altitude of any star, we usually find that it varies according to the time when we look at it. There is one exception to this rule, and that is the Pole Star, which seems to the naked eye always to be at the same altitude. As a matter of fact, its altitude does vary slightly, since it does not occupy the exact celestial pole, but makes a very small circle round it. The celestial pole is the one point in the sky which always remains at the same altitude. Evidently it must do so, because it is the end of the axis on which the real rotation of the earth and the apparent revolution of the celestial sphere are performed.

The actual north celestial pole is not marked by any star, but it is easy to find, because it is the centre of the circles which all the stars appear to describe in twenty-four hours. Its altitude is found in practice by measuring the latitude of any convenient circumpolar star when it crosses the meridian above and below the pole, and the average or *mean* of these two altitudes will obviously give the altitude of the pole. A glance at the diagram will make it clear that the altitude of the pole at any particular place must be exactly equal to the latitude of that place. Thus, at the north pole of the earth the altitude of the celestial pole is 90°; in other words, it coincides with the zenith; at the equator the altitude of the celestial pole is zero, and thus it lies on the horizon. As we go north from the equator the north celestial pole gradually comes into sight, and rises higher in the sky; at London its altitude is about 51½°.



13. PORTABLE TRANSIT TELESCOPE

Stellar Measurements. Two measures, as we have seen, are enough to fix a place on the earth's surface, and they will similarly fix the position of a star in the sky. There are various ways in which these measures may be taken. We might measure the *altitude* of a star at the moment when it crosses the meridian to the south of the pole, and the *time* at which it crosses the meridian. We might measure the distance of the star from the celestial equator, and its distance from any fixed point on that equator, and thus determine its celestial latitude and longitude. We might measure its distance from the zenith, or its altitude, and its distance from a fixed point on the horizon, which is known as its *azimuth* when measured from the south point.

This would be an inconvenient system, because such measurements would be continually changing with the diurnal rotation, whereas the angular distances of an object from the celestial pole and from a fixed point on the celestial equator are constant.

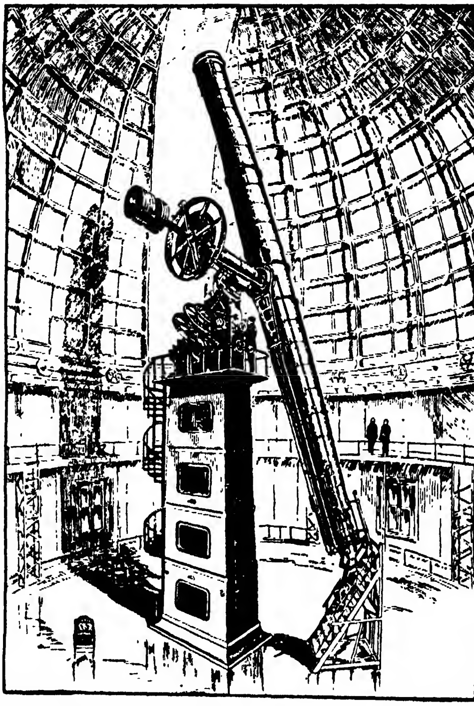
Right Ascension and Declination. The measurements by which an astronomer usually fixes the place of any star are known as its *declination* and its *right ascension* [12]. The declination of a star is its distance in degrees north or south of the celestial equator; for convenience it is always written with the sign + if north, and − if south of the equator. Declination corresponds precisely with the latitude of a place on the earth, as right ascension does with its longitude, but the words *latitude* and *longitude* in astronomy are applied to entirely different sets of measurements—which is rather inconvenient but cannot be helped.

The right ascension of a star is the angular distance between the great circle passing through that star and the pole, and another great circle passing through the pole and a fixed point on the celestial equator which is known as the vernal equinox. Right ascension is always reckoned from the equinox, which is zero, completely round the equator, which is divided into 360°. As the celestial sphere apparently makes one complete revolution in 24 hours, the meridian will pass over 15° of the celestial equator in every hour. It is usual, for convenience, to reckon right ascension not in degrees, but in hours, minutes and seconds. One hour is equal to 15°, one minute of time to 15 minutes of angular measurement, and one second of time to 15 seconds of angular measurement—thus expressed in symbols: 1 hr. = 15°, 1 min. = 15′, 1 sec. = 15″. As the position of a place on the earth is given by saying that it is situated in latitude 51° 30′, longitude 0°, so the position of a star like Sirius is given by saying that its right ascension is 6 h. 40 m. 12 sec., and its declination is 16° 35′.

There is used in practice a very convenient method of determining the right ascension of any star. If we know the time at which the imaginary point on the celestial equator known as the vernal equinox crosses the meridian of our observing station, and then observe the time at which the given star crosses that meridian, the interval of time between these two events will always give the right ascension of the star. Similarly the declination

of a star can easily be found by measuring its *north polar distance*, or the number of degrees which divide it from the north celestial pole. If this distance be less than 90°, the declination of the star is got by subtracting it from 90°; if it be greater, the declination is obtained by subtracting 90° from the north polar distance and prefixing a minus sign.

The Measurement of Time. Astronomy, as we have seen, introduces us to a measurement of time which differs somewhat from that in ordinary use. The ordinary day of twenty-four hours is simply the period in which the earth completes one revolution, as measured by the apparent movement of the sun. But since this motion is not quite uniform, the real solar day differs in length by nearly a minute at different times of the year. There is no such difference in the period of the earth's rotation, which is the most absolutely uniform measure of time that we know. We use consequently what is called *mean solar time*, which is a measure of this rotation. But we have already seen that the earth completes its apparent revolution in rather less than a day—to be exact, in 23 hours 56 minutes 4·09 seconds. This sidereal day is the interval of time which elapses between two successive passages of the same star across the meridian of a place. It is easy to understand the difference between the solar and the sidereal day when we notice that it amounts to exactly one day in a year. The sidereal day is measured by the rotation period of the earth. But the earth not merely rotates, it also revolves round the sun in a yearly orbit. In the course of this revolution it completes one additional rotation on its own axis. Therefore the earth makes only about 365¼ rotations in a year with regard to the sun, whilst it makes 366¼ with regard to the stars. This is why the sidereal day is shorter than the solar day by about $\frac{1}{366}$ part.

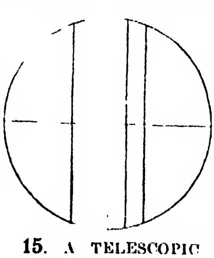


14. MODERN EQUATORIAL TELESCOPE

The Astronomer's Clock. One of the most essential pieces of apparatus in an observatory is a clock set to keep sidereal—not solar—time, and so regulated that it points to 0 h. 0 m. 0 secs. at the moment when the vernal equinox crosses the meridian. This clock [11] is always divided into twenty-four hours, to avoid the inconvenience of having to say morning or afternoon. For the same reason astronomers divide the solar day into twenty-four hours, beginning at noon so that the hours after midnight are known as 13, 14 etc. With the aid of this clock the right ascension of any star can be immediately found by observing the instant at which it crosses the meridian; the hour then shown on the sidereal clock will give its right ascension.

The Ecliptic. There is one other great circle of the celestial sphere which is of importance. This is the ecliptic, or great circle in which the sun appears to travel [see **10**]. It is really, of course, the circle in which the plane of the earth's orbit intersects the celestial sphere. The poles of the ecliptic are the two points 90° distant from it. The ancient astronomers usually defined the places of the heavenly bodies by their celestial *latitude* and *longitude*, measured respectively north or south of the ecliptic, and along the ecliptic from the vernal equinox. These measurements have nowadays given place to the more convenient system of right ascension and declination.

The Transit Telescope. We now come to consider the instruments by means of which astronomers measure the position of the stars and planets. The telescope is an essential adjunct to this work, but it is not used in this instance to magnify the celestial object, as is the case in other branches of astronomical work, but simply to define its position with the greatest possible accuracy. Before the telescope was invented astronomers could only determine the apparent position of a star by pointing a straightedge to it as nearly as possible. They achieved a wonderful degree of accuracy with the instruments made on this principle, but it was only the invention of the telescope which rendered possible the achievements of modern astronomy. The telescope is now used by astronomers in exactly the same way as the surveyor uses the theodolite—in order to give precision in getting the exact direction of the object. The field of the telescope used for this purpose is divided into a number of parts by the finest possible threads of spider's web, which are arranged so that two of them intersect in the exact centre of the field [15]. When the image of the star or planet is made exactly to coincide with this intersection, we are sure that the telescope is pointing absolutely to its apparent place.



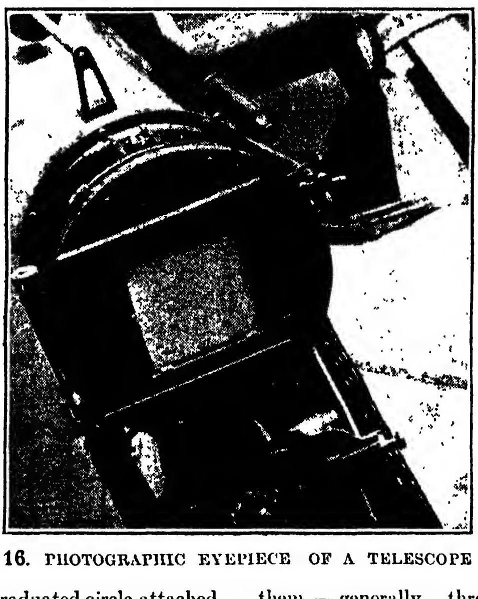
15. A TELESCOPIC FIELD

The *transit instrument* [**13**], which is the one chiefly used for the determination of stellar places, consists of such a telescope with a lens 10 in. or 12 in. in diameter. It is fixed up on the diameter of a large circle, known as the *transit circle*, whose circumference is divided into 360° and their fractions. This transit instrument is set up in the observatory so that the plane of its circle coincides with the plane of the meridian. The telescope is mounted on a horizontal

axis, so that it is free to swing up and down in this vertical plane, but cannot move out of it. The central thread in its field is so adjusted that it precisely coincides with the meridian, however the instrument may be turned on its axis. The greatest precautions are taken to insure absolute rigidity in the mounting of a transit instrument, which is usually placed on a very massive block of masonry so as not to be affected by local tremors of the earth.

Finding Stellar Places. When it is desired to observe the meridian passage of a star, the telescope is turned by means of the graduated circle to the known altitude at which the star culminates. The sidereal clock stands also beside the transit instrument, beating seconds very audibly. When the star is almost due, the observer begins to count the seconds from the beginning of the last minute. As it flashes into the field of his telescope, and hastens across the threads, he estimates the exact moment at which it crosses each of them, usually five or seven in number, and by taking the average of all these readings he gets the precise instant at which the star has crossed the central thread, or the meridian. In modern practice the electric chronograph is called to the astronomer's assistance, and by merely pressing a button as the star crosses each wire the time is registered with greater accuracy than was possible under the old method. The time of meridian passage, when various minute corrections for the error of the clock, the observer's personal equation, and so forth have been applied to it, gives the right ascension of that star.

The transit instrument can also be used to measure the declination of a star. As a matter of convenience, what is measured is not the star's actual declination, but its zenith distance. The field of the telescope contains a horizontal spider line [**15** AB] as well as the vertical ones used in recording transits. This line is movable by a screw. When the star whose declination it is desired to observe is approaching the meridian, the telescope of the transit instrument is pointed as nearly as possible to its place, and as the star rushes across the field of the telescope this horizontal line is adjusted so that it bisects the image of the star just as it crosses the meridian. By means of the graduated circle attached to the telescope the angular distance between the star and the zenith can then be measured accurately, and if we know the latitude of the observing place it is a simple calculation to find the star's declination [**15**]. There are many other forms of instrument, all consisting of a telescope in conjunction with some means of measuring its changes in direction, which will be found fully described in such a textbook as Mr. G. F. Chambers's "Astronomy."



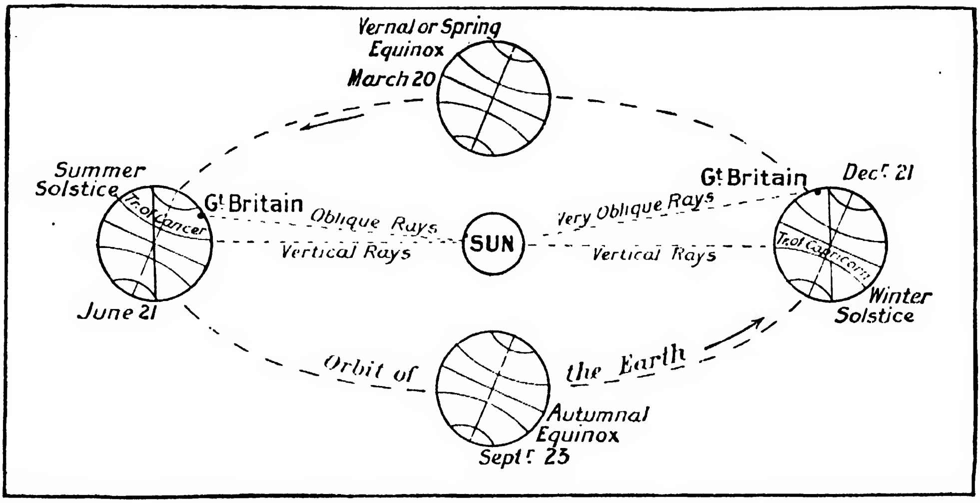
16. PHOTOGRAPHIC EYEPIECE OF A TELESCOPE

The Telescope. The telescope is an essential part of most astronomical instruments, and must be briefly described, though for fuller details the student is recommended to consult the course on OPTICS and page 6126. The telescope has two functions in astronomy. One is to enlarge celestial objects by collecting into one focus the rays received on its lens or mirror. The other is to ascertain the exact place of a stellar object by enabling us to be sure that our instrument is pointed exactly towards it. The former function of the telescope is chiefly employed in studying the moon, sun, and planets, and the latter in studying the stars. Telescopes are of two kinds, *reflecting* and *refracting*. The former brings the rays of light to a focus by means of a concave mirror, the latter by means of a convex lens. Galileo's original telescope was a refractor, and the most powerful modern telescopes are built on these lines.

The Achromatic Refracting Telescope. The reflecting telescope was introduced by Sir Isaac Newton on account of the great difficulty which existed in his day in obtaining large discs of glass sufficiently pure and homogeneous to form the lenses of large telescopes. This difficulty has now been practically overcome, and lenses as large as 4 ft. in diameter can be constructed with great accuracy. The lens, however, has an essential imperfection from which the concave mirror is free. Ordinary light consists of a great many rays of different colours and of different degrees of refrangibility. The concave mirror brings these all to a focus at the same point, whereas the glass lens does not, and consequently the early refracting telescopes gave blurred images, which became less distinct as the lenses were made larger, and the distances through which the different rays were deflected increased.

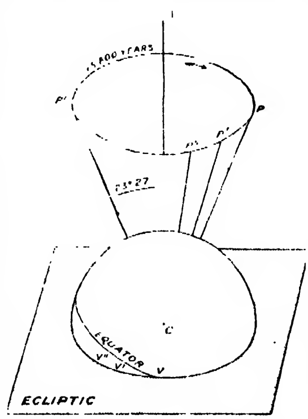
This difficulty has been largely obviated since Dollond's discovery of the *achromatic lens*, which is made up of two lenses of different kinds of glass. The modern refracting telescopes give images almost as clear as the reflecting telescopes, and they have practically superseded the latter. For all purposes of mathematical astronomy, which deals with the motion of the planets and stars, little or nothing is gained by increasing the size of the telescope beyond 10 in. or 12 in. in aperture. The gigantic telescopes [**14**] which are made nowadays for such observatories as can afford them — generally through the munificence of millionaires like Mr. Lick and Mr. Yerkes—are designed for the use of the physical astronomer, who endeavours to find out the conditions which exist on the surface of the various planets, and to discover the constitution of the sun and its brother stars.

Photography and the Telescope. Nowadays the photographic camera is largely used in conjunction with the telescope as a supplement to the eye of an observer. The photographic plate is capable of recording impressions which are far too faint and illusive to be recorded by the human



17. EQUINOXES AND SOLSTICES AND THE ECLIPTIC

eye. If one gazes very long at the same object the eye grows fatigued, whereas the photographic plate never wearies and continues to accumulate information from the successive rays of light which are allowed to reach it, often for many hours at a time. In this way a great many new celestial facts have been discovered, such as the existence of the vast nebula which envelops the Pleiades, and is quite beyond the reach of the most powerful telescope in the hands of a human observer. The light rays which have most effect upon the photographic plate are almost invisible to the eye, and, consequently, special photographic telescopes are now made with the lenses so curved that these actinic rays are brought by them to an exact focus in preference to the rays of longer wave length by which normal vision is conducted. The latest survey of the heavens has been made by means of a number of similar photographic telescopes [**16**], erected at observatories in all parts of the world, which have succeeded in charting something like thirty million stars.



18. THE PRECESSION OF THE EQUINOXES

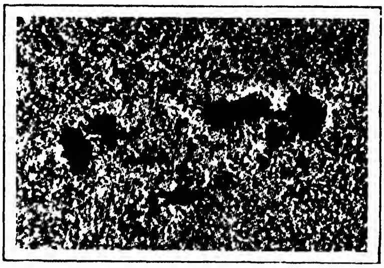
The Spectroscope. After the telescope, the instrument which is of greatest value to the modern astronomer is the spectroscope. It is by means of this marvellous instrument that we have been enabled to analyse the constitution of the sun and the far-off stars, and to satisfy ourselves that the universe is everywhere composed mainly of the same chemical elements which are found upon the earth. In its simplest form it consists merely of a telescope and a prism. Newton discovered more than 200 years ago that when ordinary sunlight was passed through a glass prism it was split up into a band of colours [see Frontispiece opposite page 6097], gradually shading off from red at one end through orange and yellow and green to violet at the other. For a fuller explanation of this fact the course on OPTICS must be consulted; it is enough to say here that it means that light consists of vibrations or waves in the ubiquitous ether, which vary merely in length. Light of one particular wave-length is always associated with the sensation of a particular colour when it falls upon our eyes, and white light is a mixture of a great number of rays of all possible wave-lengths. The action of the spectroscope is simply to analyse the light which falls upon it from a distant object into a regular series of wave-lengths, each of which is recognisable by its particular colour and also by its place in the *spectrum*, as the colour band shown by the prism is called.

Spectrum Analysis. The first great step in spectroscopic analysis was taken when Kirchhoff and Bunsen discovered, in the early part of the last century, that a heated gas gave out light rays of the same wave length as those which it absorbed when ordinary white light was passed through it. White or solar light is made up of rays of very various wave-lengths. But these do not form a continuous series. When we examine this solar light with the aid of a spectroscope, we see that the long band of variously coloured light, into which it is drawn out by the train of prisms, is crossed from end to end by a series of dark lines, varying in width. Each of these dark lines, of course, is simply the negation of light at this particular place in the spectrum. Something between us and the luminous body of the sun has stopped the ray of light whose wave length would make it visible at the particular spot in the spectrum where a dark line occurs.

If we apply the spectroscope to analyse the kind of light which we produce in the laboratory by heating some element until it becomes incandescent, we find that we get an entirely different kind of spectrum, which consists of a few bright lines. If a piece of sodium is held in the flame of a Bunsen burner, and looked at through the spectroscope, we see a few bright yellow lines, whereas, when iron is similarly treated, the spectrum consists of several hundred bright lines.

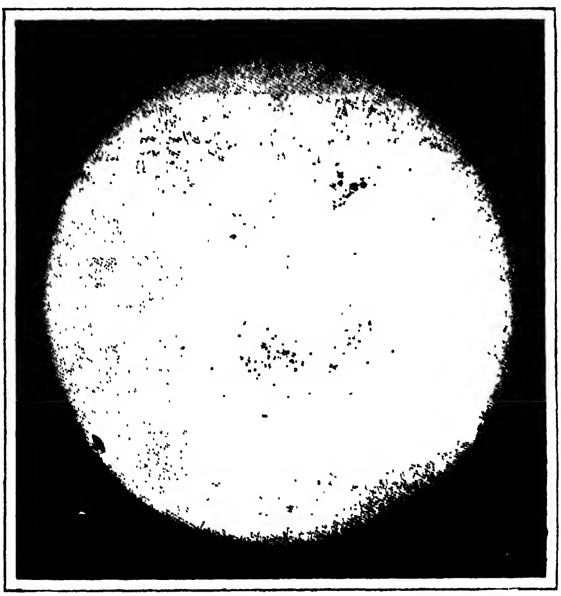
It is further found by experiment that the same element, when reduced to the condition of incandescent gas, invariably makes its presence known by the appearance of the same series of bright lines. Consequently, the spectroscope affords a simple and conclusive test of the presence of any particular element in a body which is hot enough to be reduced to the condition of an incandescent gas.

This is the physical state of all the visible stars, and the reader will now begin to see how it is possible for us to detect the chemical constitution of such stars. When we turn the spectroscope upon a star, though it be so far away that its light may have taken hundreds of years to reach us, and see the bright lines which characterise the spectrum of hydrogen blazing out in their unmistakable positions, we say at once that the atmosphere of that star must consist of white-hot hydrogen, and so on with all the other elements which have been discovered as existing in stars.



19. SUN-SPOTS AND GRANULATION OF SUN'S SURFACE
(Photographed at Meudon Observatory by M. Janssen. From "Knowledge")

Selective Absorption. But the discovery of what is called *selective absorption* by Kirchhoff and Bunsen carries us a step further. When a white-hot solid body is examined with the spectroscope, it invariably gives what is known as a continuous spectrum, in which there are no dark lines, but the colour shades off uniformly from one end to the other. The spectrum of the sun and many of the stars is of this character, with the addition of the numerous dark lines which have already been mentioned. Kirchhoff and Bunsen discovered by experiment that if light from an incandescent solid body were passed through a volume of gas, that gas absorbed exactly the same kind of light which it would emit if it were hot enough to shine by its own light. Consequently, if we find that the spectrum of a particular star is a continuous spectrum crossed by a series of dark lines which correspond in number and position to the bright lines which form the spectrum of incandescent hydrogen, we can say at once that the star consists of a glowing solid body encompassed by an atmosphere of hydrogen.



20. PHOTOGRAPH OF THE SUN, OCT. 22ND., 1905
(By E. W. Barlow, F.R.A.S., from "Knowledge")

As a rule, stellar spectra are much more complicated than this simple example, and we find in such spectra dark lines which prove the existence of a large number of elements in the atmospheres of these remote orbs. It will now be seen how the spectroscope is able to tell us of what elements the stars are composed. Its use affords the basis for a very important branch of astronomy known as astrophysics, and some of the facts deduced from it will be explained later.

The Equatorial Telescope. The large telescopes which are used for studying the physical condition of the stars and planets are mounted in a peculiar fashion which must here be explained. We have seen that the telescopes used for measuring the position of the stars are mounted in such a way that the star to which they are pointed appears to rush rapidly across their field, and only a fleeting glimpse can be had of it. This, of course, is due to the fact that the telescope shares the earth's rotation. But when it is desired to watch a star or planet through the greater part of a night, it is necessary to have some method of keeping it constantly in the field of the telescope. The larger the telescope the more does it exaggerate the apparent motion of the star, and to continue to move it by hand so as to keep the star in its field of vision would be quite impossible in the case of the huge telescopes with which the most important work of this kind is done. This difficulty is obviated by what is called an *equatorial* mounting [14]. The essential part of this is an axis pointing with great accuracy towards the celestial north pole, and borne on the top of a solid pier of masonry: this is known as the polar axis. Through a socket on the end of this axis passes another axis at right angles to it, known as the declination axis.

The telescope is rigidly attached to the upper end of the declination axis, and balanced by a weight at its other end, so that it has no tendency to turn round on the polar axis. The polar axis is attached to a system of clockwork which makes it turn slowly round from east to west at the rate of one revolution in twenty-four hours. As the earth completes a revolution from west to east in the same period, the one movement exactly neutralises the other, and if the telescope be pointed at any celestial object, by turning it on the declination axis it will continue to follow that object so long as the clockwork is kept in motion.

All that the observer has to do, when he has once fixed his telescope in the proper direction, is to move from time to time so as to keep his eye at the eyepiece of the telescope, which appears, of course, to be revolving with regard to him. It is with these two instruments—the transit circle and the equatorial telescope, supplemented by the spectroscope and the camera when necessary—that by far the greater part of modern astronomical research is carried out. The transit circle provides the data for mathematical or descriptive astronomy, and the equatorial, with the spectroscope and camera, provide the data for physical astronomy.

We shall now pass on to a general account of the solar system, as its mechanism and constitution have been revealed by the use of such instruments.

The Solar System. The solar system consists of a central star, the sun, round which there revolve eight major planets with their satellites, a swarm of nearly six hundred minor planets or asteroids, and an unknown number of comets and meteorites. The planets are divided for convenience into two groups of four each. The inner planets in order are Mercury, Venus, Earth, and Mars; the outer planets are Jupiter, Saturn, Uranus, and Neptune. The minor planets, with only one exception yet known, occupy the space between Mars and Jupiter. The only planets which have no known satellites are Mercury and Venus; Earth has one—familiar to us all as the moon; Mars has two; Jupiter, seven; Saturn, ten; Uranus, four; and Neptune, one. All the planets move round the sun in elliptical orbits, which are not very far from being circular, whereas the comets and meteorites move in extremely eccentric orbits, some of which are strongly suspected not to be ellipses at all, but hyperbolic curves which carry them away for ever into space after a visit to the sun. The following table shows the diameters, masses, distances from the sun, and periodical times of the eight major planets.

Planet.	Diameter in miles.	Mass (Earth = 1).	Mean Solar distance in millions of miles.	Periodical time in years.
Mercury ..	3,030	0·047	36·0	0·24
Venus	7,700	0·82	67·2	0·62
Earth	7,917·6	1·0	92·9	1·0
Mars	4,230	0·107	141·5	1·88
Jupiter ..	86,500	317·7	483·3	11·86
Saturn.. ..	73,000	94·8	886·0	29·46
Uranus ..	31,900	14·6	1,781·9	84·02
Neptune ..	34,800	17·0	2,791·6	164·78

The Immensity of the Sun. The great luminary which warms, lights and rules the solar system is, like the majority of its fellow stars, a gigantic bubble. In other words, it is a globe of glowing gas, which is nowhere solid, though the immense pressure which must exist in its interior probably causes this gas to assume there a density greater than that of any solid which we know. The sun appears to human vision as a brilliant globe of a little more than half a degree in diameter. It is about the same apparent size as the moon, since the size of the sun is to that of the moon very nearly in the same proportion as their relative distances from the earth. In reality, however, the sun is a gigantic orb, so huge that if the earth were at its centre the whole orbit of the moon would lie well within its circumference. The diameter of the sun is about 866,500 miles. If the sun were represented by a globe 2 ft. in diameter, the earth on the same scale would be the size of a large pea, less than a quarter of an inch in diameter.

The mass of the sun is about 332,000 times that of the earth, but its specific gravity is only about a quarter that of the earth—1·41 if that of water be taken as unity. The mean distance of the sun from the earth is about 92,900,000 miles; but as the earth's orbit is not circular but elliptic, this distance varies by about 3,000,000 miles, being smallest in January, and greatest in July.

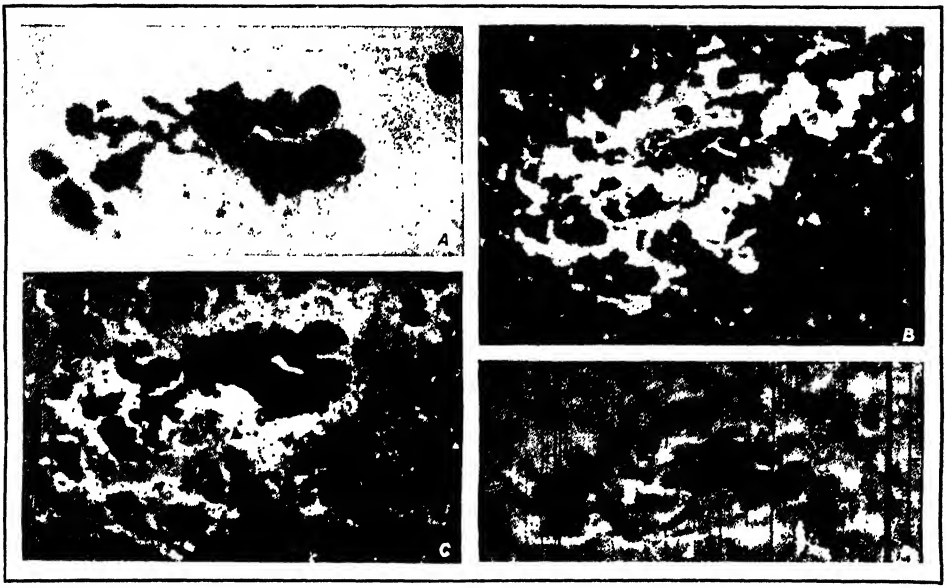
Solar Movements. The sun rotates on its own axis just like the earth, as has been discovered from the fact that the spots on its surface invariably cross its disc from east to west. It completes a rotation in 25¼ days. The apparent period of the sun's rotation as seen from the earth, however, is 27¼ days—the difference being due to the fact that the earth is constantly moving round the sun in the same direction in which the latter rotates.

The sun appears to move round the earth in a plane which is inclined to the plane of the earth's equator at an angle of about 23½°. This plane is known as the plane of the *ecliptic*, from the fact that eclipses only happen when the moon is crossing it, and the angle which it makes with the plane of the equator is called the *obliquity* of the ecliptic. This angle is obviously equal to the sun's maximum declination, or distance from the celestial equator in June and December, at which times the sun is respectively north and south of that equator as viewed from our latitudes. The two opposite points in which the great circle of the ecliptic crosses that of the celestial equator are known as the *equinoxes*, because when the sun passes these points on March 21st and September 21st, day and night are equal in length. The two points in the ecliptic which are equidistant from the equinoxes are called the *solstice*, because when it reaches them on June 21st and December 21st, the sun appears momentarily to stand still, and thereafter reverses its motion in declination [**17**]. The plane of the ecliptic is really the plane of the earth's orbit.

Precession of the Equinoxes. It has been known for more than two thousand years that the equinoxes do not remain constantly at the same point in the ecliptic, but that they are slowly moving westward along it. They complete the circle in about 25,800 years, so that since Hipparchus discovered this movement in 125 B.C., about one-twelfth of it has been described. Consequently, as we shall see directly, the Zodiacal signs no longer correspond to the constellations after which they were named three thousand years ago, but each of them has drifted into the next constellation. This movement, known as the *precession of the equinoxes*, is due to the fact that the earth's axis does not remain strictly parallel to itself, but travels round the outside of a cone, just like the axis of a sleeping top [**18**]. Consequently the plane of the earth's equator, and of the celestial equator, is continually changing; and, as the equinoxes are simply the points at which the equator intersects the ecliptic, they must change too. One result of this is that the celestial poles are also changing; they move in small circles round the poles of the ecliptic.

The present Pole Star happens to be close to the celestial north pole; but in the lapse of many centuries the latter will move away from it, and other stars will be known as Pole Stars. About 14,800 A.D., the brilliant Vega will be sufficiently near the Pole to become the Pole Star.

The Zodiac. The belt of the sky which occupies 8° on each side of the ecliptic is called the *zodiac*, and it is within this belt that the moon and the chief planets confine their movements, since none



21. THE GREAT SUN-SPOT OF 1903, OCTOBER 9

A. The Spot photographed at Greenwich B. and C. Calcium flocculi at different levels D. Hydrogen flocculi (From "Knowledge")

of their orbits is inclined to that of the earth by more than 8°. The Zodiac, which circles the celestial sphere, is divided into twelve signs, each of which occupies 30°, and roughly coincides with a constellation. The following lists give the *signs of the Zodiac*, with the seasons in which the sun passes through each of them:

Spring: Aries the Ram; Taurus the Bull; Gemini the Twins.

Summer: Cancer the Crab; Leo the Lion; Virgo the Virgin.

Autumn: Libra the Balance; Scorpio the Scorpion; Sagittarius the Archer.

Winter: Capricornus the Goat; Aquarius the Water-bearer; Pisces the Fishes.

Owing to the precession of the equinoxes, the signs of the Zodiac do not now correspond with the constellations of which they bear the names. Thus the sign Aries, in which the sun is seen on March 21st as it passes the vernal equinox, with which the solar year begins, is now in the constellation of Pisces, and in the course of the next 23,000 years it will move steadily backward through the constellations until it returns to the Ram, where it stood when its name was first given to it.

The Sun's Photosphere. The bright visible surface of the sun is known as the *photosphere* [**20**], or sphere of light. It probably consists of a vast sheet of incandescent clouds floating in a less luminous atmosphere, and it is intensely brilliant for the same reason as the mantle of an incandescent gas burner, because of the intense temperature to which it is raised. It is not easy to estimate the actual brightness of this photosphere, but the most powerful electric light which we are able to produce looks absolutely black when projected against it. The temperature of the photosphere cannot be measured with any exactness, but it is certainly greater than any which we can attain on the earth, being at least 6,000° C. The temperature of the sun's interior must undoubtedly be very much higher than that of its surface. The photosphere examined through a telescope is not homogeneous, but consists of a darker background, sprinkled over with *rice grains* or *granules*, which are much more brilliant [**19**]. The rice grains are usually about 500 miles in length, but here and there are drawn out into long streaks known as *filaments* or *willow leaves*. The surface of the sun is mottled here and there with brighter specks and patches called *faculæ*.

Sun-spots. The most interesting fact about the photosphere is the existence in it of *sun-spots*, which vary greatly in size, number, and duration [**19**, **20**, and **21**]. Sometimes these spots are exceedingly numerous, so that hardly any part of the equatorial belt of the sun is free from them; at other times, hardly one is to be seen. Some of them seem to appear and disappear again within the space of two or three days; others persist for months at a time, and it is by means of these persistent spots that the periods of the sun's rotation has been measured. The smallest spots visible through our telescopes are only about 500 miles in diameter, whilst the largest may be seven or eight times as big as the earth. A typical spot consists of a central part, called the *nucleus*, surrounded by a border, the *penumbra*, which is intermediate between the dark centre and the surrounding brilliance of the photosphere [**21**]. The penumbra surrounding a group of spots has been known to be as much as 150,000 miles in diameter, and spots of this size can be seen with the naked eye, when the sun is viewed through a cloud or piece of smoked glass.

The real nature of sun-spots is still disputed, but there is little doubt that they are something of the nature of whirlpools or storms in the photosphere. It has been discovered from a long series of observations that the number of spots visible on the surface of the sun varies through a period of about 11 years. 1905 was a year of sun-spot maximum, and in 1912 the number of sun-spots will probably have sunk to a minimum, rising again to a maximum about 1916.

Various attempts have been made to trace the influence of the spot cycle on terrestrial meteorology. There is little doubt that it has some influence of this kind, because the development of a large sun-spot is invariably accompanied by electrical disturbances on the earth. It is practically certain that the appearance of a large number of sun-spots on the sun's photosphere indicates that the sun is in a condition of abnormal activity, but we can hardly go further than that yet.

The Chromosphere and Prominences. Above the photosphere of the sun lies an atmosphere called the *chromosphere*, which is probably about 10,000 or 12,000 miles in thickness. This "sphere of colour" is so called because it is of a brilliant scarlet hue. We do not usually perceive it, because its light is usually drowned in the intense radiance of the photosphere. But on the rare occasions when the sun is eclipsed by the passage of the moon between it and the earth, this scarlet chromosphere suddenly flashes into sight when the photosphere is hidden. The spectroscope shows that it is chiefly composed of incandescent hydrogen, mingled with helium and calcium vapour.

The lower portion of the chromosphere is known as the *reversing layer*, because when the spectroscope is turned upon it during an eclipse at the moment of totality, all the dark lines which usually cross the solar spectrum suddenly flash out in brilliant colour against a dark background. This means, as we have already seen, that these dark lines are due to the absorption of light, of the wave lengths corresponding to each of them, by the lower portion of the chromosphere. It is from these lines that we deduce the existence of a large number of terrestrial elements in the sun, of which the most important are hydrogen, helium, carbon, iron, copper, silver, tin, lead, sodium, potassium, silicon, zinc, calcium, magnesium, aluminium, possibly oxygen, and a number of less common metals. There is good reason to suppose that all the other terrestrial elements are present in the sun, but as yet their existence has not been established. It is possible that some of them are not really elements, and are dissociated by the intense heat of the solar atmosphere.

When the sun is obscured during an eclipse, a number of fiery scarlet clouds or *prominences* [see Frontispiece opposite page 6241] are seen projecting from its edge. Since 1868, when the spectroscope was first turned upon these objects, it has been known that they are clouds or jets of incandescent gas, chiefly hydrogen and helium. They have been known to rise as much as 400,000 miles from the sun's surface, with a velocity which may be as great as 250 miles per second. These prominences can be seen actually springing up and changing form, and a very ingenious adaptation of the spectroscope, which we owe to Lockyer and Janssen, enables us to study them even when they are quite invisible to the eye.

The Corona. The outermost appendage of the sun is the *corona*. It has been known from very remote antiquity as a wonderful halo or crown of light which surrounds the sun at the moment of eclipse but is quite invisible at other times, even to the eyes of science, though there is reason to believe that before very long we may be able to study it also at any time that we choose. Its nature is not yet fully understood, though we believe that it is some kind of extremely tenuous atmosphere which stretches out for millions of miles from the solar surface. It varies greatly in form from eclipse to eclipse, and its changes appear to be in some way connected with the number of spots visible on the sun. The spectroscope shows that it consists of glowing gas, chiefly *coronium*, but its extreme rarity is proved by the fact that comets have passed right through it, as in 1882, without any apparent checking of their motion. There is good reason to suppose that its luminosity may be an electrical phenomenon, somewhat analogous to the Aurora Borealis.

The Heat and Energy of the Sun. The sun has two great functions in our system. The first is, as we have seen, to keep the planets moving in their orbits by the power of its gravitational pull. The second is to supply heat and light to those planets. As far as the earth is concerned, there can be no question that the existence of life is made possible entirely by the radiations which reach us from the sun. If it were not for them, the earth would be a sterile globe, with a temperature approaching absolute zero, on which not only the water, but even the air would be frozen solid. The quantity of heat which the earth receives from the sun in a year is sufficient to melt a sheet of ice 200 ft. thick over the earth's whole surface. Every square foot of the earth receives annually enough energy from the sun to raise a weight of 100 tons to the height of a mile. As the sun is radiating heat in all directions alike, it is calculated that it must be giving out continuous energy equal to nearly 120-horse power for every square yard of its surface. How is this immense output of energy kept up? We know from the geological record that it has been going on, at the very least, for 10,000,000 years, and there is no visible sign of its diminution. The old notions that the sun derived its heat from any form of combustion, or that it was merely an intensely hot body which was gradually cooling off, are quite inadequate to account for this marvellous expenditure of energy.

When the Sun will Solidify. The true explanation is undoubtedly that given by Helmholtz and Lord Kelvin, that the sun is a gaseous globe which is continually shrinking as it loses heat. It is not possible to explain within our limits why this shrinkage should keep up the sun's temperature, but it is physically certain that it would do so, just as the fall of a clock weight or the head of water in a reservoir has the power of doing work [see page 315]. The shrinkage of the sun means that its outer parts are steadily falling towards the centre, and in this process they give out sufficient energy to keep up the solar radiation. An annual shrinkage of 300 ft. in the solar diameter is amply sufficient to supply this energy which the sun gives out as heat and light. There is no doubt that such a shrinkage is actually taking place. As yet, it is impossible to apply the test of measurement, since it would need about 10,000 years for the resultant change in the sun's diameter to be perceptible to our most accurate micrometer.

The time will undoubtedly come in the history of the sun, as it has already come in that of the inner planets, at which its surface will begin to solidify, and from that moment its emission of heat and light will begin very seriously to diminish. But at the most moderate computation that time is at least 5,000,000 years ahead of us, and we need not be seriously alarmed about this particular form of the Day of Judgment.

PHILOSOPHY & ITS PROBLEMS

The Desire of Philosophy is to get "to the bottom of things." Truth and Knowledge. Scepticism. Agnosticism. Materialism. Is Mind an Accident of Matter?

Following [illegible] from page 6101

By Dr. C. W. SALEEBY

PHILOSOPHY is a great and noble word, which means the *love of wisdom.* In the primitive sense there are none but the basest few who may not humbly call themselves philosophers.

But, of course, we know that the term philosophy is now employed in a special sense. It is used in order to indicate a special department of knowledge or inquiry, and it is this department which we must first of all seek to define. Biology is concerned with life, astronomy with the stars. What is philosophy concerned with?

Now, it is certainly true that there have been professional philosophers whose works from first to last have amounted to nothing more than mere word-jugglery or verbal gymnastics. Their books may have an elegant appearance, they may be apparently intelligible or apparently unintelligible: but in the upshot, as other writers soon show, there has been nothing said about anything whatever, except merely *words.* It is not by the word-jugglers however, that philosophy must be judged. Its proper subject-matter is not words but realities of some kind: and the business of man's mind is with realities—urgently and necessarily.

The Problem of Philosophy is the Nature of Reality. Indeed it is just precisely the nature of reality that philosophy is concerned with. Phrased in popular language, its desire is to get to the bottom of things. Looking around him, man finds many appearances—"stars and street mud," plants and children—whilst he is, at the same time, conscious of his own self, to which all that is outside it appears. What, then, he asks himself, amidst all this diversity and change and magnitude—what is the inner nature of all these things, or of whatever they represent or are produced by? The problem of philosophy, then, is the *nature of reality* or the *nature of being.*

In comparatively recent times a special word, which may be novel but is not difficult, has been invented in order to do away with the former confusion of names, and that word is *ontology*—which simply means the science of being. It was high time to introduce such a word, because what with such terms as philosophy, metaphysics, logic, epistemology, and a host besides, confusion was becoming worse confounded; and it is confusion that is the pre-eminent danger of the philosopher. At least one of these words must, however, be noted here, and that is the word metaphysics. Metaphysics is a famous old name of scarcely less antiquity than philosophy itself. It was apparently coined by the followers of Aristotle, the greatest pupil of Plato, who was the greatest pupil of Socrates, as a general term for the subject-matter of the treatise which their master composed after his "Physics." Metaphysics simply means *after physics.* Evidently there is no particular virtue in the term, which explains nothing, and may be and has been defined in many very varying senses—including, for instance, what we now mean by "logic." At the present day, however, the best rule to make is to leave the word out of one's vocabulary altogether. So far as the search for truth is concerned, it is of much less than no use at all.

The Question at the Root of all Philosophies. We shall content ourselves for the present, then, with the use of the famous old word, in its best recognised meaning of the search for reality, or we may define it as the quest of truth—meaning by that not merely the practical truth concerning the facts around us, but the ultimate or final truth of those facts and of the facts of mind. But, pray, what is the distinction between the practical kind of truths on which we daily act, and ultimate truth or absolute truth? In what sense can anything be more true, more thoroughly true, than the ordinary facts which we observe in the behaviour of matter around us? This simple and very pertinent question is at the root of all philosophies whatever, and we must do our best to answer it. There is a well-recognised name, indeed, for the doctrine which asserts that truth, as we think we know it, is absolute truth, and that things are what they seem. We may call this doctrine crude realism.

Beyond all question this is the oldest of all philosophies. It is the unformulated philosophy of a child, and, indeed, of anyone who has never thought about the subject. To a child, or to such a man, there can be nothing more real than the reality of—let us say—a chair. It is a thing that can be seen and felt, and "seeing is believing." A chair is plainly a chunk of reality. Things are as they appear to us; there is no more of them than appears to us: and what we see is simply what is there to see. Mind is conceived as a thin sort of matter, and the question of the relation between mind and matter is never asked.

"Chaotism." On this view in its earliest form man lives in a chaos; all around him is infinite multiplicity and variety, which cannot be resolved into anything more simple. As to any relations that may exist between the mind or minds to which these objects are presented and the objects themselves, crude realism asks no questions.

But, as we may readily believe, this earliest of stages is very soon passed. However various the facts of Nature, it very soon becomes evident that there is at least some degree of relation between them. An unsupported stone falls not once or twice only, but always. The sequence of day and night and of the seasons,

the apparent movement of the sun, the growth of crops—these all display some degree of order and hints of interdependence. So unmistakable is this that it had to be recognised long before the birth of science, the business of which is to discuss the relations between the phenomena of Nature; so salient are these relations that the mind must recognise them directly it begins to think at all. Thus, whilst all other conceivable philosophies, one may suppose, have been held by men, there is at least no record of any philosophy that might go by the name of *Chaotism*. Whatever else is uncertain, the fact of order around us cannot be gainsaid.

The Idea of Order. Now surely we have already made a discovery of capital importance. Here, at any rate, is something which is so palpable that, however various men's minds or temperaments, their age or place or training, they must light upon it the very moment that they begin to think at all. There have been many philosophers who declared that there is no external world, many to say that if there is an external world we can know nothing of it, some to say that mind is only an accident, looking on at the matter which produces it—but never yet was there any philosophy that did not admit, to some extent at any rate, this idea of order. The order is outside us, say some thinkers; there is nothing whatever outside us and the order is within us, say others; the order only applies to some things, say the savage and the superstitious; order is universal, says the thinker—but none of them will deny the existence of order at all. Men have subscribed to every philosophy but Chaotism.

Now, once the mind has begun to recognise traces of order here or there, it has a way of going a little further afield, in order to see how far this principle may be traced. The whole history of science is a history of the ever widening demonstration of the existence of order, and it is the profound belief of all men of science to-day that order is universal. As a matter of fact, however, philosophers have not waited for, let us say, the perfecting of meteorology in order to assent to the proposition that order is universal. Those who have contributed anything at all to the history of thought have always believed that the order which we can recognise is indicative of order everywhere. Some have said that the order is without the mind, some that it is within the mind, but at any rate, it must be a general truth.

The Simplification of Things. Now, philosophy is a most difficult and arduous study, yet we may at least credit it with having simplified our ideas of the world. Let us take, for instance, what we commonly call matter. As we know, science has lately simplified our varying notions of varying kinds of matter, and has presented matter to us as one thing—whatever its real nature be—which presents itself to us under various forms. Later still, science has told us that this one thing may be expressed in terms of yet another thing, still more general, which we call energy. But philosophy has not had to wait for these conclusions of science. Recognising signs of order, and believing them to be indicative of universal order, philosophy has long anticipated science by regarding the external world as essentially a unit. Now, this is a great and most desirable simplification. It would be long ere we reached our goal, which is the heart of things, if we had first to make a specific examination of every object without us, every object that we can lay our hands upon, and every object that no hands can be laid upon. But philosophy has long ago agreed upon this, at least—that the exterior world, despite its apparent multiplicity, may be looked upon as a unit. The world we live in—whatever that phrase really means—is not a chaos but a cosmos. Science is every day more clearly proving that this is true, demonstrating, or beginning to demonstrate, its truth, where hitherto it had to be taken on trust. Hence, what was a most warrantable inference even for the first philosophers is a still more warrantable inference for us. We proceed, then, in all further discussion, to speak of what is without us—the "universe," the "cosmos," the "external world"—as *one thing;* we may speak of it as "it" and not as "them." Now, this is really a magnificent simplification of things; and, from the point of view of philosophy, the great service of science is that the more she advances the more does she afford warrant for this great simplification.

The External World. But though this constitutes an incalculable advance upon any supposition that we live in a higgledy-piggledy, it leaves us with abundance still to think about. It still affords room for differences of opinion which are profound and irreconcilable. Let us see, if possible, what forms these differences may take. The first opinion as to the external world is that which the phrase itself expresses. It is the opinion of common-sense and of crude realism. It is also the opinion of philosophers more advanced than these, but it is denied totally by a school of thinkers who, in their various forms, may be called idealists, and who regard what we call the external world as having no existence apart from mind.

But let us agree, for the present, at any rate, that there is this external world, whether it be the whole fact or only an aspect of the fact. The doctrine which denies its existence may here be left out of account. There still remains a great issue which goes right down to the depths of our subject. This is the issue between crude realism, which boldly asserts that things are what they seem, and the doctrine or doctrines which assert that the external world, as we know it, is not wholly known to us. And here there may occur to the reader the question which really does begin at the beginning: What do we mean by knowing?

The Criticism of Knowledge. For, after all, before we assert anything we should begin by ascertaining how we come to know it, in what sense we know it, what are the conditions and the limits, if any, of our knowledge. Certainly, knowing cannot be an absolute and perfect process as practised by us, since the results differ in every case, and furthermore,

we are each of us well aware of facts within ourselves that affect the measure and the quality of our knowledge. Plainly, therefore, all kinds of philosophising are premature until we have ascertained something about the instrument which we mean to employ. In what sense do we know anything, and to what extent?

The Great Work of Kant. Now, this was the great work of Immanuel Kant (1724–1804), and it is one of the most amazing facts in the history of thought that the doing of his work should have been left for so long. It is because the great work of Kant constitutes a criticism of men's thoughts and of the conditions of their thinking that it is generally described as the "critical philosophy." A somewhat uncouth word has also been employed—and is, indeed, now found indispensable—in order to indicate the study with which Kant chiefly concerned himself. This word is *epistemology*, from the Greek word *episteme* (knowledge). Just as biology, then, is the science of life, so epistemology is the science of knowledge, the science or the department of philosophy which concerns itself with the knowing process, the conditions, the limits, and the validity of all that we know or think that we know.

Now, there is one school of philosophers who have no use, so to speak, for any theory of knowledge. Epistemology offers them no difficulties and no problems. These are those who regard the external world as the creation of our minds. But for the rest of mankind this question of the validity of our knowledge is supremely important in its philosophic implications. Certainly we know something of, or concerning, the external world. Daily life demonstrates that. Whatever a man may call himself or wish to be called, he cannot be an absolute sceptic. Absolute scepticism is not to be found even within the walls of a lunatic asylum. A man may have many delusions, and they may all be ridiculous, but he will still retain a practical belief in gravitation.

The Value of Empirical Truth. There is, then, at any rate, some kind of validity in our knowledge. We act on the assumption that an unsupported object will fall, and we are found to be right. So far, very well. There is at least open to man some proximate, practical, working kind of truth. There may be more, but, at any rate, there is empirical truth, the word empirical meaning experimental or dependent upon experience. You know that under the present condition of things the sun will rise to-morrow. That is an empirical truth, demonstrated to be true by experience. Now, before we go any further, let us at least attempt to do justice to empirical truth, for it is too much scorned, perhaps, by professional philosophers.

The physical life is not the whole of life nor the most of it, nor the best of it; but for the most and best of life the physical life is at least necessary. Contempt of the body can evidently be pushed too far. Now, so far as this physical or bodily life is concerned, in point of fact, we *live* by empirical truth. As we look at it, it may be a most grotesque parody of the real truth. Critically considered, it may be worth very little or nothing for the purposes of philosophy; very often it may have led men ludicrously astray in their search for reality—but whatever defects it may have, whatever charges may be levelled against it, yet, at any rate, it is in virtue of our practical recognition of empirical truth that we men and women live. Even the philosopher who decries it is daily dependent upon his daily recognition of it; otherwise, any one of a hundred occasions in the course of a single day would put an end to his life. Empirical truth may not be—indeed, it certainly is not—the whole truth, but by it we live our physical life. Many men have lived and died and worked and suffered and achieved and sung with the aid of empirical truth alone.

We Have Enough Truth to Live by. The great fact of human life, indeed, is that men can and do live by empirical truth, proximate truth, relative truth—call it what you will. It is much more than doubtful whether Shakespeare had what the Germans call a *Weltanschauung*, or a consistent view of the world. It would be quite impossible to ascribe any philosophy to the greatest men and women in history. Even the kings of thought, after devoting all their lives to this study, have commonly confessed themselves baffled. Absolute truth may or may not be beyond the ken of man; it may or may not have been attained by any in the past; we may protest, if we please, against the nature of things for hiding itself from us—but most certainly it might retort that *we have enough to live by*. If human history demonstrates anything at all, it certainly is that even such light as is afforded to the simple-hearted is abundant for the living of worthy and even of glorious lives.

This is not, of course, to deny the truth of the great saying that "man cannot live by bread alone," but it is to deny totally that what is technically called philosophy is in any sense whatever a human necessity. The search for the deepest deep may be, and is, both valuable and fascinating, and well worthy of the fine striving that distinguishes the human mind, but it is not required to reveal the *vital* realities, as, for instance, that vital reality which St. Paul called the greatest thing in the world.

Truth and the Search for Truth. These are the realities by which we live, and they can be no more real to the profoundest philosopher than to the child on its mother's knee—though truly they may be less so. Certainly the man who neglected love and duty in order to search for remote truth would be convicted as no lover of wisdom and as blind to her, even when face to face. It is such considerations, also, that enable us to understand the full meaning of the famous assertion made by another great German philosopher, Lessing. He said that if God offered him truth in one hand and the search for truth in the other hand, it was the search that he would choose. At first sight this seems meaningless and monstrous, for pray what should give the search for truth its meaning or purpose but the possibility of finding her? Yet Lessing was profoundly right. He knew that the truths by which we live have already been given to us; he knew that one of these vital truths is the necessity to strive. That is why he desired to be given the

search for truth. He knew also that that absolute truth which philosophers seek, whatever her attractions, is assuredly not necessary to salvation. Human history denies on every page the doctrine that no one but a metaphysician is entitled to a religion; and all the philosophers of the past are but humble scholars at the feet of the child who risks its life in order to save another from the flames.

The Truth that is Essential. In a word, empirical truth—as, for instance, gravitation—suffices for the physical life, and the super-physical life is nourished by truths which may be hidden from the wise by their own vain imaginings, and yet revealed to babes and sucklings. Compared with either of these, philosophical truth is a thing of little moment. If, some day, there were revealed to us the nature of ultimate reality, the knowledge would not affect in one jot or tittle the ordering of our daily lives. The philosopher of that date would have the same difficulty as all philosophers of the past in bearing toothache patiently—as Shakespeare hinted. Nor, on the other hand, would this revelation be of the smallest moment for the moral ordering of life. Such words as justice, love, and duty would find nothing added by it to their significance.

So much, then, for the value of orders of truth other than philosophic truth. We must remember that the realities which vitally concern us are the realities of life and experience, and not the realities with which ontology seeks to deal; otherwise, where, after so many failures, should we be, and whither would there be any prospect of our going?

Having said so much, let us return to Kant's criticism of knowledge, and let us observe the conclusions to which he was led. They were briefly these: Our knowledge of the external world is limited and conditioned by the limits and conditions of our own minds; it is knowledge, not of reality but of appearances. The reality which lies behind those appearances must be in its essence not dissimilar to the perceiving mind itself.

What is a Phenomenon? The opposed words which Kant employed were *phenomenon* and *noumenon*. This word phenomenon, which is so familiar to us, is one of the most valuable and important words in philosophy, since it expresses for all those who know its meaning one of the most important ideas in philosophy. In vulgar use the word means anything that is out of the way or wonderful, and we apply the adjective phenomenal to anything which we wish to signalise as extraordinary. But these employments of the word are most unwise and unfortunate. The adjective phenomenal should be absolutely confined to its proper philosophic use of describing anything that has the character of a phenomenon. We shall see in a moment how convenient the word may be. A phenomenon, then, is literally an appearance or something that appears, and whenever we use the word we are to associate with it in our minds the idea of a something which, though hidden from us, and not apparent, is yet the reality, the self, or the thing-in-itself, lying behind the appearance or phenomenon, which is all that we can directly know. There is, then, on this terminology the real or the noumenal, and the apparent or the phenomenal. Our knowledge is only of what appears to us, and is therefore only phenomenal knowledge. (The reader will contrast this proper use of the word with the ordinary misuse of it.) Nothing is further from being suggested than that there is any opposition or contradiction between the real and the apparent—between the thing-in-itself and the thing as it appears to us. We are freely entitled to argue, in so far as we may, from phenomenon to reality. Merely it is asserted that our knowledge of reality must always be inferential, and can never be immediate or direct.

The Limitations of Knowledge. Now if the Kantian criticism of knowledge be valid —and we are about to see reasons for thinking it so—if it be true that our knowledge of the external world is only relative, the most serious conclusions must be faced. Here, again, is a case where the idealist escapes all our difficulties. To him the external world is just "such stuff as dreams are made off," and there is nothing behind phenomena, which are of the mind's own making. But if we class ourselves as realists, believing that something corresponding to what we call matter really exists, then observe what the Kantian criticism involves. We can know matter only by its appearances or attributes. That which stands under matter—the *substance* of matter (a great philosophic word being used in its great sense), we can never know; for we are aware only of the changes which its attributes produce in us. What we understand by science, then, is all phenomenal knowledge, and no more. It is a science of appearances, of the "co-existences and sequences between phenomena"; it is not knowledge of being or reality. This is by no means to say that phenomena are inconsistent with that which underlies them, or that if immediate knowledge of reality were vouchsafed to us it would be found to give the lie to our phenomenal knowledge.

The Limitations of Science. Ever since the publication of the critical philosophy, all but very shallow and soon-forgotten thinkers have found themselves compelled to admit that in positive science, as it is called, there can be found no final answer to the world riddle. This is by no means to decry science or to question the immense practical value of science—its services as a source of intellectual interest, and its facts as directly related to human life; it is merely to recognise the basis on which science rests and to which she is confined. Positive science cannot give a positive answer to any ultimate questions, but only to phenomenal questions or questions regarding phenomena. It was John Locke, one of the greatest of Kant's predecessors, who, in his "Essay Concerning the Human Understanding," defined the impassable barrier to our scientific knowledge. He showed that we have no innate ideas, and that we are dependent for all our knowledge and all our ideas upon *sensation*, in the first place, and, in the second place, *reflection* on previously gained sensations. His famous conclusion was:

"Nothing is in the mind that was not first in the senses." Now, this assertion in itself is not equivalent to the assertion that all our knowledge is only phenomenal. It might be that, as some of the Greeks supposed, sensations were due to faint copies of objects—ghosts or emanations—which were given off by them and entered our eyes But, as we all know, that very naïve idea has long ago been superseded, and the nature of sensation has been, in some measure, elucidated.

We Know Only Ourselves. The question, observe, is as to the nature of sensation, not as to its range. Our knowedge, of course, is imperfect so far as the range of sensation is concerned; our eyes appreciate only a narrow portion of the compass of a certain type of ethereal waves, our ears only a few octaves of those waves which, if audible, we term sound, and so on. But the really vital matter is not the range or extent of sensation, but the kind and degree of validity that must be attached to such sensations as we *do* obtain. The beginning of all that we know and all that we can conceive consists of changes in our own consciousness. We may make many inferences from these changes, and undoubtedly these inferences may be commonly justified by results. Nevertheless, at bottom, we know nothing more or less than changes in ourselves. When you look at this page you are aware of a change in yourself, a change in your consciousness, and nothing more. At first sight this may seem a somewhat startling way of stating the facts, and yet it will bear continuous thought, and only seem more and more valid. Here, in the admirably clear words of Lewes, is the reply of Kant and Locke to the dogmatist, after they have investigated the elements of thought:

"But this Understanding can never know Things *per se*. It is occupied solely with its own Ideas. It perceives only the Appearances of Things. How would it be possible to know Noumena? By stripping them of the *forms* which our Sensibility and Understanding have impressed upon them—*i.e.*, by making them cease to be Appearances. But to strip them of these forms we must annihilate Consciousness; we must substitute for our present Sensibility and Understanding a faculty or faculties capable of perceiving Things *per se*. This, it is obvious, we cannot do. Our only means of communication with Objects are precisely this Sensibility and this Understanding which give to Objects the forms under which we know them."

The Philosophy of Idealism. The philosophy called idealism may seem to each of us to be the very last thing that he could conceivably believe, yet it is interesting to observe how, again and again, the idealist thrusts his voice into our argument. At the stage which we have now reached, for instance, we have the voice of Berkeley, who overhears us saying that "all we are aware of are changes in our own consciousness." "Can you not see, then," he would say, "that what you are aware of and what you have admitted that you are alone aware of, is all that *is*? Material things have no objective existence—no existence outside yourselves: the external world which you persist in postulating as the noumenon or substance, the attributes of which cause changes in your consciousness, is a figment of your imagination. You put together in your mind certain attributes, such as form and colour and extension, shall we say, and then you invent something in which they subsist and which you call matter. But this is a creation of your mental act, and nothing more." "Verily," as David Hume remarked, "these are arguments which admit of no answer and produce no conviction." But at least let us try to understand them, and to respect them. They cannot be answered, as Dr. Johnson foolishly thought, by kicking a stone. Their conclusion is absolutely incredible, but they have never yet been answered at all.

Scepticism. So much for one solution of our difficulties when we come to criticise the conditions of knowledge. Apart from it, however, we seem to find ourselves landed in scepticism. Here, again, is a philosophic term which, like all the rest, has been used in many senses, and, as in the other cases, we must try to get from the word its full value. The doctrine of Kant, that our knowledge can only be phenomenal, is, of course, a form of scepticism. That is evidently a proper use of the word. There is happily passing from currency its employment to indicate someone who, for instance, doubted the truth of the story of the manufacture of Eve. Whatever we do, let us at least see in this word a purely philosophic term without any moral or theological implications of any kind.

The Kantian doctrine, then, we have said, is a form of scepticism, but we must clearly distinguish it from, for instance, the classical scepticism, or even from that of Hume. The sceptics of the antique world did not distinguish between the possibility of a science of phenomena and the possibility of a science of noumena or a science of being. Reflecting upon the limitations and conditions of our knowledge, and especially on the impossibility of discovering any absolute test of truth, they felt themselves compelled to deny the validity of all our knowledge whatsoever.

The Absurdities of Absolute Scepticism. But some indication of the absurdity to which such an attitude leads us may be found in such a remark of the sceptics as this: "We assert nothing—no, not even that we assert nothing." Such must be the absurdities in which absolute scepticism lands itself, and there is a world of difference between it and the position of Kant who said that "the understanding was not treacherous, but limited; it was to be trusted as far as it went, but it *could* not go far enough: it was so circumscribed that philosophy was impossible."

It is this relative scepticism, or this renunciation of scientific dogmatism, this formal assertion that science deals only with proximates, appearances, or phenomena, that characterises the greatest thinkers of to-day. It is, of course, a form of agnosticism, or, rather, agnosticism is a form of it Here, again, is a word to which

moral implications have been attached, but these we must here ignore. Now let as recognise at once that this renunciation of the right to dogmatise works out in more ways than one.

Agnosticism. For the moment let us assume that the preceding arguments are all valid, and let us see what follows on this assumption. First of all, certainly, there follows the explicit limitation of the range and rights of science. That limitation is extremely unwelcome to certain students of science, and is very commonly ignored by those who confine their study to the material sciences alone. On the other hand, this agnostic assertion of science regarding her own powers is extremely welcome to those who were distressed or disgusted at the claims which certain people used to make for science not so very many years ago. Everything pure and lovely and of good report, every belief that contained a vestige of beauty or of hope, the basis for everything and anything that made life worth living at all—these, we were told, must be abandoned. They were condemned by science, the all-knowing, and must away. This dogmatic position was held for some decades of the nineteenth century, though not by its most illustrious men of science. The complete renunciation of any right to dogmatise on ultimates has naturally enough brought great relief to those in whose eyes it seemed as if the dry light of science, claiming to illuminate human life, would succeed only in charring and blackening it.

But this is by no means all. It might well have been foretold that when, of two rival schools of dogma, one was found to declare that, after all, its knowledge was only relative, and its best dogmas were symbols, the opposing school should count the recantation as almost equivalent to an admission of *its* set of dogmas.

Dogmatism. It would be idle on a serious page to ignore the all-important historic fact of the controversy between scientific and theological dogma—a controversy which became so acute in the second half of the nineteenth century. But if we are to endeavour to be impartial we must be consistent with our criticism of knowledge. The honest man of science, for instance, will candidly admit that, owing to the fundamental structure and circumstances of the human mind, his knowledge is not ultimate, but relative, his dogmas are not literally true, but merely tentative symbols—all his knowledge, in short, only of the relative, only of phenomena, only of the surface. "But," he will go on to say to his adversary, "you, my friend, are in the same boat; you cannot have it both ways. You make many assertions of a striking character, not merely as regards the spiritual world of love and duty which you and I alike can know directly, but also regarding the world of sense and phenomena. The conditions of knowledge for me, so far as the world of phenomena is concerned, are also the conditions of knowledge for you."

In the light of such imbecile phrases as the "bankruptcy of science," it is well, perhaps, for us to state this aspect of the question. Having done so, let us go on to observe the consequences which have followed the application of the critical method to that which is by far the oldest, the most popular, and the most plausible of all philosophic systems—the system called materialism.

As has happened so often before in our reading, here we come upon a word to which improper meanings and innuendoes have been attached, more especially by those whose own philosophy, if it were to be examined, would be found ludicrously materialistic. By some curious set of sequences, the word materialism, which is properly a technical term of philosophy, has come to signify, in popular usage, nothing more nor less than Mammon worship. How this should have come about really does not matter at all, except that in part it has undoubtedly been due to the *odium theologicum*. At this late day, perhaps the best that we can do is to employ qualifying adjectives which will enable us to distinguish between two totally unconnected things—practical materialism and the philosophic doctrine called materialism.

Materialism. The confusion of terms is perhaps of lessening consequence since materialism as the name of a philosophic doctrine is no longer of any current value. The doctrine which was formerly called materialism requires to be renamed energism in its new form, as we shall see. Meanwhile, let us ask what the doctrine is. The philosophic doctrine known as materialism asserts that all reality, everything that exists, may be finally and completely expressed in terms of matter or "matter and force" or "matter and energy" or "matter and motion." As a working hypothesis this doctrine has never been so widespread and so generally accepted as it is to-day. It is interesting to note, however, that it is quite definitely, in these days at any rate, the philosophy of the half-educated. It would be very difficult to name any great living thinker who is a materialist, and it would be impossible to name any professed student of psychology who subscribed to this doctrine. Nevertheless, its importance as a system of thought cannot be over-estimated, and we must study it most carefully. We shall have to note, also, that materialism is now taking a somewhat more refined and subtle form in consequence of recent advances in the physical sciences, and that in this form it certainly gains both in plausibility and in importance, for it will now be found to make an appeal to many people whom the cruder materialism would have repelled. On the other hand, it loses weight with people of less mental calibre. Let us look at the history of this subject.

The Father of Materialism. Materialism may claim as its first parent one of the most illustrious men of the antique world, Democritus of Abdera (about 460–360 B.C.).

Beyond a doubt his was one of the greatest minds in history, not only in its actual constructiveness but also in its seminal or seed-bearing quality. His ideas, taken up by other men, have made a dozen great reputations that have lasted from antiquity until to-day. Yet of all his great sayings there is, perhaps, none greater than this, "We know nothing really, for the truth lies in the depths." This is a

profound epigram which his followers, as is the manner of followers, have too often forgotten. The vaguest part of his philosophy was certainly that which concerned itself with mind, and he does not seem to have been consistent in this respect. This is a characteristic of all materialists—if, indeed, we are absolutely warranted in calling Democritus such. At one time he certainly taught that "the body was made up of material atoms, the brain as well; the mind is a function of the brain, and for him the soul was the mind. It was made up of fine smooth, round atoms, similar to the atoms of fire; these are the most mobile of all; penetrating the body, they give rise to the phenomena of life."

The Essence of Materialism. Among his fellow countrymen Democritus found successors. Empedocles, for instance, working upon the idea of what his master was the first to call "atoms," wrote of the "loves and hates of the atoms," a doctrine which, as we must see, regards the atoms—that is to say, the physical—as the ultimate reality, and the psychical as a mere attribute or function or property of it. This is the essence of materialism: that mind is an attribute or property of not-mind, or, to phrase it in the older terms, that mind is a function of matter.

The most illustrious of the materialists after Democritus himself is the Roman poet Lucretius (about 95-52 B.C.). His great work was a long poem, "Concerning the Nature of Things," in which he expounds the principles of Democritus, transmitted to him through the writings of Epicurus. The poem is absolutely unique in literature: it is a poem not merely in form but also in substance, one of the most truly poetic, elevated, and beautiful poems that have ever been written. A line in it—directly due to Democritus—was destined, after some 1800 years, to generate the idea of the nebular origin of the solar system in the mind of a Teuton-Scot named Immanuel Kant—himself one of the greatest but one of the least poetic of men, destined also in later years by his criticism of knowledge to destroy the whole edifice of materialism at its very foundations.

Truth in the Dark Ages. Not long after the time of Lucretius, the life and thought of Europe were obscured in the thousand years of darkness. There were no great thinkers: truth, or even error seeking for the truth, had ceased to grow; nothing was achieved, nothing was learnt; materialism and all other philosophies might never have come into being. Then at last men awoke from their horrible sleep, and the breath of life was found to be not wholly extinct in the mind of man. It was not until the nineteenth century, however, with its wonderful unifications of scientific knowledge, that materialism really came to the fore again as a philosophic doctrine. It is fair to say, however, of the great materialists of the generation that is gone, as it is probably fair to say of Democritus himself, that they did not really regard materialism as the whole truth. They also realised that "truth lies in the depths" even though, short of that, everything, including even the facts of mind, seemed to be explicable in terms of matter and motion. The most notorious materialists of the nineteenth century were very far from being the greatest, and they certainly renounced any such doctrine as that truth lies in the depths. Some of their names may be noted.

Some Materialist Ideas. The first of them was Feuerbach, who will long be remembered as the author of the saying, "Man is what he eats." Closely following him was Carl Vogt, whose name in its turn will be remembered for his saying, "Thought stands in the same relation to the brain as the bile to the liver or the urine to the kidneys." Then Moleschott coined the famous phrase, "Without phosphorus no thought," leading him on to the conclusions that thought is a movement of the matter of the brain and that "without matter there is no force, without force no matter." Then there came the exceedingly celebrated work of Büchner called "Force and Matter" (*Kraft und Stoff*). It is the most famous of all materialistic treatises, and its date of publication, 1855, is worth noting. Many of the so-called materialistic assertions of that book are now commonly admitted. Our concern here, however, is not with them, historically important though they were, but with his assertion that mind, "like light or heat, electricity or magnetism or any other physical fact, is a movement of matter." His own words are that psychical activity is "nothing but a radiation through the cells of the grey substance of the brain of a motion set up by external stimuli." This involves the doctrine that your consciousness of yourself, your self-consciousness, is a material motion.

This is evidently the most ludicrous assertion that can be made; but that is materialism—which we are about to analyse more closely.

The Newer Materialism. There are really good reasons why the word "materialism" is ceasing to have any but historical interest. One such reason, certainly, is the confusion of the word with certain moral issues in a wholly irrelevant manner. Yet another, and a still more important, reason is that in the present state of science the word does not at all express any form which can be assumed by the doctrine for which the word stands. What materialism really means is that the external world is the only reality, and that the psychical is a more or less accidental property of it. But the word as it stands says more than this, for it suggests a purely scientific proposition—namely, that the external world can be resolved into matter. Büchner himself, at the last, besought his followers to abandon the word "materialism" and to substitute "*monism*" for it, his reason being the very proper one that "a philosophy not of matter as such, but of the unity of force and matter, is not materialism." Nowadays we substitute the word "energy" for "force," and then the criticism holds—indeed, it much more than holds, as we shall see. Büchner's advice has, indeed, been followed, and the word "monism" has come to succeed very largely the older term. The word is important, and we must examine its uses.

INFECTIOUS & NERVOUS DISEASE

Typhoid, Diphtheria and other Infectious Diseases. Organic and Functional Diseases of the Nervous System. Ill-Health of the Special Senses

By Dr. A. T. SCHOFIELD

INFECTIOUS ILL-HEALTH

THE subject of infectious ill-health has been treated from a hygienic point of view in some detail. What is said here will be supplementary to the consideration already given to the subject in the HEALTH articles.

Typhoid Fever. Cholera and smallpox have been fully treated. In typhoid fever, we have a disease that runs for three to four weeks or more. It is generally preceded by a fortnight of weakness and depression, and then the temperature rises to 103°, and the diarrhœa begins. There is often a slight rash on the stomach. The third week is the most critical. The ulcers in the intestines are then at their worst, and if they perforate through the walls, death ensues. There is often delirium and extreme weakness. There may be hemorrhage. About one in six dies of exhaustion. In this disease skilled nursing is essential, as well as medical care, and nothing but liquid food must be given until the temperature has been normal for one week. Great care is needed in convalescence, as the heart is always much weakened, and for a month or two after there should be no violent exercise or strain of any kind.

Diphtheria. Diphtheria has also been spoken of as regards its causes. It is an epidemic and poisonous sore throat that starts gradually. The local inflammation is severe, and the temperature rises to 102°. The membrane, that forms like wash-leather, may extend down the throat or up the nose, and produces great difficulty of breathing and swallowing. There is great weakness, and death often occurs from exhaustion as from suffocation. Recovery is very slow. The great principle is to support the strength in every possible way, so as to enable the body to fight a victorious battle. Of course, the patient is kept in bed, and the air must be kept warm and moist. A skilled doctor and good nurse are needed, and in bad cases the injection of antitoxin is the most efficacious remedy. In convalescence, very generous diet and bracing air is needed.

Measles. Measles is an infectious catarrhal fever, with a crimson spotty rash. In the German variety there is more sore throat and less rash. All the mucous membranes are inflamed, and the sneezing and coughing distribute the infection through the air. It is most contagious at the beginning of the disease, when the catarrh is acute: the eyelids are red and swollen. The eruption appears on the fourth day, and lasts four days, and is in the form of red dots arranged in crescents. It often affects the eyes and ears permanently, and hence care is required in all bad cases to avoid this. Medicine is not much needed; a bed in a warm room, well isolated, with mild milk diet, is required.

Typhus and Scarlet Fever. Typhus fever is so rare now in this country that it need not be described, nor must it be confounded with typhoid fever, which is still common. Scarlet fever or scarlatina is an infectious fever in which the skin becomes scarlet from a very minute eruption, which starts about the second day and subsides about the fifth. The throat is inflamed and very sore. Like measles, it is common in childhood, but is more dangerous and leaves worse results behind it. The fever rises higher, and there is special danger of inflammation of the heart and kidneys. After the rash has subsided the old skin begins to peel off, either in fine dust, like bran, or in larger pieces. This is a slow process, and sometimes takes six weeks, as the bits of skin spread the infection everywhere; the patient has to be most strictly isolated until it is quite completed, the toes being always the last to be affected.

In simple cases, a warm room, light food and free action of the skin by warm drinks is sufficient. When the peeling begins, the skin should be oiled to prevent the particles from flying about. As soon as the temperature is normal good nourishing food is required, and after all is over a month or so of convalescence is needed. A doctor should always be called in to watch the heart and kidneys.

Chicken-pox. Chicken-pox would be a trifling complaint were it not that the rash, which consists of large scattered vesicles, few in number, tend to form large and unsightly scars which, when they occur on the face, are most disfiguring. Every care should be taken to prevent the face being marked, but little other treatment is required.

Influenza. Influenza has been spoken of pretty fully in the section on HEALTH. It is enough here to impress the fact that the weakness caused by the disease is out of all proportion to the apparent severity of the attack. Every care should be taken to avoid chill, especially after the attack is over. This is the time when fatal pneumonia may readily be set up and death ensue. The nervous system often suffers severely after this disease.

Erysipelas. Erysipelas is a contagious disease that, as a rule, attacks some wound or sore in the skin. It produces great redness and swelling, and in the head it is very dangerous. The parts affected should be either treated with poultices or ice cloths, and the strength kept up and all chills avoided.

Relapsing and Remittent Fevers. Relapsing fever runs very high, up to 107°, with remission caused by profuse perspiration, which lowers the temperature. This generally occurs on the fifth or seventh day, and then for an equal length of time the patient appears quite well, when the fever returns as before, but for a shorter period. There is no special treatment.

Remittent fever is a malarial one due to the bite of a gnat, and is somewhat like relapsing fever, but the fever does not wholly abate, but only lessens, and that only for a few hours. Quinine is of great efficacy here.

Mumps. Mumps is a highly infectious disease that attacks the glands at the angles of the jaw, with acute pain and swelling. There is fever, and a difficulty in taking any solid food. It is common

in children, and lasts about a fortnight. Poultices, warmth, and light diet are needed.

Whooping-cough. Whooping-cough is an infectious disease of childhood consisting of violent paroxysms of coughing. It lasts about six weeks. The e is a spasm of the bronchial tube and a feeling of suffocation. Fresh air is good. In severe cases a doctor should be seen. It lasts from four to eight weeks, as a rule, and causes great weakness.

The other infectious diseases, such as plague, yellow fever, anthrax, glanders, tetanus, etc., are, fortunately, sufficiently rare in this country not to require special mention.

Finally, one may say that the infectious diseases are theoretically all preventable, and most of them are so, practically; and while with regard to treatment, if the case be mild, simple rest in bed till well is the main thing. In the severe cases, and those with complications, medical care is essential.

NERVE DISEASES

We now reach a class of disease that is of unusual interest, as with the increasing complexity and pressure of life it is getting more and more common: so common, indeed, that it is probable that there is no one who reads these pages whose family is wholly free from it.

The worst is that there are not only a large variety of nervous diseases, but, as the nervous energy is really the driving power of all the complex organic machinery of the various systems of the body, when it is deficient in force it is quite possible there may be no definite disease. And yet there is such a general lowering of the activity and force of all parts of the organism that it amounts to a condition far more distressing than many diseases. This nervous debility is very common in minor degrees amongst many who work hard, all who worry, and more who idle; and yet it is only when it is very severe that it is recognised as a disease and called neurasthenia.

We will briefly glance at the leading organic diseases, and then at those which are functional.

Neuritis. This is a rare disease when it consists of inflammation of the nerve trunks, but as an affection of the minute nerve endings (peripheral neuritis) it is fairly common. There is a great feeling of numbness, together with pain in the part affected, which may be a limb or some part of the body. When it affects the body it is often called *Herpes*. It throws out a cup of small pearly vesicles over the course of the inflamed nerve often like a girdle halfway round the body. These are intensely painful, and last a week or more. In neuritis we get little or no general fever, but the affected parts must be protected and the patient got into good general health. Neuritis often arises from some form of nerve poison, particularly arsenic. Hot fomentations and water dressings are often needed, and some faradic electricity is useful in resting the sensation of the affected part.

Apoplexy. Apoplexy is a sudden state of insensibility brought on by a clot of blood in the brain or the rupture of some blood-vessel. It is therefore common in elderly or plethoric people, where the blood pressure is too great, or the arteries too weak. High living, sedentary habits, short necks, and obesity also predispose to it. The patient becomes suddenly unconscious, and paralysis of one side (the opposite to the part of the brain affected) often follows; or death may ensue at once. The respiration is slow, the body clammy, and froth appears at the mouth. All clothing should be loosened, and cold water applied to the head; great care is needed in giving anything by the mouth, and enemata are often useful. It is, of course, necessary for a doctor to deal with the case.

Meningitis. Meningitis is an inflammation of the membrane covering the brain. It is most dangerous, and when tubercular, as in consumptive people, rapidly fatal. It is common in children, and may arise in its simple form from a blow or fall, or ear disease or sunstroke. The symptoms are fever, great pain, twitchings, delirium, squint, and, when it extends to the upper part of the spinal cord, retraction of the head. Medical advice should be sought at once. The brain itself may be inflamed.

Encephalitis. The symptoms are similar to meningitis, with vomiting and convulsions. The disease is fatal.

Chorea or St. Vitus Dance. This is a disease of childhood, with irregular movements and twitchings due to some brain disturbances. The child should be isolated, well fed, and kept quiet and restful until the disease is cured, which generally takes several weeks. A doctor is needed.

Insanity. Insanity may spring from a variety of causes, the chief of which is hereditary. If acute, it is called mania; if partial, monomania; if nerve weakness, dementia; if the intellect is absent, idiocy. The best treatment is removal from all exciting causes with plenty of distraction or occupation, healthy surroundings, good plain food, and plenty of sleep.

Diseases of the Spinal Cord. Diseases of the spinal cord are either paralysis or spasms of various parts of the body, according to the region of the cord affected, or the inflammation of the cord, with agonising pain over the spine. As a rule, spinal diseases are incurable, and though they do not threaten life like diseases of the brain, they often cause lifelong misery.

We now turn to the functional nerve diseases, which we will consider in more detail, inasmuch as they are more common and easier to understand and treat than the organic diseases of which we have been speaking.

Headache. Headaches fall naturally into two great classes, those inside and those outside the skull. We will first of all consider the causes and varieties of "external headaches"—headaches due to something wrong between the skull and the skin. In every case this "something wrong" is a nerve or nerves; all external headaches are, therefore, essentially neuralgias, or nerve-pains. Frequently they are across the forehead, less often they are at the back of the head; sometimes, again, they may include "tic" or faceache, and involve the nerves of the face. Sometimes, again, they seem to start from the ear as a centre, and play more round the side of the head.

These headaches are not generally caused directly through study, but are due either to general ill-health, or to some local chill or inflammation. A tight hat, pressing as it does severely on all those scalp-nerves, is often the cause; great bunches of hair coiled up behind is another. A cold east wind blowing on the forehead is another. They may spread from other nerves; toothache or earache, for instance, may cause this headache.

These are the headaches where local applications are very good, such as menthol, crystal and ointment, cold and heat, many liniments, and, if the ear be affected, a single drop of chloroform on cotton-wool.

One particular form of this headache seems to take exactly half of the head or face, beginning

with a disturbance of the eyesight, and going on to violent sickness, often accompanied with a terrible pressure.

In headaches of this intensity sleep is a panacea, and it can generally be obtained naturally or artificially, the former being of course the best. We will consider means of best producing this later on.

Neuralgic Headache. Let us always remember that in these neuralgic headaches, heat, properly applied, will always subdue surface pain. For instance, for a neuralgic headache that will not yield to other remedies, put the kettle on the fire, and a basin on the table, with two squares of flannel. Pour boiling water on them, and then nip one up by the corner, and drop it in a towel fixed by one corner round the leg of the table, or anything else, and then twist away at the other, wringing the flannel dry. Put this on the head, and immediately seize the second piece, wring it, and now taking off the first piece, and dropping it in the water (kept boiling) put it on the head. Now take the first piece out of the water again, wring it, and place it on instead of No. 2, and so on without ceasing, and in a few minutes the pain will be subdued.

Let us now think of the larger subject of true internal headaches, commonly arising from too little or too much blood circulating in the brain.

Internal Headaches. Some people have very little and very poor blood in the body—not enough to be everywhere at once; so if they study, it goes to the head and leaves the feet cold, while if they eat, it goes to the stomach and leaves the brain bare, and brings on a headache. It is indeed difficult for anyone effectually to use body and brain at the same time.

Headache from deficiency of blood in the brain may be recognised by its being at the top of the head, by pallor, by dizziness, and frequently by noises in the ears. These are the headaches benefited by slight stimulants—strong tea or coffee, hot soup—anything, in short, which increases the circulation; also by lying down with the head low. Such people should also sleep with the head low.

The opposite state is when the head is too full of blood, the face flushed, the temples throbbing, the pain excruciating, and the patient unable to bear a strong light or much noise. This is a "splitting headache," and seems to be all over the head. It is brought on in those who have plenty of blood by worry, by too much study, by irregular or too rich living, by gout, and is often accompanied by palpitation of the heart and dyspepsia. Mustard foot-baths are very good in these cases.

Bilious Headaches. We all recognise a bilious headache with its weight across the forehead, its spots before the eyes, its feeling of nausea, and the intense and instant relief when at length sickness comes on. Of course, such a headache in a weak or sickly person is much intensified.

A fourth variety arises from pressure or disturbance of the nerve substance of the brain itself. It is a dull, heavy pain, sometimes splitting in character, and sometimes with dim sight. It generally reaches from the forehead right on to the top of the head. Here again, strong light and noise are much disliked.

Amongst other causes, it is brought on by a long railway journey, the vibration of which has produced innumerable slight concussions of the brain, and altogether shaken it pretty considerably. A good meal will sometimes relieve it, sleep at other times, or the mustard footbath again; but in many cases nothing will do but medical advice.

Yet another headache seems to spring from sheer exhaustion. It is a headache all over the head, and is relieved by a good meal and cessation of all brainwork. Strong coffee with a biscuit will relieve it.

In the aged headaches are common from defective circulation in the brain arising from changes in the blood-vessels consequent on age. They are hard to cure, and hard to bear. Sleep also is not easy to obtain in advanced age, and probably the best remedies are gentle stimulants; if too strong they become dangerous.

How to Prevent Sleeplessness. Sleep is such a cure for most head troubles that one or two hints as to how to best obtain it may fittingly close our remarks on this painful subject.

A cold bed is often a great hindrance to sleep. Cotton sheets instead of linen, and in cold weather a warming pan, will frequently make all the difference between a good and a bad night.

Cold feet, again, are another fertile cause. These can be best cured by having, just before going to bed, two basins, one of very hot, and the other of cold water, and putting a foot in each, then crossing them and putting the warm foot into the cold water and vice versâ. The constant change violently stimulates the circulation. If, then, a pair of fleecy sleeping socks be drawn on, no sleeping draught will probably be needed.

If you wake in the night, and lie awake, getting up in the cold and taking a turn, and then returning to the warm bed will often produce sleep.

If the body is too hot, an arm or a leg left outside the clothes will lower the temperature.

Fresh air is a truer and better soporific than poisoning with carbonic acid gas. Therefore sleep with the window open and the door shut.

If the head be hot or throbbing, lie with the head high, and, if necessary, wrap the legs round with wet clothes covered with waterproof. This is an excellent plan.

Hunger and Sleeplessness. Hunger is a common and unsuspected cause of sleeplessness and also of headache. People dine at six or seven, and have nothing more till nine next morning. Others dine at one or two, and have a cup of tea and a slice of bread-and-butter at seven, and nothing till next morning. These people go to bed hungry and lie awake. A sufficient supper at a reasonable hour—a chop, or a bowl of hot bread-and-milk, or a plate of oatmeal porridge—will make all the difference, and in drawing the blood to the stomach will enable the brain to rest.

Another cause of sleeplessness is brain excitement late at night. The brain gets so full of blood that it cannot rest. Here the remedy is obvious.

Functional nerve diseases generally are, as a rule, little understood, and meet with little sympathy.

Listen to the usual treatment of a nervous case. When one of these victims to hypochondria, who are commonly called *malades imaginaires*, has recourse to medicine for the relief of pain, or some other disturbance, he is usually told it is of no importance; that he is fanciful, and some anodyne is carelessly prescribed. The patient, who is really suffering the pain he has suggested to himself, feels convinced that his malady is not known, and that nothing can be done for him. The idea that his complaint is incurable becomes intense in proportion to his high opinion of the physician's skill; and thus the patient, who was suffering from the painful affection suggested by his mind, often goes away not only uncured, but incurable.

A disease due to the imagination is not necessarily an imaginary disease, but may produce various functional and even organic disturbances. A wise physician once said: "If a man is so ill as to say he is ill when he is not ill, he must be very ill indeed." The diseases grouped under the heads of neurasthenia, hysteria, and so on, are real in origin and effects, and formidable in their nature; and it is high time that the ridicule, the offspring of ignorance, with which they have been so long surrounded, be entirely done away with. A nervous invalid is a far greater sufferer than a man with a broken leg; but we are content to dismiss the former as "only hysterical," and more sympathy and less contempt is often felt for a drunkard than for a neurastheme.

Nervous people are the very salt of the earth, and the leading in every profession are drawn from their ranks. They are men with brains that thrill, that feel, that are quick in action, firm, clear, and of high organisation. It is the nervous men that rule the world, and it is the children of these people who, inheriting the nervous organisation of their parents without having their safety-valve of hard work, form the bulk of our nervous sufferers. At the same time, just as a man can get gout from too little food as well as too much, so we have a large class who are ill from too much work and worry, instead of too little. The nervous diseases among this class far outnumber all others.

A Disease that is on the Increase. Neurasthenia is the general result of overstrain of the nervous temperament, and is said to be on the increase, the growing tension of life being quite a sufficient cause. Constant brain irritants in the ideal centres, in the shape of small but perpetual worries, render the other nerve centres as morbidly sensitive as a constant succession of slight needle-pricks all over the body would the terminal sensory nerves. The manifestations of the early irritant stages of neurasthenia are numerous. Physically they may include constant movement of the body and face, sharp cough, hoarseness, quick breath, starting and palpitation, timidity, irritability, melancholy, and a dread of being alone or in a crowd. If neglected, it may end in hysteria or organic disease.

Referring to the three divisions of the brain, the cause may be said to be largely the result of want of control by the upper over the middle district, which may be due to inherent weakness or to exhaustion from overwork or worry. The constant movement characteristic of this condition is in itself a sign of weakness in the higher centres. A baby is always in motion. As we grow older we get quieter, and the man with the strong brain only moves for a definite purpose. Repose, not movement, is a sign of brain power.

The further stage of nervous debility is a still worse disorder. It is the manifestation of nerve exhaustion rather than irritation. It is the frequent result of excesses of all kinds. It is characterised by physical weakness, mental lassitude and apathy, occasionally varied by a false and capricious, but evanescent, energy. It is often combined in varying degrees, as would naturally be supposed, with nervousness. In both of these disorders the first step in treatment is to seek out, and, if possible, remove the cause. Skilled treatment of a special character is, as a rule, needed.

Hysteria. Hysteria is a nerve disease of a different nature altogether, though it may be the result of the preceding disease, or may arise from any sudden mental or physical shock; or it may spring from hereditary causes, as we have already seen. The disease is most common in the spring, when the nerve system is least balanced. It often consists in the distinct manifestation, or perfect simulation, of disease not merely in irregular bodily or mental action. In hysteria proper there is no intent whatever to deceive, and it must carefully be distinguished from malingering, which is a direct attempt at fraud, and for which no contempt and ridicule can be too severe.

Hysteria is, on the contrary, a real and most distressing disease. It is common in the under and overworked, in the badly trained and imperfectly educated; in boys from ten to fourteen, in girls from sixteen to twenty-five. Over-education and subsequent idleness combined are fertile causes. It is often found in people otherwise strong-minded and clever.

Hysteria is so common that in many classes of ailments it is the general cause, organic disease being the exception. Sir B. Brodie states that four-fifths of joint disease among the upper classes are hysterical, and one-fifth amongst the lower.

Hysterical Symptoms. Amongst other symptoms of hysteria may be included sharp cough, spasms, convulsions, and choking from a ball rising in the throat. The spasms may be of any muscle, as of the chest, producing difficulty of breathing; or of the arm, or leg, or finger, or toe, producing temporary or permanent contraction of the part. The convulsions or hysterical fits are violent, and are greatly aggravated by any notice or sympathy. The patient falls without hurting herself, and the fit rarely occurs when there are no bystanders. Nevertheless, the hysterical convulsion is not a sham. It is generally preceded by the feeling of a swelling in the throat.

Hysteria also simulates every known disease, including tumours, deafness, blindness, dumbness, paralysis, St. Vitus dance, and so on, and is capable of producing, curiously enough, the highest temperatures of fever.

The first thing in treatment, of course, is to ascertain that the disease is hysteria only. This is a most difficult thing to verify in such patients, and nothing is more common than to find a disorder of the mind treated as a disease of the body. If there is, however, clearly no organic disease at the bottom, then the case must be one arising from nerve disorder, the cause of the nerve disorder being either physical or mental, or often a combination of both, the brain being, of course, wholly dependent for healthy action on good blood.

The Course of the Disease. A vicious circle is often kept up in these cases which it is absolutely essential to break. They begin, it may be, with loss of appetite from some slight cause. This, in these cases, leads to disordered thoughts, and the idea of disease begins. This, again, makes the appetite still more capricious; the thoughts, therefore, get still worse, and so the body starves the brain, and the brain the body, and the emaciated patient having, probably enough, first of all worn out her friends, sinks at last into her grave from sheer exhaustion.

The first thing, obviously, is to remake, as far as possible, the vitiated body and brain with fresh flesh and blood and nerve; and then, when we have put the patient into the best possible bodily health, we shall have cured the physical cause of the nerve disorder, at any rate. Then, or even simultaneously, any mental and possibly moral, cause must be deliberately, scientifically, and systematically attacked by the careful substitution of good habits of thought and action for bad. This

is done mainly by suggestion, but without any of the doubtful and unpleasant accompaniments of hypnotism.

Cure by Suggestion. It is important to remember that when the brain is restored to health by good nerve tissue and healthy blood, it can be made by suggestion to exercise as healthy an influence over the body as previously it exercised a harmful one. If ideal centres can produce ideal diseases, surely the rational cure is by first bringing these ideal centres into a healthy condition, and then making them the means of curing the ideal disease. Mental disease requires and can ultimately be cured by, mental medicine. Tonics, in helping to build up the new flesh and blood, are, of course, valuable.

Electricity, properly applied, is also a therapeutic we can seldom wholly dispense with; and the reason of its value is obvious when we consider it is the most powerful agent that we possess for direct action on the nerves.

If the case be a severe one, it must be withdrawn from all its surroundings during the cure; and afterwards, if these were bad, it must never return to them again.

DISEASES OF SPECIAL SENSES

In considering, as we will now do briefly, diseases of the special senses, we will at first confine our attention to diseases of the eye.

Squinting. Squinting is often caused in children by short sight, and sometimes by over brain pressure. It can often be remedied if treated early enough. If allowed to persist, the sight soon deteriorates in the squinting eye. If an operation is required, it is a safe one, and, as a rule, successful

Styes. A stye is an inflammation of the root of the eyelashes. It can sometimes be cut short by pulling out the inflamed eyelash and touching the part with caustic or carbolic. Hot fomentations are also good. An ingrowing eyelash should be pulled out.

Cold in the Eye. If the cold, or *conjunctivitis* is severe a doctor should be consulted. In any case, the patient should remain indoors, and bathe the eye with warm water in which alum has been dissolved in the proportion of half a teaspoonful to a large jugful. It is very dangerous in these cases to use any old eye lotion, as incurable blindness may result.

The ophthalmia in inflamed eyes of children is extremely contagious, and should be cured at once.

For a " black " eye, hot fomentations, or bathing with spirit and water, tincture of arnica or hazeline, is best.

If anything gets in the eye, rub the sound eye well, and the dust will often fall out of the other. Never rub the injured eye. Drawing the upper eyelashes over the lower often wipes the dust out.

Myopia. Myopia is short sight, resulting from the eyeball being too long, so that the rays of light, instead of coming to a focus or point at the retina, or back of the eye, come to a focus in front of it, and by the time they reach the retina have separated again and produced a blurred image.

This is corrected by concave glasses, which, by separating the rays of light, prevent their converging so soon and bring them to a point on the retina, giving a sharp, clear image.

Hypermetropia. This is short sight from exactly the opposite condition. It is very common among children, and leads to bad squinting. In this case the eyeball is too short, and the rays of light have not time to get to a focus on the retina, but would come to a focus behind it. The image in this case is also blurred.

Owing to the power we have of making the lens in the eye rounder, we can make the focus the right length by a strong muscular effort. This, however, not only tires us, but as the same nerve that supplies the muscle of the lens also supplies the muscle that moves the eyeball inwards, this gets contracted too, and thus, in the effort to obtain clear sight, children produce an internal squint.

The proper way to treat this condition is evidently to wear *convex* glasses, which, by bringing the rays of light together more quickly, enable them to get to a focus in the short eyeball without any strain.

Cataract. Cataract is an opacity of the lens of the eye. It is one of the most curable of serious eye diseases, and in China and India the operation is often performed successfully many times each week by young English lady students and others. It consists in making a small slit in the side of the cornea, through which the opaque lens is slipped out. Of course, to see properly afterwards, glasses of proper convexity must be worn to take the place of the missing lens.

Presbyopia. This is a hardening of the lens from old age, and generally begins to come on at 45 or 50. For reading, and any use of the eyes that make it necessary for us to alter the shape of the lens, which has become difficult, great relief is found in wearing slightly convex glasses.

We must now turn to diseases of the ear and voice.

Deafness. Deafness is generally the result of repeated and neglected colds. Beware of putting drops in the ear without medical advice, or of using sharp instruments. Medical advice is always required in these cases, and also in all discharges from the ear, which, however, may be gently washed away with a syringe and a little Condy's Fluid.

In cases of abscesses in or behind the ear early advice should be sought, as in neglected cases the inflammation may extend to the membranes of the brain and produce fatal meningitis.

Vertigo. Vertigo may almost be called a disease of the ear, as it is dependent on a disturbance in the semicircular canals.

Noises in the ear are most distressing. They may be caused by the pressure of wax on the drum of the ear, but as a rule are the result of some chronic trouble the in internal ear, and are incurable. The best plan is so to improve the general health that the noises can be endured.

The Voice. The voice, too, is often in trouble. In sore throats and laryngitis it is reduced to a whisper, and the loss of voice often persists long after the cause has disappeared, particularly in nervous people.

Sometimes the loss of voice is not from any such cause, but is due to paralysis of one of the vocal cords, or some pressure on them from a new growth. Persistent loss of voice not due to colds or sore throats should at once be seen to by a medical man.

MILITARY ENGINEERING

The Work of the Military Engineer in Peace and War. Bridges, Roads, Trenches, and other Work

MILITARY engineering differs from civil in that *time* is the governing factor. The military engineer should be trained to have a thorough knowledge of civil practice, of labour and trade methods, of all mechanical engineering, of machinery, locomotives, rolling-stock and motor transport, of electrical engineering, of power, lighting, telegraphs and telephones, and of all railway work, including both traffic and permanent-way departments. It is his business to adapt all this knowledge to the furtherance of the wishes of the commander-in-chief in war. To this end he must also be thoroughly trained in all branches of the art of war, including strategy, tactics, military history, in the organisation and composition of all branches of the service, and must have a complete knowledge of all armaments, with the effective ranges of all arms and the penetration and explosive radius of their shell. These duties in the British Army are carried out by the corps of Royal Engineers.

Engineering on Active Service. On active service, military engineering roughly divides itself into the following heads:

Passing rivers; bridges of the floating, trestle, frame, tension, suspension, or cantilever type; aerial tramways, railway construction and administration along the lines of communication; the repair of steel bridges, roadmaking, water supply, field fortification, including trenches, redoubts, blockhouses, defensible posts, siege works, sapping and mining, telegraphs, field telephones, and searchlights; balloons, housing of hospitals on the lines of communication, and housing of troops.

In peace time only the following can be called military engineering—namely, the construction of magazines, coast defence, and permanent fortification generally.

Passing rivers may be accomplished by fords, or on rafts and boats, or by bridges: floating bridges are the quickest to make when suitable materials are at hand.

Fords (or drifts) should be marked by stakes driven in the river-bed. A ford, to be passable for infantry, should not exceed 3 ft deep; for cavalry, 4 ft.; and for carts containing ammunition, 2 ft. 4 in. Large stones should be removed from the river bottom, if possible. If the river is swift, a life-line stretched tightly across on strong stakes is of great value. Approaches must be prepared on both banks; the exit should have a good straight pull for teams of animals, and should be made up as described later under Roads.

Floating Bridges. The site will most often be roughly fixed by the military requirements of the case, but for convenience of construction the banks should be low, with good, firm ground to furnish approaches; and the bed of the river at the banks, in tidal waters, should have a gentle slope on which the barrels or piers used in the bridge can rest as the tide falls, thus obviating complicated rise and fall of tide arrangements.

After selecting a site, measure the width of the river. If direct measurement is difficult, the far side of the river being inaccessible, the following device will serve. Select some convenient point, A, on the opposite bank [9], and mark the point B on the near bank, where the end of the bridge is going to rest; then peg out any point, C, in line with A and B. Lay off a line, CD, at any convenient angle. Take any point, E, in this line; lay off the angle DEF equal to the angle DCA; mark the point F in a straight line between D and A; measure DE, DC, and EF; then AC : CD :: FE : ED. Hence, AC and AB are known.

Floating bridges consist of a continuous roadway on piers of pontoons, boats or casks. The minimum width of roadway required in the clear is as follows: 1½ ft. to 3 ft. for infantry in single file; 6 ft. for infantry in file, cavalry in single file, or military carriages man-handled over; 8 ft. for infantry in fours, cavalry in sections, or military carriages fully horsed; 9 ft. is the normal width allowed, and 10 ft. allows a single man to pass over in the opposite direction to the stream of traffic. If hand-rails are given, allowance must be made for projection of axles.

The following weights per lineal foot of roadway must be allowed for in all bridge calculations (they include an allowance for shock or "live-load"): Infantry in single file, 140 lb.; in file, 280 lb.; in fours, 560 lb. Cavalry in single file, 196 lb.; in half-sections, 390 lb.

Infantry *actually* weigh 160 lb. "dead," when unarmed, and 200 lb. armed per man; 1 ton per axle will cover the weight of field and horse artillery, and axles average 8 ft. apart. Weights of other carriages may be got from service manuals.

Pontoon Bridges. The simplest floating bridges are made with pontoons. They are of three kinds—*light*, for infantry in single file; *medium*, for infantry in fours, and guns; and *heavy*, for cavalry in half-sections or a 6-ton steam sapper, elephants, etc.

Pontoon waggons each carry one bi-partoid pontoon, and one 15-ft. bay of superstructure 10 ft. wide. This superstructure consists of five baulks, 15 chesses (or flooring planks), two ribands, and various small lashings. Each pontoon is fitted lengthwise with a saddle, on which the baulks (3½ in. by 6 in.) rest, being secured by iron claw ends. The chesses (1½ in. by 12 in.) are laid across these baulks, and are secured by lashing ribands (3½ in. by 6 in. timber) over their ends. Figure 23 is illustrative.

For *medium* bridges, five baulks are normally used, spanning from one pontoon to the next, and each whole pontoon with its set of superstructure will provide 15 ft. of bridge.

For *light* bridges, the half-pontoons are used separately with three baulks from one to the next. The chesses are placed longwise on top. For *heavy* bridges three half-pontoons are joined together, and nine baulks are used to each bay. Two saddles must here be used to each pier of pontoons, and the roadway will be made no wider than for the medium bridge [see **1, 2,** and **4**].

A bridging company, Royal Engineers, can make 165 yd. of light, 85 yd. of medium, and 55 yd. of heavy bridge; a field company Royal Engineers can make 25 yd., 15 yd. or 10 yd. respectively.

The *buoyancy* of each half of a pontoon is 7,000 lb., immersed up to the gunwale, of which 1,000 lb., 2,500 lb., or 3,500 lb. (light, medium, or heavy) is taken up by the weight of the bridge itself.

Bridges with Boats or Barrels. *Boats* can be used instead of pontoons. The best way to test their buoyancy is to load them with men down to the safe limit; the weight of men, and hence the buoyancy, is then known.

A rule of thumb for infantry in fours is given. The number of unarmed men that the boat will safely hold (with 1 ft. of gunwale above water) divided by 4 equals the central interval between the boats. At the same time, the width of waterway between piers must never be less than the width of one pier.

In other respects, boats are treated just like pontoons, the only difficulty being the fixing of saddles to transmit the weight of the bridge to the boat. This should be done by upright struts to the keel, or cross-pieces across the gunwales. If two boats are to be joined together in one pier, place them stern to stern [5].

Barrels or *casks* can be used, lashed to long spars to form piers; good watertight barrels will rarely be found in sufficient quantities to be of any practical use, except for shore ends.

The buoyancy of a barrel $= 5\,C^2L - w$, where C is the mean circumference of the barrel in feet, L is the length in feet along a stave, exclusive of the end projections, and w is the weight of the barrel in lb. (usually neglected). Only nine-tenths of this result should be taken in practice. Another rule of thumb is buoyancy in lb. = contents of the barrel in gallons × 10.

Barrels are made up into piers by lashing, bung upwards, to spars, as shown in **3** and **6**. These piers are treated in the same way as pontoons. The lashings *must* be made tight.

Shore Ends. If the water-level be fairly constant and the banks be quite low, the baulks of the inshore bay may rest on a timber sill bedded in the ground; if the banks are high, an approach road will have to be cut through. The slope of this and the end bay must never exceed 1 in 7.

In tidal waters, shallow near the banks, the inshore piers may be allowed to ground, provided that the 1 in 7 slope is not thereby exceeded, and that the bottom will not injure the pontoons. For this purpose barrels are preferable, and should always be placed near the shore if there are both barrel piers and pontoons in use in one bridge. If the 1 in 7 slope would be exceeded by this method, owing to the steep slope of the river-bed, a long gangway may be used. The bridge would thus be available for infantry, although impassable for animals except at high tide. A better arrangement is got by the use of trestle-piers, which float at high water, and have their length arranged so that when the tide falls they ground in succession, taking the weight of the bridge off the boats on to themselves [**11**].

These trestles can be improvised. The service *Weldon trestle* is carried for shore ends, having a transom which can be raised or lowered by a differential chain tackle as the tide varies. The superstructure is the same as for pontoons. If the river is too deep for the use of trestles at all, the question becomes very difficult. No definite suggestions can be given, but the site should be avoided if possible.

A very rapid method for forming a two-plank bridge for infantry in single file is shown in **7** and **8**; anchors are required as for all other floating bridges, or each barrel may be secured by lashings to a cable stretched across the river.

Pier heads can be made with service pontoons, one to two bays being pushed out from the shore, and properly moored.

A *flying bridge* consists of a large boat, or pontoon, or barrel raft set at an angle to the current, made fast with a long cable to some fixed point, such as another boat, moored in the middle of the stream well above the proposed point of crossing. By attaching the cable to the raft by a sling in a suitable place, the current will force the raft across the river [**10**].

Strength of Spars. The strength of rectangular spars may be calculated thus for cross breaking: Let w be the weight per foot run on the spar, l be the distance in inches between the points of support, and b and d the breadth and depth of the baulk available for use (*timber, ordinary fir*), then:

$$\frac{wl^2}{8} = \frac{12}{6} \times 1200 \times bd^2$$

For example, to test a timber baulk $3\frac{1}{2}$ in. × 6 in.; how much will it carry across a gap of 15 ft. 9 in.?

Substituting in the formula, we have:

$$\frac{w \times 189^2}{8} = \frac{12}{6} \times 1200 \times \frac{7}{2} \times 6^2$$

$$\therefore\ w = 70 \text{ lb. per foot run.}$$

Therefore, if required to carry infantry in fours at 560 lb. per foot run, eight baulks will be used. Compare the fact that five of the proper Kauri pine pontoon baulks will suffice.

For round spars, let D = the mean diameter; calculate as for a rectangular beam, taking b and d as equal to D, and multiply the result by $\frac{6}{10}$.

Trestle Bridges. The simplest form of bridge in most cases, and the only one for railway work, is the *trestle bridge*. The river must necessarily not be too deep. Figure **12** shows a simple framed trestle for railway work; modifications of this, subject to loads given above, will do for road bridges.

The governing factors in design are the need for rapid construction and the nature and paucity of materials and labour available.

Sleepers on the bridge should be placed 1 ft. to 2 ft. apart, or closer, so as to distribute the weight.

Stringers, or rail-bearers, extend from one trestle to the next; the length of timber available for these will usually determine the spacing of trestles. Timber baulks, rails, rolled steel beams, or trussed timber beams may be used; any number of stringers are permissible; for timber baulks, the number is usually four placed two under each rail. Try to get stringers long enough to span over two trestles, and let them break joint on alternate trestles. If there is only a single stringer under each rail, use a bolster to get a bearing [**14**].

Stringers should be given a 1-in. check over trestle cap, and be spiked, bolted, or dogged to it. Timber baulks are suitable up to spans of 15 ft. to 20 ft. Four 12 in. × 12 in. baulks will do for a 15 ft. spacing of trestles for all locomotives at low speeds. The sleepers are spiked to the stringers.

Rails are good for short spans (such as broken culverts), laid close together side by side; the ends of the rails should be embedded in the ground under the permanent way, if possible, at each side of the gap. Five rails (steel, 56 lb. per yard) under each rail will carry all engines over an 8-ft. gap.

To calculate timber stringers, consider the heaviest pair of engine wheels as placed at their centre, and let their weight be W on each wheel in lb.

23. MEDIUM PONTOON BRIDGE

Then, using same symbols as given above,

$$\frac{W \times l}{4} = \frac{1200\ bd^2}{6}$$

For example, let the span be 15 ft. Let 7 tons be the heaviest *wheel* load. Then, substituting

$$\frac{7 \times 2240 \times 15 \times 12}{4} = \frac{1200\ bd^2}{6}$$

$\therefore bd^2 = 3428.$

Assuming that two baulks will be used, then bd^2 for each $= 1714 = 12^3$ (nearly). Therefore, two baulks 12 in. × 12 in. will do under each wheel.

Trestles. Framed trestles are made in one panel up to 20 ft. to 30 ft. high [12]. Above this, make them in two panels—that is, with a horizontal member half way up, and a double set of cross-bracing. A convenient spacing for trestles is 15 ft. The posts may be 12 in. × 12 in. or 10 in. × 12 in., the cap 12 in. × 12 in., and the sway bracing 9 in. × 3 in. or 12 in. × 3 in. The cap is drift-bolted, or dogged or spiked to the posts. Dogs are bars of iron 18 in. long pointed at the ends, and bent round into a flat ⊔ shape; they are driven into adjoining baulks of timber to hold them together.

For trestles up to 6 ft. high, use four vertical posts; above 6 ft. the outer two should slope; the inner two should be underneath the rails. There is no need for sway bracing for trestles under 12 ft. high. Place the trestles in position with their tops as nearly level as possible; the exact levelling up should be done by wedging after the stringers are in position. The base of trestles must be anchored against a serious rush of water. When the bottom is soft, trestles are sometimes built on piles; these would be cut off level after driving. They are slow and rarely used. Figure **24** shows a trestle pier bridge over the Zand River, South Africa.

Crib Piers. A substitute for a trestle is a *crib pier*, made by piling sleepers crosswise on top of each other. These crib piers are very wasteful of sleepers, but are quickly erected by a party of infantry; a very large number of men can be employed at once carrying the sleepers. They block up a lot of waterway and must be filled with stones and spiked if required to resist a serious flow of water. For erection in water, construct the lower portion on shore, spike it together and floor in the bottom; float it off to the right place and sink it by filling with stones. The maximum height for crib piers is 25 ft., and they are most useful for crossing dry gaps on land.

All bolts should be about $\frac{3}{4}$ in. diameter; drift bolts are $\frac{3}{4}$ in. square or round iron with a head at one end; they can be made on the spot with a field forge.

Smooth bolts hold better than jagged in timber, and round have 25 per cent. more holding power than square. The holding pull of a round bolt in fir is 300 lb. per square inch of surface of the bolt.

All bolt holes should be bored $\frac{1}{8}$ in. smaller than the bolt.

The best foundation for a trestle on rock is got by cutting the rock level, or making it up with concrete.

On ordinary soil, rest the sill of the trestle on a platform of sleepers cut in half.

On sand, put in a long, low crib pier of sleepers, floored underneath. For mud, piles are necessary. Where the water may cause scour, surround the base of all trestles or piers with piles of large, loose stones.

Frame Bridges. For a span where the water is too deep for a trestle bridge *frame bridges* may be convenient.

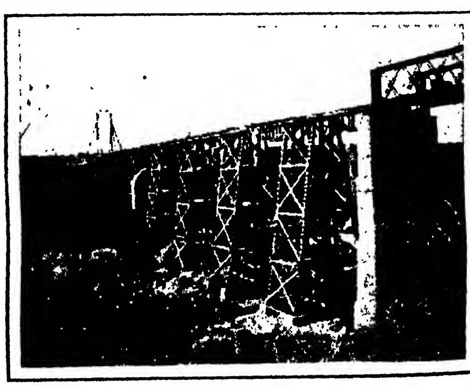
Figure **13** shows the remains of a demolished arch and a single lock bridge in position. Two heavy frames are made, one on each bank, and when good footings have been obtained, they are lowered forward until they meet and lock as shown. The trestle on the right is slightly narrower than that on the left, so as to lock inside it. A transom is placed across and road-bearers are laid with chesses or planks on top in the usual way. Calculations for road-bearers are the same as for pontoon baulks, except that they are usually round. Such a bridge is suitable for a 30-ft. gap and is very rapid if made by skilled labour.

For bigger spans up to 50 ft., a single sling bridge can be used, as shown in **17.** There are four gaps of 12 ft. 6 in. for the road-bearers to span. The great difficulty with these bridges is to get good footings for the base of the trestles, and they require very large spars of good quality.

Tension Bridges. For spans of 60 ft. and upwards, a tension bridge is more suitable; its strength largely depends on cables, which are easy to transport.

A strutted tension bridge is shown in **20** for 100 ft. span and a roadway 6 ft. wide in the clear; if required for a smaller span one set of ties on each side of the centre can be omitted, which will reduce the span to 78 ft. The loads on all transoms except that at the centre are carried by the tension of a pair of ties and the compression of a pair of struts.

The central transom is carried by a pair of ties. The height of the pier at each abutment should not be less than one-fourth the span. The vertical frames are made as in **16.** The uprights may be made of two spars, one shorter than the other with the top transom resting on top of it.



24. TRESTLE BRIDGE, ZAND RIVER, SOUTH AFRICA

The frames are raised with back struts, and back guys are fixed to the anchorage. In loam, anchorages may consist of one large or three smaller buried logs; they should be placed well back from the pier; three 10-in. logs, 15 ft. long, would suffice if 3 ft. below ground.

A tackle from the head of each frame is used for pulling out the struts of the opposite abutment into position; the ties are secured to the transoms, and the roadway is laid outwards from both banks. Steadying guys should be brought from the ends of the central transoms, crossed under the roadway, and brought to the bank, where they should be hauled taut and secured well to the left and right of the bridge to prevent sideways oscillation.

The stresses in the different guys are marked in **20**, and are for a single tie—*i.e.*, one on either side of the roadway.

The strength of cables is found thus: Let W be the breaking weight in tons, and c be the circumference of the rope in inches. Then for hemp rope $W = \frac{1}{3} c^2$, and for steel rope $W = 2{\cdot}5\, c^2$.

This value should be divided by a factor of safety of 5 or 4 according to the condition of the material.

A tension bridge can also be erected without the timber struts underneath.

Figure **21** shows such a bridge designed for an 80-ft. span. The loads are supported by the ties and by the resistance to compression of the outer road-bearers, which here take the place of struts. The footings for these must be carefully prepared to take the thrust. The outer spars should be in one piece long enough to extend beyond M in **21**.

25. CANTILEVER BRIDGE, CHITRAL

The ties should be tightened up so as to lift the bridge well up above its proposed camber of 1 in 20. When loaded it will soon come down again owing to stretch.

Suspension Bridges. *Suspension* bridges are suitable for large spans, and, depending as they do on cables for their strength, are very portable; they are specially suited for light infantry bridges.

They are of three kinds—namely, the common form, in which the roadway, consisting of transoms, road-bearers and chesses, is suspended below the cables by slings; the ramp suspension bridge, in which the roadway rests for the most part directly on the cables, and consists of chesses only, road-bearers being required for only one bay at each end; and the trestle suspension bridge, in which the cables are quite low, and the roadway consists of chesses and road-bearers supported on trestles which rest on the cables. For the first type, the cables rest on timber frames on each bank. The anchorages must be carefully formed, the pull of the anchor cables being kept flat. From the cables slings are suspended at 10-ft. intervals carrying the transoms: the road-bearers are laid on these, followed by the chesses. The usual *dip* of the cable is $\frac{1}{10}$ to $\frac{1}{12}$ of the span. In erection it should be hauled up well above its final position to allow of stretch. A stretch of 1 in. in a cable gives an increase of 2 in. to 3 in. in the dip. The length of slings can be worked out beforehand, and they can be fastened to their transom and prepared on the bank before sliding them out along the cables. Let y = length in feet of the sling required, and suppose it is intended to be fixed x ft. from the centre of the span. Let a be the span, and d the dip in feet. Then

$$y = \frac{4d}{a^2} x^2$$

Lateral guys must be brought to the banks, well out to the right and left, to steady the bridge against swaying in the wind.

The trestle suspension bridge has the advantage of requiring no timber frames at the banks to carry the cables, since a log buried in the ground as a sill will suffice; but it is more difficult to construct and takes a good deal of timber.

The stress in the main cables is found thus: Let w be the load on the bridge per foot run in lb., and let T be the maximum tension in all the cables together in lb. (occurs at the centre); let a and d be as before.

Then $T = \frac{wa^2}{8d}$ lb

The cables may be of rope or steel wire, one or more being used at each side as required; or they may be made of twisted telegraph wire.

This latter expedient is very useful for light infantry bridges two planks wide. Two lengths of ordinary wire fence, posts and all, may be slung across the gap, with their lower edges fastened together so that they hang in a V-shape. A wide plank is laid along the bottom between them, and infantry can then cross in single file at two paces distance. There are many other military bridges, but the commonest have here been dealt with. Figure **26** shows a suspension bridge.

Cantilever Bridges. *Cantilever* bridges are very much used in India, their chief advantage being that they can be built out from both banks until they nearly meet; the gap is spanned by road-bearers; they require no cables or trestles.

The principle consists in using several layers of long spars projecting out over the gap. Their centres rest on a ground sill, in the case of the lowest layer, or a transom in the case of upper layers; their inshore ends are anchored down with wire to a buried anchorage or are weighted down with a mass of stones and earth. Figure **25** shows such a bridge.

Aerial Cableways. *Aerial cableways* are of frequent use in steel bridge construction: they can also be improvised with advantage for slinging stores across a ravine or river, or from a ship at anchor to the shore.

The strain of the cable can be found as for suspension bridges. A steel wire cable is usual—and its size can be selected by the rules given above (Tension Bridges).

The cable is carried over a trestle at each end and passes on to an anchorage in the ground. Strong trees or the masts of a ship can sometimes be utilised

to fasten the cable to. A cradle, or merely a hook, running along the cable by means of a pulley-wheel constitutes the traveller, and hauling lines must be supplied to work the traveller to and fro. Such a device would be most useful where waggons have to cross a river by means of a bad drift with a steep pull out the other side; they can be lightened, half their loads being sent across overhead.

Roads. *Roads* must be 10 ft. wide to take a single stream of traffic; 6 ft. will do for infantry in file or pack animals. The gradient must not exceed 1 in 10 for long inclines, although for very short bits with level at either end, 1 in 7 for artillery or 1 in 20 for infantry is permissible. For making a road, lay out the centre line with pickets; it should be as straight as possible, especially avoiding sharp curves on a gradient.

Drains must be cut along both sides and underneath the road at intervals to get rid of water; loose earth should be removed. If metal is to be applied, large stones should be spread as a foundation, and above this should come a layer of smaller stone 3 in. or 4 in. thick. A thin top layer of gravel or other binding material should be rolled in or rammed, plenty of water being used. For rough roads the camber, or curved shape, should be much exaggerated; a road, once a hollow has formed in the middle, will never last, and can never recover its shape. If gravel is the sole metalling material, mix it with loam to bind the pebbles together.

A road on the side of a hill is made partly by cutting and partly by embankment, unless the hill is very steep, in which case it should all be cutting.

The ground on which the embankment rests may have a step cut along it to prevent the bank slipping; the surface of the road should slope well inwards towards the hill, catchwater drains being made above.

Water Supply. Each man requires 3 gal. to 4 gal. of water per diem for drinking, cooking, and washing; 5 gal. or 6 gal. should be given if possible. If washing can be done in a river, 2 gal. is enough Every horse or draught animal requires 8 gal. to 10 gal. Horses drink 2 gal. at a time, taking five minutes over it, and occupying 4 ft. of space laterally.

Water supply may be from springs, streams, rivers, wells, or lakes. If a camp supply be from lakes or streams, separate places must be marked out for drinking, animals, and washing, the first being up-stream of all, and the others in the order named. Red, white, and blue flags should be planted, and policemen posted to ensure careful observance of these rules. If it is necessary to dip vessels in the stream, arrangements should be made to prevent the bottom being stirred up; a sunken barrel is a good device; dipping should be forbidden if pumps are available.

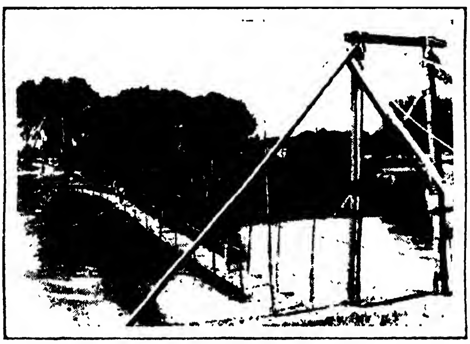
If the supply is from springs, these should be opened up and surrounded with a low puddled wall to keep out rain-water; arrangements should be made to catch the overflow in barrels, or canvas tanks sunk in the ground. Springs are rarely sufficient in themselves to supply a camp.

The flow of a stream may be gauged thus: Select some 12 yd. of a stream where the channel is fairly uniform; drop in any sort of float, and obtain the surface velocity of the water in feet per second. Take the breadth and average depth of the stream; multiply this sectional area by four-fifths the surface velocity, and this gives the yield in cubic feet per second.

All drinking water should be boiled if it is in any way doubtful. Filters are impracticable on service; 6 gr. of alum per gallon will precipitate all sediment in water, and a little permanganate of potash acts as an antiseptic. The water should just look pink-tinted.

Field Fortification. *Trenches* divide themselves into "fire," "communication," and "cover trenches." Dealing with the first, its site, extent, shape, and profile must depend on many considerations—namely, the tactical condition of affairs, on whether the trenches are intended for the defence of a position or as cover to an attacking force; on the force to be protected, on the time available, and on the nature of the ground and the enemy's guns.

Siting of Trenches. The principles governing the proper siting of trenches belong to the subject of tactics and choice of positions, but a few unalterable principles are given. Trenches must fit the force they are to cover, must have a good, clear field of fire for at least decisive rifle range, must be concealed from view, and should have easy means of reinforcement and support. These principles outweigh all others. In defending a line of hills, fire trenches may be placed at the top or the foot of the slope. A high position has the following advantages: good moral effect, as the defenders feel safer, reinforcement from behind the hill is easy, a better view is obtained of the enemy; but the fire from the trenches is inclined to be plunging, the position is more conspicuous, and the attacking infantry can be supported by their artillery firing over their heads until the last moment.



26. SUSPENSION BRIDGE

Nearly all hills are convex at the top and concave at the bottom. For steep hills, put the fire trenches at the foot, in the convex slope, just about where cultivation ends. This ensures a good flat field of fire, but sacrifices efficient reinforcement from supports. If, however, such a position would be too much overlooked by surrounding high ground, it is better to go back to the reverse side of the top of the hill. From here the forward slope of the hill will be invisible, but should the attacking infantry gain the top of the hill it is met with a withering fire at close range. Support in such a position is easy. On gentle slopes the forward crest line is the most suitable place. Trenches should be either in front of or behind sky-lines, as seen by the enemy; they should usually follow the contour of the ground; freshly turned earth should be covered or scattered.

Profile of Trenches. Trenches may have a parapet 12 in. high for fire lying down, 3 ft. for fire kneeling, or 4 ft. 6 in. for fire standing. The latter should be provided if time allows. A trench should never be narrower than 2 ft., 3 ft. being the usual width. This enables men to sit in the trench well

under cover, which is most desirable. Figures **15**, **18**, and **19** show three types of trench.

The *thickness* of the parapet depends on the penetration of a rifle bullet, the effect of high explosive common shell being ignored. Two feet is the minimum at the top. The exterior slope is usually the natural slope at which the earth will stand: the interior slope should be as steep as possible, usually 4 in 1; it will generally require revetting, as explained later.

The *command* or height of the parapet above the surrounding ground is governed by the visibility of the ground in front. One yard per man gives a suitable length for fire trenches.

As the direction of the attackers' fire will not always be from the front, all trenches must be protected from oblique and enfilade fire, by breaking them up into short lengths with *traverses;* these, consisting merely of earth banks, should cut the trench up into lengths of 8 yd. to 10 yd., their frequency depending on the degree to which the trench is overlooked or commanded from the flanks, etc. All trenches should be drained by making occasional sump pits, into which rain-water will collect, and can, if required, be baled out. If trenches are intended for long occupation, they may be undercut to give additional cover.

A certain number of picks and shovels are carried by every R.E. and infantry unit: the number is laid down in field service manuals. Each unit, as a rule, digs its own trenches under R.E. supervision.

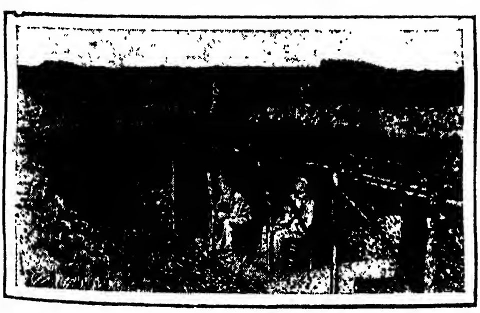
Making a Trench. The proposed trench is first laid out on the ground with a tracing tape along the crest-line. From this line are measured the cutting lines at front and rear edges of the trench. These are marked with tapes, and the tape is removed from the crest-line. Simple works, such as shelter trenches, are, as a rule, marked out by spit-locking their cutting lines on the ground with a pickaxe.

If the section of parapet is complicated, "profiles," or forms made of light wooden battens nailed together in the required shape, are erected at all angles of the trench, and at every 30 ft. in straight faces.

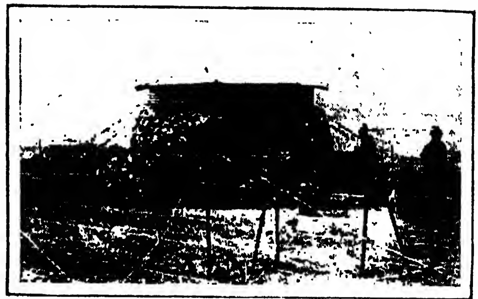
The working parties march up to the work, pick up their tools, and extend along the cutting-lines. Men should be spaced from 5 ft. to 10 ft. apart—4 ft. cramps them—and must use their pick facing the front. Working sideways is dangerous, and likely to make noise from clanging of tools.

Men work best in short *reliefs*, say four hours actual digging. In easy soil six hours may be resorted to. In heavy soil increase the number of reliefs rather than the length.

Most careful arrangement must be made to ensure rapid distribution of working parties. Each man's task should be marked out for him before if possible. A man can dig 30 cubic ft. per hour, or 20 cubic ft.



27. REDOUBT



28. BLOCKHOUSE ON LINES OF COMMUNICATION, SOUTH AFRICA

if continued over four hours in ordinary soil; in very soft ground allow $\frac{3}{2}$ this, or in heavy soil $\frac{2}{3}$. This includes 12 ft. horizontal and 4 ft. vertical throw. Men work better on task work than by time. When their task is done the men should rest. When the throw exceeds the limits stated above, extra shovellers become necessary; one per two or three diggers will suffice. Each relief should, if possible, leave a vertical face for the next to work on. Figure **22** shows the work of each relief on the parapet of a redoubt; the trench in front is required to provide enough earth to give the requisite command of the parapet.

It will be seen that the first relief (four hours), with tasks 5 ft. wide, do 80 cubic ft. in the trench and 75 cubic ft. in the ditch in front. No. 2 relief do $77\frac{1}{2}$ cubic ft. in the trench and only 25 in the ditch; these men go on filling sandbags etc., for head cover. No. 3 relief finish off the digging and give nearly all their attention to head cover.

Revetments. When any bank of earth is required to stand more steeply than its natural slope, it must be revetted with some other material. In first cutting the ground for a trench the turf should be taken off in sods, which are very good, and should be laid, grass down, in two rows of stretchers and one of headers; the steepest slope at which they will stand is 3 in 1. Two builders and three cutters and carriers can cut and lay 100 per hour. Other revetting materials are boards, wattle hurdles, gabions, canvas sheets, brushwood, stones, sandbags, and sacks.

Boards would be placed longwise at the back of the parapet, being held in by occasional wood posts having their lower and upper ends anchored back by wire to logs or stones buried in the parapet. Brushwood could be treated in the same way, the interval between supporting posts being smaller. The brushwood should be packed in as the parapet grows, or it may be made into *fascines*, or long bundles, 18 ft. long, and an average diameter of 9 in. These are tied round with wire every 18 in. as tightly as possible.

Hurdles are a more convenient revetment if found ready made. They are anchored back to logs buried in the parapet by wire as before described. If made on the spot they take three men $2\frac{1}{2}$ hours each, and are 6 ft. long by 2 ft. 9 in. across.

Stones are not good as they splinter a great deal, but if safe from bullets they make a quick rough revetment.

Sandbags are nearly always available. They should be filled four-fifths full of earth and be tied up. They measure 20 in. by 10 in. by 5 in. when filled. For revetments they are built into the rear face of the parapet in alternate layers of headers and stretchers; a bag laid lengthwise to the parapet

is called a *stretcher*, and one laid across, a *header*. The tied ends should always be buried. Two builders and three fillers can fill and lay 70 bags per hour. Corn sacks or others can be profitably utilised in the same way.

Providing *head cover* consists in building the parapet up 18 in. to 2 ft. higher than firing level, and making loopholes at 3 ft. to 4 ft. 6 in. intervals. It is not essential if time is scarce, but is most desirable on account of the immense moral support it gives to the defenders, in addition to actual protection. This latter is almost counterbalanced by the visibility which loopholes are almost bound to occasion, and the restriction of the defenders' view and line of fire. To give lateral fire, loopholes must be splayed, the narrow end outwards; they are 10 in. high, 6 in. wide on the outside, and 20 in. inside.

Sandbags are usually employed for this purpose; two bags are laid on the parapet at each side of the loopholes, splayed to the proper angle; some small sticks, etc., are laid across their top, and more bags are laid on them, one layer of headers, and one of stretchers [**19**].

Communication trenches afford means of reinforcement from the flanks and rear under cover. They would not be provided unless reinforcement has to be done over a long stretch of open fire-swept ground. They are merely plain trenches approaching the front diagonally so as to be covered from fire.

Cover trenches are for the supports to rest in. They require no loopholes, but should have a parapet in front and rear to provide against back-blast from high explosive shells. They also serve as a rallying point if the first line is temporarily driven in.

Redoubts. A *redoubt* is a work entirely closed by defensible parapets; it is usually rather conspicuous, and not so well suited to the defence of extended positions as are trenches, but it breaks up the cohesion of the attack, is very strong, and gives great moral strength to the defenders, who know that their flanks are secure and that their commanding officer intends to hold on to the last. In the case of surprise or night attack, liable to come from any direction, the redoubt is invaluable. The *trace*, or shape, of a redoubt, depends on the garrison and the direction in which the strongest fire is required. Regularity of trace is of no importance. A redoubt must have no dead angles; when firing through a loophole a man cannot conveniently fire more than 15° to one side or the other. This in the case of a rectangular redoubt would leave a large undefended area at each corner. It is avoided by blunting the angles of the rectangle (radius 20 yards), and this is perhaps the commonest trace of an isolated redoubt. A circle is not so good, as it has no strong fire in any direction.

The entrance should be on the least exposed side, and should be well traversed, and closed at night by some obstacle such as tangled wire.

Reverse cover is often required to prevent bullets aimed at one face hitting the defenders of the opposite face in the back. This must depend on the command and position of the redoubt, and the height of the enemy's position from which he is firing. Traverses also may be wanted. Beyond this the construction of a redoubt is exactly similar to that of good trenches, carefully made profiles being required. For redoubts of a somewhat permanent nature, such as would be required in the protracted defence of a position, good splinter-proof overhead cover must be given inside the work for men not actually engaged on the walls. The height and size of this cover is a matter of time and material. The simplest consists of a timber framework on which is laid brushwood [**27**]. This is covered with sods or sandbags and earth, to a thickness of 12 in. to 18 in.

Field of Fire. *Clearing* the foreground in front of trenches is important, so as to give the defenders free use of their weapons within effective ranges. Growths that block fire or impede the view must therefore be removed, but such natural obstacles as merely break up the enemy's formation of attack should be left standing or be improved. Cut down hedges parallel to the front, but leave those perpendicular to the front. The same applies to walls. One man can cut down 2 yd. of thick, quickset hedge in 10 to 15 minutes. Large trees are better left, as they give less cover standing than when felled. Brushwood must be cleared wholesale, if at all: the outer fringe may be left standing with advantage; it will not usually affect the fire of the defence.

Hollows in the ground in front must be filled up with earth or denied to the enemy as rallying points by filling them with felled trees, or mines.

Obstacles in the field of fire are always provided if possible, and are of two kinds: (1) To check the enemy's advance, and delay him under the defenders' fire; and (2) by passive obstruction to compel the enemy to choose other certain lines of attack.

For the former, the obstacles must be under close rifle fire, say 50 yd.; they must give no cover to the enemy, must not be easily damaged by artillery fire, and must not be easily removed.

Abatis, or tree entanglements, are made by felling trees and pinning them down to the ground, with their tops towards the enemy, and their stems resting in a trench. The branches may be pointed with a hand-axe, and barbed wire may be tangled among them.

A stiff hedge, felled by cutting the stems half through, and picketed down, is very effective and rapid.

A wire fence across the front is useful as an alarm at night, if hung with empty tins with a pebble in them.

Thin trip wires fixed on posts about 12 in. off the ground, with their ends tied to a friction tube, are useful as alarms; when kicked or walked on, they explode.

Wire entanglements form the most efficient obstacle. The low wire entanglement is made about 12 in. to 18 in. off the ground, being strung tightly between posts placed chequerwise, 6 ft. apart. It is not now much used, except in fords. High wire entanglements made with barbed wire are, however, excellent. The posts are driven 6 ft. to 7 ft. apart, and are 4 ft. high. Such an entanglement is shown in **28**. It takes one man three minutes per square foot of ground covered.

Land mines, or fougasses, are now practically a thing of the past for field fortification.

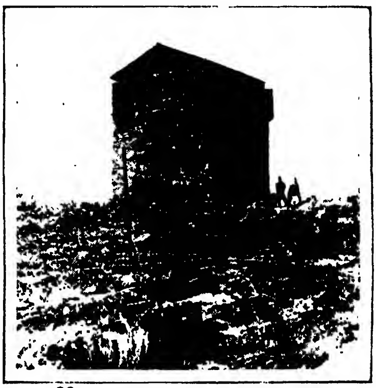
The second order of obstacles, such as a stream or marshy ground, can often do with improvement. Remove all bridges, entangle the bed of the stream or throw cut trees in.

Blockhouses. *Defensible posts* are frequently provided along the lines of communication to protect them, at important points, such as railway stations, camping grounds, bridges, etc. They are usually very small, garrisoned by a handful of infantry. They may be liable to attack from all sides, and generally take the form of one or more blockhouses. Figure **28** shows the type that was

most used in South Africa. A large hollow cylinder of curved corrugated iron is bolted together, 4 ft. high and 13 ft. 6 in. diameter. It is placed whole on the correct spot, and a rough stone wall is built up round it. If stones are not available, a second envelope of corrugated iron may be made, 18 ft. 6 in. diameter. This is placed concentrically outside the other, and the annular space is filled with earth. The earth is got from a trench dug round the block house. When this earth or stone wall is finished, the top is levelled off with a course of filled sandbags, and on this is put a cylindrical hollow screen, consisting of two rings of corrugated iron, 5 in. apart. This has loopholes made in it all ready. The screen is filled with carefully rammed gravel or broken stone, and on top of it is placed a light roof for protection against weather. The entrance is through a small square hole in the side, or by a passage leading from the surrounding trench up through the floor of the blockhouse. It is surrounded with a belt of high wire entanglement. The sentry at night is stationed in the trench, and anything approaching is seen against the sky. These blockhouses take six sappers and 20 infantry about eight hours to construct. The garrison is one N.C.O. and seven men.

Stone Blockhouses. Another type of blockhouse, built of masonry, is shown in **29.** This has three tiers of fire provided, with two *machicoulis* (overhanging) galleries for fire downwards on to the attackers.

The loopholes consist of ⅜ in. steel plates, 24 in. by 12 in., with a 5 in. by 3 in. hole in the middle. These are built into the masonry and give plenty of splay for lateral fire.



29. MASONRY BLOCKHOUSE

Other defensible posts sometimes occur where isolated depots of stores have to be guarded, or where a village or well-marked hill projects out in front of the general line of a defensive position that is to be held. In such cases, any existing building, if not exposed to artillery fire, may be utilised.

Defending a House. The defence of a house is common in history, and may recur, especially against savages. All openings must be closed up and made bullet-proof; windows and doors should be built up with sandbags or screens of corrugated iron and gravel. Loopholes may be left in these, and others must be knocked through the walls. Doors, even if they cannot be made bullet-proof, must be barricaded. Loopholes must be high enough above the ground (7 ft. to 8 ft.) to prevent the enemy rushing up and firing through them; the defenders can reach them by using chairs or planks on barrels, etc.

Communication from one room to another must be secured by knocking holes through the walls, if necessary. All inflammable material outside should be removed, and loose earth should be collected in the rooms for fire extinction. The house should be surrounded with wire entanglement or other obstacle, if time permits.

Village Defence. Villages may become defensible posts on a large scale. They are rarely worth defending. Under artillery fire they are practically untenable, and they use up a lot of men. If they are to be held, the foregoing principles all apply. A good central building should be selected as a keep, where a final stand can be made, and both first and second lines of defence should be prepared. Lateral communication from one section to another is important.

Siege Works. The regular siege of a fortress comprises the following stages: the investment and entrenchment of the besiegers, the establishment of heavy siege artillery, the infantry approach, by sapping, into the first and second parallels, the further approach by mining, and the final assault.

The line of investment is drawn in as close to the fort as the defenders' fire will allow in the ordinary way, and is there entrenched. From this trench, at several specially selected spots, a *sap* is begun.

This consists of a deep trench run out diagonally towards the fort, in such a direction that the defenders of the fort cannot shoot along it. When it has gone some way, a trench is cut out in both directions from its head, and is called the *first parallel*, and troops are moved up into this. From here, more sapping is done, into a second or even third parallel. By this time, the proximity to the enemy is such that further sapping is out of the question, and *mining* has to be resorted to.

Shafts are sunk, and galleries are driven towards the enemy; heavy charges are exploded in the mine to form craters in the ground. The infantry dash forward and occupy these, and so on, until near enough to breach the walls of the fortress and deliver the assault.

In sapping, all work must be done under cover. The trench is 3 ft. wide and 5 ft. deep. The excavated earth is thrown out of the trench towards the enemy; the head of the sap is protected by a steel sap-shield, 2 ft. 6 in. by 2 ft., with two detachable legs, resting on the level ground. Only two men can work at the sap-head with picks, and two shovellers help them behind.

The soil should be thrown well forward of the sap-head, to get efficient cover to the workers.

Mines. When *mining* has to be resorted to, a vertical shaft is sunk, 4 ft. 4 in. by 2 ft. 4 in. in size. One N.C.O. and four men is the best working party. If the soil requires it, a shaft is lined, as it proceeds, with timber frames, which are an article of store. When the required depth is reached (15 to 20 ft.), a common gallery is driven towards the enemy, 5 ft. 10 in. by 2 ft. 4 in. in size. This is lined with timber sheeting or special frames. One N.C.O. and four men is the best allowance, with an extra man for shovelling, to every 20 ft. advance underground. Recesses should be provided every 30 ft. along.

If no opposition is experienced, these galleries will be driven up as close to the fort as possible: if not, right into the ditch, or under it. This occurred in the Japanese siege of Port Arthur.

But, underground galleries built in masonry generally form part of the defence of a fort; from these galleries an energetic defender will drive countermines with a view to preventing the progress of the attacker, by blowing in his galleries or, after he has formed and occupied a line of craters, by blowing up the troops in them. Countermines are in every respect similar to mine galleries. Mining trucks and light rails are invaluable for removal of soil. Intercommunication, ventilation

and light must be provided, and the most accurate plans are essential.

Luminous paint on sheets of zinc gives enough light for the powder chambers or gallery heads. Listening is the surest way of detecting the approach of an enemy's gallery; during this listening, all work must be stopped. Mine charges must be tamped, and the gallery should be closely packed for a distance of one and a half to twice the line of least resistance (depth below ground) of the charge. Filled sandbags form the best tamping, though loose earth will do.

Demolitions. The explosives used for *demolitions* are broadly of two kinds: powder when a steady upheaving effect is required, and guncotton or other high explosive when a sharp, cutting blow is necessary. Powder explodes by combustion, taking a very appreciable time for the formation of all its gases, whereas high explosives detonate (or decompose) in an instant.

Powder would be used in mining for making large craters or for bringing down large masses of earth or rock—as, for instance, in blasting a road in the side of a hill—whereas guncotton would be used for breaking up large boulders, destroying steel bridges, houses, forts or cutting down trees. The object of mines in siege work is to form a continuous line of craters parallel to the front, such that the attacking infantry can occupy them as cover.

Gunpowder is supplied in barrels of 100, 50 and 25 lb. Charges should be made up as compactly as possible in a waterproof bag. A service sandbag holds 40 lb. of powder. For destroying masonry walls, powder charges are calculated thus: let B = length of wall to be demolished in feet; let T = thickness to be demolished in feet; let C = charge in lb. Then, for a brick wall or the haunch of a brick arch, $C = BT^2 \times \frac{3}{2}$. This charge should be subdivided into smaller charges, placed about twice the thickness of the brickwork apart. For a wooden stockade allow 40 lb. to 100 lb.; for a fort gate, 200 lb. in one charge; for a stockade of earth between timber allow 70 lb. per 5 ft. run. In the presence of the enemy increase above charges by 50 per cent. Powder charges can be fired electrically or by safety fuse. The end of the safety fuse is cut off on the slope so as to expose the burning composition, and is placed well in the middle of the powder charge.

Explosives. *Guncotton* is carried wet in slabs of 1 lb. to $2\frac{1}{2}$ lb. weight; it can be cut up with a plain saw, plenty of water being used as a lubricant. Wet guncotton is absolutely safe and will not detonate with the ordinary detonator. Each slab has a round hole in it into which can fit a dry guncotton *primer*. If this dry primer be detonated it will also detonate all the wet charge, consisting of several slabs, provided that they are in close contact with each other. The dry primer is itself detonated by a detonator and fuse, or electric detonator. The charge must always be in close contact with the object to be demolished, and must extend across the whole length of the object to be cut. For applying charges to walls, stockades, or steel work, they should be made up carefully on a board, and can then be placed whole against the object. For cutting a brick wall up to 2 ft. thick allow 2 lb. per foot run; for a brick arch dig the earth roadway off the haunch and give $\frac{3}{4}$ BT^2 (symbols as before); for a brick wall over 2 ft., $C = \frac{1}{2} BT^2$; for a brick pier $C = \frac{2}{3} BT^2$; for a hardwood stockade, $C = 3\ BT^2$; to destroy a field gun use $1\frac{1}{2}$ lb. on the chase near muzzle, heavy gun 4 lb. at bottom of bore with water tamping; steel rail $\frac{1}{4}$ lb. against web; iron rail $\frac{2}{3}$ lb.; for iron and steel plate, $C = \frac{3}{2}Bt^2$, where t = thickness of plate in inches. For a blockhouse or frontier tower of stone and mud, place 20 lb. to 30 lb. in the middle of the tower, and block up all openings (doors). Trees and posts can be cut down by placing two or three primers in a 2 in. auger hole, or by surrounding them with a necklace of primers threaded on a wire, so long as each piece is in contact. *Cordite* can be used, but requires a guncotton primer to detonate it.

Dynamite is most suitable for blasting rock. One or two cartridges are exploded in a hole made with drills or jumping bars. Detonation is done with a commercial copper cap. Dynamite freezes at 40° F. and is then dangerous. It must be thawed before use by placing in a dry vessel standing in warm water.

Ignition. *Safety fuse* burns at 4 ft. per minute; it is waterproof; for use with a detonator it is cut off square and the end is inserted into the tube end of the detonator, where it is secured by pinching. The end for lighting is slit down the middle about 1 in., and a fusee is employed to light it. If the charge is some way below ground instantaneous fuse is sometimes used to save time, in combination with a short length of safety fuse. The detonator contains fulminate of mercury and should be handled with great care: it is an article of service equipment.

Electric firing is done by means of an exploder or batteries; the former is an article of service equipment. The batteries suitable are the Grove cell with constants 2 volts and ·1 ohm, and the Leclanché, constants 1·3 volts and ·25 ohms. The former is rarely available; the latter is carried by telegraph sections made up into batteries of six cells.

Two insulated wire leads are required leading to the charge: here they are connected to a special fuse in the case of powder, or a detonator in the case of guncotton. Electric firing is most useful when two or three charges are to be fired simultaneously or from a distance.

Balloons. *Balloons* are becoming more and more necessary day by day. The headquarters of the R.E. balloon companies are at Aldershot, where the factory makes all that is required. Military balloons are made of skin, and average about 12,000 cubic ft. in capacity [see article beginning on page 3977]. They are inflated with hydrogen gas, which is produced by the electrolysis of water. When empty, the balloon lies inside its car, in which state it would be carried in a waggon on service. When once filled, it is not easy of concealment, and its method of advance with troops would depend on military requirements; either it would be towed along aloft well out of danger, or hidden as well as possible close to the ground. Captive military balloons are employed for observation of the enemy's movements and to assist friendly artillery by discovering hidden targets. The observer, who is generally alone, sits in the wicker car and reports his observations by telephone on the ground.

MILITARY ENGINEERING *concluded; followed by* ARMS AND AMMUNITION

ILLUMINATION

Prep:ring the Vellum and Quill Pens. MSS. Decoration in Applied and Burnished Gold and in Colour. The Art of the so-called Dark Ages

Continued from page 6105

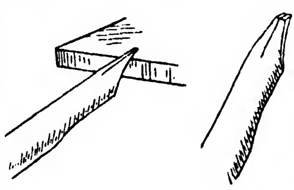
By G. A. POWNALL

THOUGH the word "illumination" is indifferently applied to all kinds of decoration upon the pages of books, it really implies decoration in raised and brightly burnished gold. Painting in colours generally accompanied it, but by no means always. Most Celtic MSS., on the other hand, are painted, but not illuminated. The idea of decorating the margins of text having originated, one may say, in Greece (although slight rubrication was practised in Egypt), and then spread through Rome to the rest of the Western world, one notices how much the earlier MSS. of different countries resemble one another, and how each branch developed along its own lines until several very distinct schools are found in the late fifteenth or early sixteenth centuries.

It was in the days of the Ptolemys that skins were first used for writing. Eumenes, king of Pergamus, aroused the jealousy of the then reigning Ptolemy by the celebrated library which he was then founding; whereupon the latter refused to supply him, as he had done till then, with papyrus. Eumenes then introduced the use of skins properly dressed for taking ink and pigment, thereby rendering himself independent of his Egyptian rival.

The Vellum and Ink. We now come to the practical side of the question, and the first thing to be considered is the surface of the vellum. Old vellum was prepared in a way which gave it a very beautiful surface, velvety to the touch and delightful to work upon. This is unfortunately a lost recipe. No manufacturer that we know of can get quite that surface.

Modern vellum has a shiny and at the same time absorbent surface which does not take ink or colour nicely, or anything else. For ordinary thick vellum (that is, neither Roman, slink, nor goat) the following method, homely though it sounds, is the best way of treating it before beginning work. Smear vaseline over a piece of rag and warm it so as to allow it to get more or less evenly greased. When you have pinned down the vellum, rub it all over with this rag, particularly where text is to appear. Then rub the vellum well with pumice powder. Dust the pumice off very thoroughly with a clean rag and the surface will be found very pleasant to write or otherwise work upon.



16. PREPARING A QUILL PEN

We then come to the matter of ink and pens. For ink, an ordinary good black writing-ink will be found satisfactory for all practical purposes. It is really quite black enough; if it is good it does not fade; and it flows, of course, far more freely than Indian, or other specially-prepared inks.

Preparing Pens. The pens are a subject about which more must be said. In speaking of writing, it must be remembered that we are always referring to Gothic lettering. For ordinary small text a quill cannot be improved upon. The pen, when you buy it, is probably cut to an ordinary fine nib point. This must be altered thus: Lay the point of the pen down on the edge of a piece of glass; then, with a sharp knife, cut off the point, so that it will resemble that shown in the illustration [16]. This must be done in one cut, by placing the knife just above the point, and pressing it down with a slant towards the point. It must be remembered that this regulates the breadth of the nib, which must, therefore, be cut to suit the particular script.

Next grease the nib inside to about three-eighths of an inch from the point, either with the invaluable greasy rag or a brush, and feed the pen from another, applying the ink to the part above that greased. The ink will then only flow down the slit of the pen, and your writing will be clean and sharp. After much use, the point may want re-greasing. A quill, however, can only be cut to a point about one-sixteenth, or, at most, one-twelfth, of an inch in width. For larger writing a reed must be used. These can be cut to a much wider point. The treatment of the reed is the same as that of the quill, except that the application of the grease should be carried all over the nib, to prevent the ink soaking into the wood. Both the quill and the reed may want a little working on a piece of glass or the finger-nail before the ink will run to the point.

The Gilding Outfit. So much for our text. We will now consider the gilding. A slight outfit, if it can be called such, is necessary: (1) A gilder's pad, which is a piece of wood or card, with a wash-leather pad on the face of it; (2) a gilder's knife, which has a blade about 5 in. long and about ½ in. wide; (3) a small file to run along the edge of the knife, so as to give it the character of a very minute saw; (4) an agate burnisher—claw-shaped is the most useful; (5) an ivory, or bone, or agate tracer, which is a pointed piece of hard substance; (6) several small pieces of the thinnest and most shiny tracing-paper you can procure; (7) a small piece of vellum cut in the shape of a long triangle, to be used as a gilder's tip; (8) a small velvet pad, like a diminutive hat pad, for brushing off superfluous gold leaf; and (9) a book of unrouged double-fine gold-leaf. With regard to the size with which to apply the leaf to the

17. SPECIMEN OF MODERN ILLUMINATION
(By the Author)

vellum and at the same time raise it above the rest of the surface, a very satisfactory mixture for the purpose may be made by the following method: Grind some French clay to a fine powder, and add water until it is a stiff paste. Add French chalk in the proportion of about three of clay to one of chalk. Mix this well with a palette knife on a piece of glass. Now add drops of Le Page's liquid glue until the mixture is of the consistency of thin cream. Strain through a muslin of double thickness into a saucer to dry. When required for use, pour a few drops of water into the saucer, and stir gently with a brush, avoiding bubbles, until it is again of the consistency of thin cream. It can then be applied to the work with a brush. There are also many preparations made by the leading artists' colourmen which give satisfactory results.

After a while, the illuminator may prefer to experiment with parchment size, isinglass, red lead, gum arabic, honey, glycerin, borax, glair, or other ingredients, in making a size to his own particular liking. But nowadays, one has not generally time to worry about the making of materials, there being barely time to use them.

A Simple Method of Gilding. Having thus prepared your size, you will find the following the simplest method of gilding those parts of the design desired. The gold must be done first, before any colours are painted on, otherwise the leaf will be sure to stick to parts where it should not. First, then, paint over all the parts to be gilt thickly with the size, and leave it to dry, which will take about three to four hours. Be careful not to touch any part with the fingers, even after it is dry. Then take a gold-leaf from your book, by passing your knife carefully beneath it, and lay it flat upon the pad. It must then be cut approximately to the sizes you require.

To cut it, place the edge of the knife firmly upon the leaf and move it with a saw-like motion. Take your gold tip and moisten the edge of it by passing it along the tongue. Then touch the edge of the piece of leaf with the gold tip, to which it will stick firmly, thus enabling you to lift it and place it down where you wish.

Burnishing the Gold-leaf. Next, after covering up all but the particular bit of size you are gilding with the thin pieces of tracing-paper, breathe fairly hard (but exactly how hard must depend on experience) twice or three times upon the size, and lay the gold-leaf on it, being careful to keep the leaf as flat as possible. Place a piece of tracing-paper on it, and press down very hard with the finger, running the tracer round the edges, if necessary, to make it adhere firmly. Remove the tracing-paper and burnish the leaf very carefully. If the gold does not take the burnish at once, you have breathed too hard upon the size, thereby moistening it too much. Leave it a few seconds to dry slightly before burnishing. If the leaf comes off when rubbed with the burnisher you have not breathed hard enough, or you have touched the size with the finger; in that case, you must brush the leaf off with the velvet pad, breathe again, and apply another piece of leaf as before. If the burnish comes at once on the first trial, you are lucky. In that case, repeat this process till you have gilt all the parts of your design where raised gold is to appear. This method applies equally, of course, to any leaf other than gold.

If you wish to stamp the gold—that is, make a design upon it in depressed spots—this should be done as soon as possible after the leaf has

18. SPECIMEN OF ILLUMINATION FROM THE HARLEIAN MSS.

been laid on and burnished. Press the point of the tracer down firmly on to the gold, and it will leave the required depression. This practice of enriching still further the raised and burnished gold was very much in vogue all through the Edwardian period, and very magnificent is its effect.

Silver and Platinum Leaf. In mediæval work we frequently find attempts at treating silver in the same way as gold-leaf; but they appear never to have been satisfied with the result. This is not surprising when we remember that they had only silver-leaf to work with, which tarnishes into all the colours of the rainbow in a very short time. Nowadays, we have an excellent way out of that difficulty. Platinum leaf is made which will burnish almost to the brilliancy of silver, and will remain unchanged.

For illumination in colour ordinary moist water-colours are our medium, and an almost infinite variety of schemes present themselves to our choice. It would be useless to attempt a description. Nothing but a careful study of old MSS. will teach the student what colours are most pleasing, and how to contrast and arrange and alternate them. One may say that red, blue, and green are the key to them all. But this may be said of a picture. It is not a very useful or practical piece of information in either case. In most work of all ages, styles, and countries, the colours were not left plain, but their crudeness was toned down by a fine design in white line painted all over them. For this, do not use Chinese white, but enamel white. So much for our materials and how to use them.

19. ILLUMINATED PAGE FROM THE ARUNDEL PSALTER

Mediæval Practice. We must now add a few words on illumination as practised in England and France during the Middle Ages. In a word, the tendency through the ages was to lighten the design. Greek, Roman, and even early Gothic work was decidedly heavy, though perhaps rich. In France, the work was generally better than that done in England. It was early in the fifteenth century that the two countries utterly diverged in their development of illumination. In France, the design just prior to that date had consisted mainly of coloured leaves upon a coloured stalk. Dragons, grotesques, men, birds, etc., were freely introduced as well. But about the beginning of the fifteenth century the coloured leaves became nearly all gold, with coloured flowers and buds of almost infinite variety amongst them; the coloured stalk became a fine black line with fine little twigs from it. Nothing more beautiful or delicate than some of the best books executed at this period can be imagined. In England, on the other hand, the style became suddenly much more florid, the colours brighter, and the design, to say the least of it, more free; so free, in fact, as almost to merit the description of "careless."

The Purity of Mediæval Art. Our parting word of advice is that a student should remember that in mediæval days, when a new person stepped into this world, he found the arts, and illumination among them, in a very high state. From his birth he was accustomed to look upon a pure school of art, practically unadulterated by any outside influences. By the time, therefore, that he began to work and do his share, he had not only been through a careful study of all that had gone before, but he had a taste and quiet refinement in his nature which less fortunate mortals born in another age are oftentimes denied. For, with all our wonders and comforts and wisdom, our artistic efforts do undoubtedly lack the delicacy and refinement exhibited by the best work of the so-called Dark Ages. All this means, in a word, wade through numbers of the best MSS. you can find [18 and 19], copy from them copiously, and try to get the spirit of the work into yourself. Without this, technical knowledge is useless.

THE MANUFACTURE OF PAPER

The Paper-making Fibres and their Characteristics. Treatment of Rags in Paper-making. Wood Pulp. The Hollander. Paper-making Machinery

By CLAYTON BEADLE & HENRY P. STEVENS

SINCE the advent of civilised man paper—or something which has done service for it in bygone ages—has been a necessity. And the demand for paper and its application have, from its first introduction, increased with our methods of civilisation. From the materialistic point of view, it is the medium of all literature, and no civilisation could exist without it. The annual consumption per head of the population by different nations is regarded by many as a useful index of their civilisation and enlightenment.

Paper-making Materials. The materials used in paper-making and their sources are as follow:

FIBRES

1. *Flax*—Russia, Turkey, Italy, Egypt, France, Belgium, and Ireland.
2. *Hemp* (true)—Russia, Italy, Turkey, Hungary.
3. *Hemp* (best fibres, but not *Cannabis sativa*)—India.
4. *Hemp* (leaf fibres), *i.e.*, "manilla"—Philippine Islands, India, Ceylon, Mexico, Venezuela, West Indies.
5. *Hemp*, New Zealand hemp (*Phamium tenax*)—New Zealand.
6. *Cotton*—United States, Egypt, India.
7. *Jute*—India.
8. *Straw*—Holland, Germany, and other countries.
9. *Esparto*—Spain, Algeria, Tunis, Tripoli.
10. *Wood*—Scandinavia, Germany, Austria, Canada, United States.

MINERALS

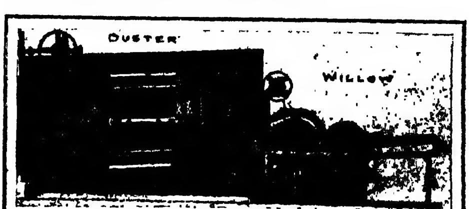
11. *China clay*—Cornwall, Devon.
12. *Agalite, asbestine, etc.*—Saxony, United States, Cornwall, South Africa.
13. *Pearl hardening*, terra alba, gypsum—England.
14. *Baryta*, barium sulphate—England, and other countries.
15. *Chalk*, whiting, carbonate of lime—Kent.

COLOURS

16. *Pigments* (ultramarine, etc.)—England, Germany.
17. *Coal-tar dyes*—England, Germany.

SIZING MATERIALS

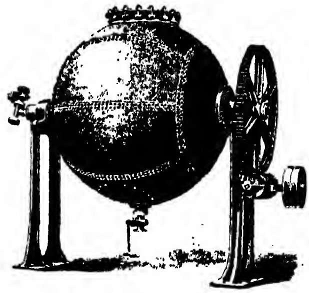
18. *Gelatine and glue*—England, Germany, France.
19. *Skins for ditto*—England, United States, Australia, South Africa.
20. *Resin*—America and France.



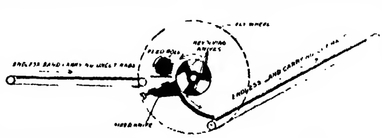
1. COMBINED WILLOWING AND DUSTING MACHINE

Paper from Rags. Cotton and linen rags may be taken together, as they are treated very much in the same way. The chief source of cotton and linen paper is derived from rags, new and old. The rags are imported into this country, and the supply is altogether inadequate to meet the present demands.

They are received, if imported from abroad, in bales weighing about 4 cwt.; if from merchants at home, in jute bags containing about 1 cwt. or 2 cwt. They are graded and sold according to quality, and are known under such names as "out-shots," "fines," etc. The trade name, however, cannot be taken as any criterion of value, as merchants' standards differ so much. The bales are "shot"—that is, opened and laid out on the floor—then fed into a "duster" [1], consisting of a cylinder about 20 ft. long by 6 ft. diameter, made to revolve slowly, and provided internally with prongs and covered externally with coarse wire netting. The axis of the duster is inclined at an angle, so that the rags travel from one end to the other while the drum revolves. The loosened dirt passes through the wire mesh. The duster is enclosed in a wooden box, and the dust which settles at the bottom is periodically removed.

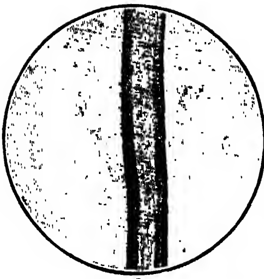


3. CIRCULAR RAG BOILER (Wm. Lord, Bury)

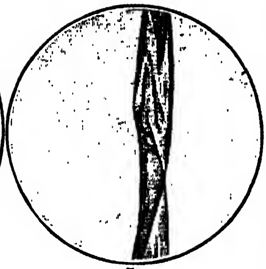


2. RAG-CUTTER WITH REVOLVING KNIVES

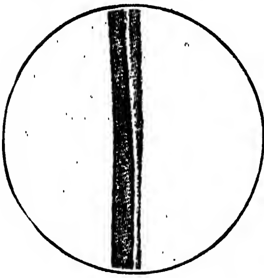
Cutting and Sorting Rags. The rags are then taken in baskets and cut up and sorted into different qualities. The "hurdle," or table on which the rag-cutters work, is covered at the top with a coarse wire gauze, and provided underneath with a shelf or drawer. As the rags are turned over on the table, the loose dirt falls through. Across the hurdle, sloping to and from the worker, and inclined at an angle, with the edge of the blade sloping towards the operator, is a broad, sharp knife. Handfuls of rags are taken by the operator, and cut up into short lengths of about 4 in. square by drawing across the knife. These are thrown into different bins according to quality. During this process, all buttons, whalebone, steel, and other harmful materials are thrown out as "mulch." All seams have to be opened, as they harbour dirt. In leading mills there are possibly twenty or thirty different qualities of rags. The general system of classification is to sort the linen from the cotton, each of which are in turn separated into different qualities from the best and cleanest to the dirtiest and weakest.



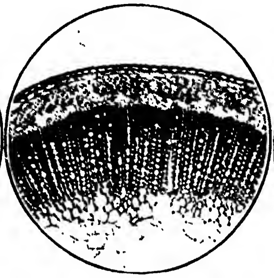
4



5



6



7

8

Machine Cutting of Rags. Hand cutting is an expensive operation, and many of the mills now cut by machine [2], but the result is not so satisfactory for very high-class papers. Machine cutting gives rise to many chips, and the rags are not infrequently crushed and bruised, and the sorting and elimination of dirt is not so easy; but the machine has the great advantage of being cheaper, and at the same time fulfils all the requirements of many mills. The cut rags are now delivered into a " willow " [1], consisting of drums revolving at different speeds in a box, and provided with an iron prong, passing between fixed prongs. This beats the rags about and loosens the dirt, after which process the rags are delivered into a revolving duster like that previously described, where more dust and dirt is deposited; then the rags are discharged into a truck ready for the boilers.

Rag Boiling. The early boilers were simply open pans heated by direct fires. The present boiler is horizontal, cylindrical, or spherical [3]. The boiler is mounted on trunnions, through which the steam and water enter; it is made to revolve slowly, otherwise it is constructed very much like an ordinary steam boiler. It is provided with a manhole, and sometimes internally with iron spikes. The rags are now boiled under pressure with soap solution preferably in a spherical boiler [3].

Soda Liquor for Rag Boiling. The general method now is to employ caustic soda solution produced either by dissolving solid caustic soda with water in an iron tank, or by " causticising " soda ash solution by adding to it and boiling with it the necessary proportion of lime, whereby the carbonate of soda is converted into caustic soda, and the caustic lime to carbonate of lime, which latter forms a deposit or sludge at the bottom of the copper, whence the clear liquor is pumped. In a large, up-to-date mill, plant similar to that employed for causticising " recovered ash " from esparto liquors would often be made use of.

The soda required varies from 1 per cent. to 5 per cent., according to the quality of the rags, about half of which is, or should be, neutralised during the first hour, and nine-tenths at the third hour. Soda forms a soluble soap with the dirt, which is easily removed on washing, and softens the resistant lumps or *shive* in the linen.

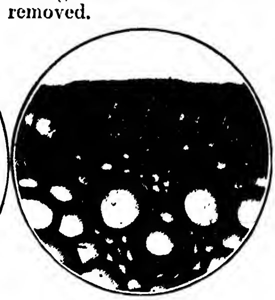
The rags are next removed t the breaker, where they are broken in and washed. The washing is carried on for two or three hours, during which much dirt is removed.

9

10

11

12



13

14

15

PAPER FIBRES—HIGHLY MAGNIFIED

Esparto Grass. Rags failed altogether to supply the demand on account of the great increase in use of paper. This demand was met by the introduction of esparto grass by Routledge in 1862. The bale of esparto when received was formerly picked over carefully by hand as it passes along a travelling band; it is now dusted and delivered, without cutting, into a boiler of peculiar construction, known as a *vomiting boiler*. By an ingenious arrangement of pipes, the liquor which drains through the false bottom rises up the side tubes and vomits as a spray on to the surface of the grass, thus producing a constant circulation.

Spanish esparto gives the highest yield and best quality, and, consequently, commands the best price. For further details of esparto and rag treatment Beadle's "Chapters on Paper-making" and "Fibrous Constituents of Paper" may be consulted.

16. SECTION OF ESPARTO MAGNIFIED 52 DIAMETERS

The Removal of Liquors. In some systems, after the boiling is completed, the material, which is now reduced to pulp, is blown into another boiler under pressure, from which the liquor is removed by water displacement in such a manner that the liquor is diluted as little as possible. As in the case of straw, the liquor is passed on to the evaporators, where it is concentrated and reduced to "ash," and after causticising, is used over again.

Sizes of Fibres. In considering different papermaking fibres it is necessary first of all to form a mental picture of their relative sizes. This can be done by referring to the first two columns of the following table:

SIZES OF PAPER FIBRES

—	No. of fibres per inch lengthwise.	Fibres per inch placed side by side.	Beaten stuff. No. per inch.	Fibres cut during beating into about.
Cotton	1	1,200	30	30 pieces
Linen	1	1,200	30	30 pieces
Straw	75	1,250	75	Not cut
Esparto.. ..	18	2,200	25	About a third

Each of the fibres in question varies considerably in length and diameter, so that the average figures only are taken. Cotton and linen fibres are about an inch in length. Straw, which is very short, would require 75 placed lengthwise to equal an inch, and esparto about 18.

As to diameter, the cotton and linen are about equal, esparto being thinner.

The last column shows the length of the fibres as manipulated for the paper machine—that is, after they have gone through the processes of beating, to be described later.

Under magnification *cotton* often resembles a spiral collapsed tube, twisted on itself like a corkscrew [**4** to **6**].

Linen or flax [**7** to **9**] consists of transparent fibres, regular, smooth, and with tapering ends, and a very small hole or canal running along the centre. Sometimes it shows a slight marking, and here and there star-shaped puckerings. By the aid of these peculiar markings the linen fibre may, in some cases, be distinguished from hemp, to which it bears a very close resemblance, enough at times to baffle the skill of the most experienced. In its raw condition it contains waxy and "pectose" substances. The ash of raw flax varies from ·7 to 1·3, and of cotton in the raw state is about 1 per cent.

Esparto fibres [**15** and **16**] are generally smooth and regular, and when seen against cotton, linen, hemp, and wood, under a microscope, appear much smaller. They can be recognised generally in papers by the presence of little tooth-shaped particles [see **15** and **16**], which are the leaf hairs.

The straw fibre [**14**] somewhat resembles esparto both in size and appearance, but the serrated cells vary according to the kind of straw or its source. There is also present in straw a number of oval cells, derived from the pithy matters attached to the inside of the stem.

The wood fibre resembles none of the foregoing. That derived from Scandinavian wood shows long, wide fibres not unlike an elongated collapsed envelope with rounded ends. Chemical pine wood fibres [**19**] have characteristic pitted vessels on their surface like rows of small eyes. Poplar wood has characteristic vessels, with scale-like markings on the surface. The foregoing, as also hemp, jute, etc., are all, perhaps, better understood by a careful examination of the several drawings and photomicrographs.

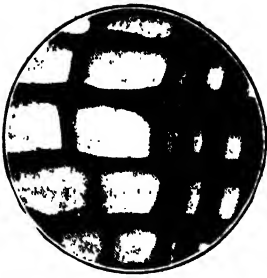
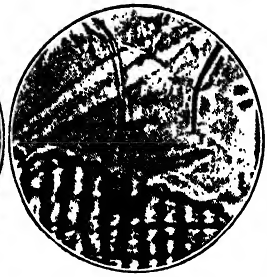
17. UPRIGHT WOOD-PULP DIGESTER

Wood Pulp. In the process of conversion of wood into pulp, there are two great divisions, which can be expressed by two words, "mechanical" and "chemical." Mechanical pulp contains practically all the ingredients of the original wood, such as resins, gums, encrusting matter, etc., in addition to the fibre proper. The chemical pulp consists of the fibrous residue obtained by the removal of all foreign bodies by

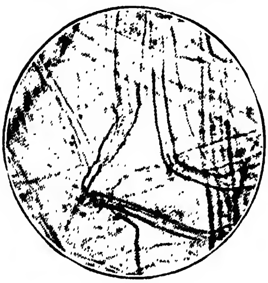


18

19



20



21

22

23

MAGNIFIED WOOD FIBRES

chemical treatment. Mechanical contains fragmentary particles, more or less fibrous, according to the nature of the wood and the care exercised in the process. Needless to say, chemical wood is much superior to mechanical in strength and lasting qualities. It is, of course, more expensive to produce.

Chemical Pulp. There are three processes for the manufacture of chemical pulp—namely, the "soda," the "sulphite," and the "sulphate" processes.

The soda process consists in "digesting" or boiling chips of wood under pressure in wrought-iron digesters or boilers, somewhat similar in construction to those described under Rag Boiling, the temperature ranging from 340° F. to 360° F., and the steam pressure from 100 lb. to 140 lb. per square in. The yield is decreased by increasing the amount of soda, and the soda used may be 15 per cent. to 25 per cent. on the weight of the wood, with sufficient water to saturate the mass. On the completion of the boiling, which takes about eight to ten hours, the digester is discharged, the strong liquors and washings carefully collected, concentrated, calcinated, lixiviated, causticised, and used over again, together with sufficient fresh soda to make up the loss on recovery.

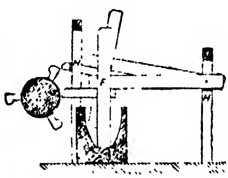
Yield of Pulp. Wood yields by chemical process approximately 50 per cent. of air dry pulp, more or less according to circumstances. The mode of cooking, etc., in the sulphate process is not unlike that of the soda: no special lining being required, this is greatly in its favour. The process has, however, the objection that quantities of sulphuretted hydrogen are generated. Works therefore need to be located where a nuisance may be tolerated.

Ten or fifteen years ago unbleached pulps lost 10 per cent. or 12 per cent. on bleaching. Now the cooking processes have been so much improved that the best brands lose on an average no more than 5 per cent. and consume approximately 10 per cent. of bleaching powder on the weight of the dry pulp. Some pulps bleach much more readily than others; hence we find pulps on the market advertised as "easy bleaching," which, however, on careful examination and compared with others, are often found to be misnamed.



24.
OLD WOODEN STAMPERS

The manufacture of wood pulp is a vast industry in itself, but inasmuch as England buys all (or nearly all) her supplies ready prepared, we shall content ourselves with a few general remarks on the subject.

A few photomicrographs of wood fibres are shown in **18** to **23**.

Primitive Beating. For the reduction of fibres to pulp, the first discoverers probably chewed the fibrous material and spat it out on a smooth surface to dry; after this some crude form of hand mill, resembling a pestle and mortar, was used. The same principle was in vogue, only on a larger scale, and driven by water power, up to about 150 years ago, but when wind and water took the place of hand power, the pestle was raised vertically by means of a cam on a shaft, and allowed to drop into a trough [**24**]. A battery of these stampers was constructed by gouging out the stem of a tree, so as to form a trough, the bottom of which was shod with iron, and nails with broad heads were fixed on the bottom of the stampers. Their general appearance would be like a batch of stampers for quartz crushing, only constructed in rather a primitive way from wood.

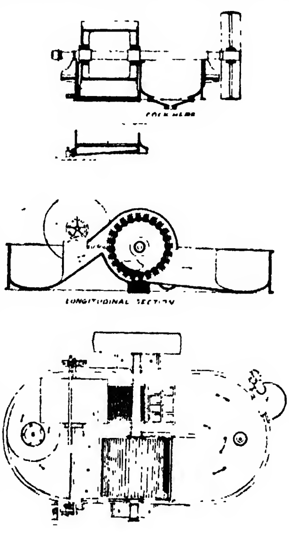
The Hollander. About the middle of the 17th century an instrument was invented in the Netherlands which yielded a hundred times as much as the stampers method, and did the work in about one tenth of the time. This instrument is known to this day as the "Hollander," and consists of a trough with semicircular ends, along the centre of which is a division known as the mid-feather. Across the trough is a shaft, bearing a heavy roll, having a diameter of about double the depth of the trough. The roll is provided with a number of knives placed a few inches apart, protruding an inch or two, and bevelled to form a knife edge. The roll is capable of being raised or lowered. The roll is brought down on to a "bed plate," provided with fixed knives placed at an angle. The trough is dished all round at the bottom to avoid sharp angles and to prevent lodgments of stuff. The centre of the bottom is practically all at one level except close to the roll, where it rises at a fairly steep gradient to the bed-plate whence it takes the curvature of the roll, to, say, halfway up, and suddenly slopes down the "backfall." The structure of the Hollander is the same in principle as it was in those early times, but, of course, with important structural improvements. The modern Hollander is larger and is constructed usually of metal instead of wood.

The Hollander at Work. The illustrations [25] of the modern Hollander in plan, in longitudinal section, and in cross section, are specially prepared to show how the machine is operated. The arrows show the travel of the stuff.

The plan shows on bottom near two ends the valve or plug to the left through which the beaten stuff is discharged to the chest; the valve to right for washing out when required; the valve at the top right hand of plan supplies wash water, which is drawn off by the revolving wire gauze covered washer drum by the scooping action of curved plates placed in side, as shown by dotted lines in the longitudinal section, the water discharging at centre, down the drain. The general contour of bottom and sides can be grasped by examining the above illustration. Just before stuff reaches the roll it is passed over a depression in the bottom covered with a perforated plate, where it deposits grit and heavy material such as broken buttons, etc. Sometimes there is an additional and larger false bottom placed at the opposite side of the mid-feather for a similar purpose. The former is shown in section. There are suitable mechanisms for raising and lowering the beater-roll and washing drums. The action of a Hollander beater-roll is two-fold.

Its first object is to separate individual fibres one from another, and, if necessary, to reduce their length to suit the requirements of the paper-maker. Its second object is to promote the circulation. For the latter purpose the bars are generally arranged in clumps, two or three together, with larger spaces in between the clumps. The front bar of each clump acts like a blade of a paddle-wheel, by pushing the stuff round and causing it to circulate. The time of circulation may be from two to five minutes, or even longer, depending upon the kind of stuff and its thickness—in fact, it varies enormously at different stages of the beating. When the beater is first filled with material, the circulation is very slow, but as the material gets reduced the speed increases. There is good reason for placing the bars of the bed-plate at a slight angle with those of the beater roll, as this tends to promote somewhat of a cutting action.

Figure **26** shows a modified form of the Hollander with two beating-rolls and washing drums. Modifications of Hollanders have been constructed in the form of a four-sided trough, each trough being provided with a beating-roll. The almost universal type, however, is the one we have described in detail.



25. HOLLANDER

From "Half-stuff" to "Beaten Stuff." The beating of rag half-stuff to finished stuff takes about four hours for writing-papers, about two hours for blottings, anywhere from six to twelve hours for "banks" and very strong papers where it is required that the stuff should work "wet." A breaker containing about 4 cwt. of rags, "dry weight," absorbs about 25-horse power, and takes four hours. The beater to the same quantity absorbs from 30 to 35-horse power. The power required is greater with strong and less with weak materials. In addition to the beating, the operation of refining is often resorted to. This is a continuous process, whereby the material is "cleared" of all knots and irregular particles.

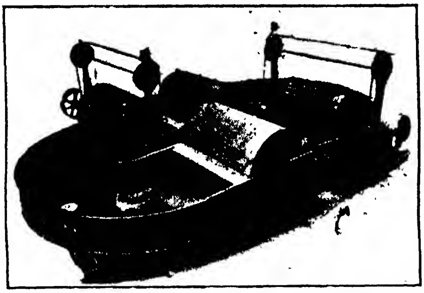
From Rags to "Half-stuff." The "breaking-in," as it is called, in the case of rags, jute, and hemp, is the first operation preparatory to beating proper. The boiled rags are discharged from truck into a "breaker," which is really a beater or Hollander, as above described, but with blunt bars. The roll is put down so as only just to clear the plate. This reduces the particles of rags to "half-stuff," or it performs the operation of unravelling the weaving. This takes about four hours. The breaker has a revolving washing drum covered with wire gauze, provided internally either with lifting buckets or syphons, by means of which it sucks the water through the meshes. A copious supply of clean water is added in front of the beater-roll, and dirty water is drawn away through the washing drum.

By this means a large amount of mechanical dirt is separated which cannot be removed so long as the rag is intact. The washing lasts about two hours, after which the operation is stopped and the "breaking-in" continued to the condition of "half-stuff." The breakers are usually situated on a higher level than the beaters into which they discharge.

An ordinary Hollander roll is provided with, say, 60 bars, and the bed-plate with 15, making, say, 900 contacts per revolution. The roll makes, say, 180 revolutions per minute, which gives us 162,000 "beats" or cuts. The bars are, say, 3 ft. 6 in. wide, so that we may compare a Hollander to a pair of blunt shears 3 ft. 6 in. wide, making 160,000 cuts every minute, through fine fibres. A "Taylor"

beater has a width of bars 60 in. and will make 1,000,000 beats in one minute. Hence, one reason for its greater rapidity of action.

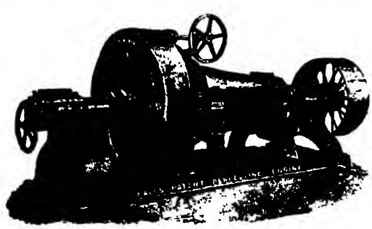
After the stuff leaves the beating engine (whether Hollander or other type) it generally passes to the "chest," or store tank, whence it passes on to the machine. It is now frequently the custom to leave the stuff from the beater in a somewhat unfinished state, and to pass it through a refiner before it reaches the machine. This type of machine is continuous in its action, the stuff passing in at one end and emerging in a finished, or "refined," condition at the other. One form of refiner consists essentially of a cone provided with bars carried on a spindle, and rotating at a rapid rate in a hollow cone provided internally with bars. The stuff in its passage between these bars is quickly refined. At the end of the cone is a rotating disc, revolving against a fixed disc, each provided with bars or knives. The well-known types somewhat on these lines are the Marshall [27], the Horne, and the Jordan, mostly, we believe, of American design. Another type is entirely on the disc principle, such as the Kingsland refiner, which has the advantage of occupying very little floor space.



26. HOLLANDER WITH TWO ROLLS

Hollanders, when first introduced, held perhaps only 50 lb. dry weight. Up to 25 years ago, they held only 3 cwt; 20 years ago, 4 cwt., with larger ones for "news." Now the largest hold 20 cwt. and over. With increased size there is increased economy, as proved by recent trials. Against this question of economy of power we must not forget that Hollanders above a certain size do not produce suitable material for all purposes. Thus, for hand-made papers, Hollanders holding $1\frac{1}{2}$ cwt. to 2 cwt. should not be exceeded, partly because the stuff is not so satisfactorily beaten, but more especially, perhaps, because the orders the makers have to fulfil are comparatively small. For fine machine-made rag papers, 4 cwt. is perhaps a convenient size.

Mechanical wood pulp, of which "news" contains about four-fifths, requires very little expenditure of energy—only a few horse-power hours per cwt—to reduce it to pulp for the paper machine. An enormous amount of power has been consumed in reducing it from pulp wood to sheets of dry or moist pulp, in the first instance, in the mills of Scandinavia and Canada, where it is prepared.



27. MARSHALL'S REFINING ENGINE (Bentley & Jackson)

The following table shows the power consumed in comparison with sulphite wood:

Manilla rope requires	87	per cent. more power than sulphite wood.
New jute threads require	110	,, ,, ,,
New twine ends require	273	,, ,, ,,
New linen threads require	331	,, ,, ,,
New rags require	409	,, ,, ,,

The "Umpherston" is a beater in which the roll promotes the agitation, as with the Hollander, but the stuff, instead of travelling round in a horizontal trough, passes underneath and up the other end, thus economising about half the floor space over the Hollander, a matter of considerable importance in some paper mills.

Why the Hollander is Sometimes Wasteful. Carefully conducted trials have demonstrated the fact that of the total power consumed by the Hollander when reducing air-dry sheets of sulphite to beaten stuff one-third is expended in agitating the stuff; and the fact has been demonstrated, after conducting numerous power trials, that there is in such cases at least 25 per cent. of the power wasted. This percentage is much greater with materials like esparto, straw, and mechanical wood than with chemical wood, but the figure would be less when dealing with rags and other strong materials which require a greater total expenditure of power in their reduction.

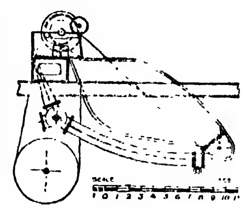
Modern Beaters. To save this useless expenditure of power, special beaters have been constructed whereby the "circulation" of the stuff is promoted by an independent agency. This circulation can now be done in patent beaters of the capacity of 700 lb. to 1,000 lb. dry weight at $2\frac{1}{2}$-horse power. The circulation in the Hollander of equal capacity might amount to from 10 to 15-horse power. There are several well-known makes of such beaters; among them may be mentioned the "Taylor" [28], the "Reed" [29], "Acme" and "Masson Tower." The stuff is either made to circulate round in a horizontal trough, as in the "Reed" and "Acme," or to travel downwards and up again, as with the "Taylor" and "Masson Tower": but in each case we have this all important factor—namely, independent circulation.

Only just sufficient material is made to overflow the bed-plate as the roll can operate upon, the roll remaining out of contact with the stuff, except where actual beating takes place. With the Hollander, the roll is immersed in the stuff up to about half its diameter, and the rapid beating and churning of the bars against the stuff uselessly absorbs an immense amount of power. With the patent beaters, the bars of the roll are placed equidistant from one another, and close; this is a very great advantage. In fact, the "bars" of the roll and "bed-plate" are located and constructed so as to beat to the best advantage, hence the economy. This course cannot be adopted with the Hollander, where the bars have to promote the circulation as well as do the beating.

When treating very strong material, such as linen rags, the percentage of power wasted is comparatively small, hence the advantages of a patent beater are less obvious than with materials like esparto, mixtures of chemical and mechanical wood, straw, etc., and there are reasons in favour of the Hollander which cannot be discussed here. In certain cases, moreover, the agitation is not uselessly

expended, as it improves the character of the stuff. And, moreover, very large Hollanders, such as those of a capacity of 20 cwt., have been proved by recent trials to be far more economical in proportion to their output than smaller ones, so that the last word has not yet been said on this subject: but in the aggregate, for the majority of papers of modern modes of manufacture, results tend in favour of that kind of beater in which the circulation is promoted by an independent agency.

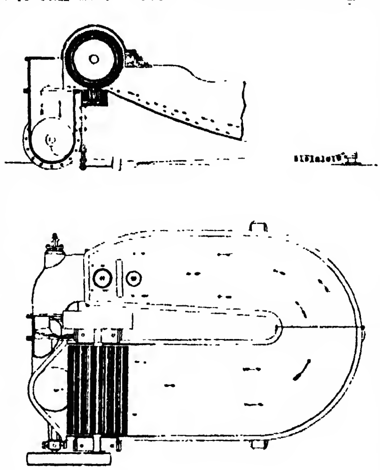
Bleaching Rag Half-stuff. The bleaching of rag half-stuff is ordinarily done by adding bleach solution to the "potcher," which resembles **25**. The bleach required varies, according to the quality of rag, from 1 per cent. to 5 per cent. This is emptied into "steeping" tanks made of brick or concrete, surrounded with cement and paved with perforated earthenware tiles. When the bleach has exhausted itself after 18 to 24 hours, the waste liquor is drained away and the bleached half-stuff dug out and lifted to the beaters.



28. TAYLOR'S BEATER

Another way is to add the bleaching liquor to the beater, the bleaching being effected while the disintegration of the fibre is being proceeded with. In this latter case, the work of bleaching has to be done in two or three hours, which necessitates the addition of a larger proportion of bleaching solution, only about half of which is actually used up, the other half having to be neutralised by the addition of sodium sulphite or sodium thio-sulphate, as antichlor. This process costs more for chemicals than the "steep" bleaching, but does not interrupt the operation, and saves time. But it can be resorted to only for the finer qualities of rags which require comparatively little chemical treatment.

Bleaching Chemical Wood. Unbleached chemical wood pulp that requires to be bleached is ordinarily added to a "potcher," when the fibre is sufficiently separated: a 6° Tw. (= 5 per cent.) bleaching liquor is added (equal to from 10 per cent. to 12 per cent. of dry bleaching powder) on the dry weight of the wood pulp. When properly mixed, the mass is discharged into steeping tanks, left for 24 hours, drained, and lifted to the beaters.



29. REED'S BEATER
(James Milne & Son, Ltd.)

Older Methods of Bleaching. The ordinary method of bleaching by adding the bleaching solution to the potcher, and emptying same to the steeping tank, involves considerable handling and labour, and usually takes 24 hours to accomplish. Moreover, after the steep-bleach is exhausted the half-stuff has to be raised again to the level of the beaters. Something better is wanted to save time and money. In paper-making, as in other industries, the modern tendency is to centralise everything, such as power, plant, etc. With such centralisation comes economy of power, saving of labour, and increase of output. Such points as these are of paramount importance to the English paper-maker, who is compelled to economise in all directions to fight foreign or neighbourly competition. The avoidance of handling results not only in the saving of power, etc., but prevents also contact with dirt, which is difficult to avoid under ordinary circumstances, even when great care is exercised.

Now, it is possible to avoid the handling of the stuff altogether from the time it enters the "breaker" until it reaches the "reel" of the paper-machine as finished paper. By operating valves, wheels, levers, etc., the stuff can be made to pass through the various mechanical and chemical operations out of contact with all disturbing influences. In order to show how this is done, we shall describe the most recent and up-to-date plant by means of which this is now so successfully accomplished. Figure **30** shows the arrangement of the plant recently erected. In this particular installation, in another building the stuff is bleached in the manner to be described later, and conveyed in diluted form through 90 ft. of copper piping to the final bleaching tower, C. This is known as a Masson Tower, and is provided with a slowly revolving gauze-covered drum, B, driven by a gear wheel, A. The drum, in this case, acts as a washer by removing or washing out the residuum of bleach after the bleaching operation is accomplished. During the operation of bleaching, and its removal by washing, the stuff circulates round and round in the tower in the direction of the arrows, being propelled by the circulator G. When the bleaching is completed the washer B draws out the residuum of chemicals. By turning a valve the circulator discharges the contents through a copper pipe into one or other of the four Masson tower beaters, marked E. These tower beaters each in turn reduce the stuff to the condition required by the paper machine, and deliver same to the stuff chests. The circulator G is driven by a motor, H. The beating, circulating, and discharging of stuff in the Masson towers is motor-driven through the shaft K.

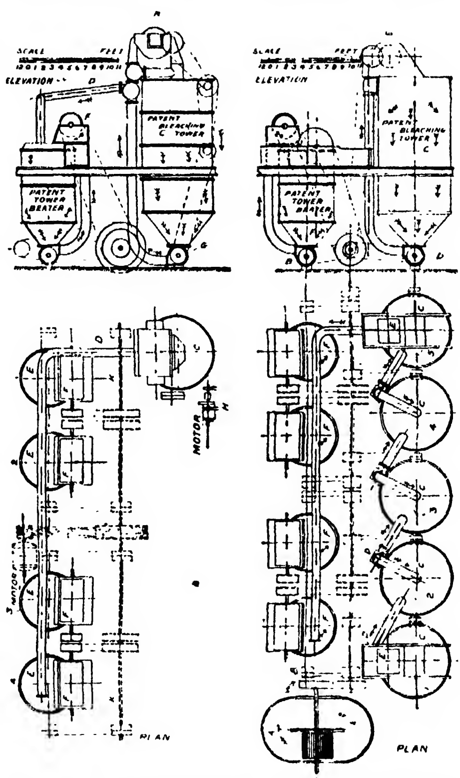
The travel of the stuff in the Masson tower beaters (E, Nos. 1 to 4) is promoted by the circulators underneath, and passes round and round in the direction of the arrows in a similar manner to that of the Masson bleaching towers. The roll F at the top does the beating. In the centre, and close to the top of each of the bleaching towers and beaters, is suspended a cone-shaped hood, which nearly fills the tower, but leaves a small space for the stuff to pass. On the point of this cone the stuff is made to flow and slide down in all directions, then passing through the narrow ring-shaped aperture, between the edge of cone and tower. By the aid of this ingenious contrivance, the stuff is thoroughly and uniformly mixed, and an absolute distribution insured, such as is not possible under ordinary circumstances with the Hollander.

Continuous Bleaching. The section on right in **30** shows how the cycle of operations can be performed in a comparatively small space under one roof, so that the man in charge has everything

at his elbow. We have here four of the Masson tower beaters F and five bleaching towers C. The stuff, consisting either of unbleached sulphite pulp or esparto, is first put into the large breaking engine A, where, if necessary, it is washed by a washing drum (not shown). Attached to this engine is a patent circulator (not shown) which empties the breaker and discharges the stuff into the No. 1 tower C. While No. 1 tower is being filled to the brim by repeated charges, the washer drum E (usually called the *circulator*) is put into operation, by which means the water is drawn out, reducing each charge of stuff to about half its former value. When the tower is full it is finally reduced by concentration so as to pull down the level a foot from the top, to make room for the bleaching liquor. Each tower absorbs 30-horse power when circulating. The passage from one to the other takes from 6 minutes to 10 minutes. The stuff rests still in towers 2, 3, and 4, for about 2½ hours; therefore, out of a total of 150 minutes in each, the circulation is promoted for, say, only 10 minutes, or $\frac{1}{15}$th of the time. If going continuously, each tower would be absorbing 30-horse power, but as each circulates for only $\frac{1}{15}$th of the time, it is absorbing on an average only 2-horse power. This applies to the three inside towers. As the two outside towers have to do the concentration and washing respectively, the circulation in each has to be in operation 30 minutes out of 150 minutes, or $\frac{1}{5}$th of the time, which is equal to an average of 6-horse power.

The Advantages of Concentrated Stuff. The tower beaters each hold stuff sufficient to produce 14 cwt. of paper. The bleaching towers, measuring 16 ft. high by 8 ft. 6 in. internal diameter, each hold concentrated stuff sufficient for upwards of two tons of paper. Their capacity in cubic feet is about 950. The five towers, therefore, together hold 10 tons (paper), and under ordinary conditions of making, the stuff passes through them at the rate of 60 tons of paper per week. The unbleached stuff emerges as a bleached product in about 13 hours to 16 hours, being about half that required in the ordinary "steep" bleach. The ordinary concentration in the Hollander or potcher is 3 per cent. to 5 per cent. of dry fibre, according to circumstances. In these towers the concentration is approximately doubled. The rate of bleaching largely depends upon the concentration, because, if we get the bleach into a smaller volume, it will be chemically more active, and will do its work more quickly in consequence. Thus it is by a system of this kind, which is quite a revolution over the time-honoured methods so long in vogue, that economies in time, labour, power, and chemicals can be effected. If such a concentration were produced in the ordinary potcher, the stuff would be too thick to travel round, and would, therefore, be entirely unworkable.

Note that right hand plan of **30** is a complete installation all under one building, such as would be installed in laying out a new mill. The "washer" is the same in construction as the "concentrator." It consists of a revolving drum covered with wire gauze, similar to the drum of an ordinary breaker, as in **25**, but capable of discharging the wash water at each end. The stuff is pumped up to it by the circulator. The concentrated stuff is paddled forward by triangular projections fixed to the outside of drum, the drum revolving in a kind of trough somewhat like the "back fall" of a beating engine.



30. THE MASSON TOWER BLEACHING SYSTEM

The Continuous Passage of Stuff. But to return to our description **30.** No. 1 tower is emptied in about six minutes by the attached circulator, D, into No. 2 tower C, where it rests undisturbed for about 2½ hours; the circulator in No. 2 tower C in about six minutes empties the stuff into No. 3, where it again rests; from No. 3 to No. 4, and then into No. 5 tower. Immediately the bleach has done its work the residuum of chemicals is quickly removed by means of the attached wash drum E. The bleached and washed stuff in No. 5 is now discharged from one or other of the four Masson tower beaters opposite. The process of bleaching is practically continuous, as immediately No. 1 tower is empty it is refilled by repeatedly filling and emptying the breaker, and passed on to No. 2, No. 2 to No. 3, etc., so that the one end, No. 5, is constantly being discharged into one or other of the four tower beaters F, which each in turn do their work and discharge the finished stuff into the stuff chests ready for the paper-machine.

This installation can easily be looked after by one beaterman, and one man in charge of the bleaching towers and breaking engine. In addition to the plan, we have shown in each case the elevation, so as to render the general arrangement more intelligible to our readers.

The above arrangement is after the manner of plant designed and installed by Messrs. Masson & Scott, Ltd., of Fulham.

THE NURSE AT WORK

Preparation of Poultices, Fomentations, and Medical Baths. Necessary Precautions in Infectious Cases. The Nursing of Sick Children

By Mrs ROBERT E. NOBLE

Fomentations. Fomentations are exceedingly useful remedies, their effects being the same as that of poultices. They have the advantage of being more quickly prepared than the latter, and are quite light, as they rest on the diseased part. To prepare a fomentation satisfactorily everything necessary should be placed at hand ready for use before the process actually begins. A kettle of water should be on the fire and a large bowl put to get warm in readiness. A short roller towel is laid across the bowl with two boiler sticks (children's hoop sticks will do well) in the loops of the roller. Between the two folds of the towel is placed the piece of soft flannel which is to be used for the fomentation. The boiling water is then poured into the bowl over the roller towel and allowed to saturate that and the flannel. Two people should twist the sticks in opposite directions, at first keeping the flannel below the level of the water, and only giving the final twists above that level. Next the flannel should be taken out, shaken up, and gently applied to the diseased part. It is covered with macintosh, and then by two or three folds of cotton-wool or flannel. Turpentine stupes are ordered for severe intestinal pains and cramp. The flannel is sprinkled with about a tablespoonful of turpentine, and the fomentation prepared as described above. Fomentations need to be replaced about every fifteen minutes, and when the treatment is concluded it is important that the parts that have been against the heat should not be chilled. A thick layer of cotton-wool covered by flannel will minimise this risk.

Poultices. Poultices are less frequently used now than they were in the past. Fomentations to a large extent take their place, but for certain purposes the poultice is still without a rival. For cleansing wounds and hastening the discharge of matter from an ulcer, the poultice is beyond doubt invaluable. In every case the poultice should be made of the most suitable size—not too large to inconvenience the patient, nor too small to perform its proper functions.

The Linseed Poultice. A rather large knife with a flexible blade or a spatula is put to get hot in a jug of hot water. A basin is rinsed with hot water to warm it, and then about a third of a pint of water is placed in it—more or less as required, according to the size of the poultice to be made. The linseed is then sprinkled in with the left hand, the right hand stirring with the spatula. The linseed is added till no more sinks into the mixture. Then, after a final stir, the ingredients are spread evenly on a piece of soft linen previously placed on a hot plate. The linseed and water should come away cleanly from the side of the basin, and it will be found that the spatula spreads more smoothly if it is occasionally dipped into some very hot water. The mixture should be spread smoothly over the cloth and may be left to come directly into contact with the patient or else covered with a fine piece of muslin. This latter method is not so good. A little vaseline may be smeared over the surface of the mixture, and the edges of the cloth neatly turned in about half an inch. The consistency of the poultice should be neither dry nor too liquid. If it is too dry it is not so beneficial to the patient; if too liquid it is decidedly detrimental to his comfort.

The linseed used should be carefully chosen. The ordinary *linseed meal* of the chemist is of little value, since it is merely ground oil-cake, from which all the value has been pressed. *Crushed* linseed, on the other hand, contains the natural oil, which has a great medicinal value.

Mustard and Linseed Poultice. Two tablespoonfuls of mustard are mixed to a smooth paste with hot, not boiling, water. Then boiling water is added and the linseed sprinkled in as before. Some people prefer to mix the mustard and linseed dry, but this is quite optional. A mustard poultice makes the skin of the part to which it is applied very tender. Vaseline is a soothing application, and the inflamed skin should be protected from cold by means of cotton-wool. Should a succession of poultices be used, as is nearly always necessary, the new one should be ready immediately to replace the one that is taken off.

Charcoal, Bread, and Starch Poultices. Charcoal may be incorporated with the linseed and part also sprinkled on the surface of the poultice. About $\frac{1}{4}$ to $\frac{1}{2}$ oz. of best wood charcoal is used. Such a poultice is generally used for unhealthy wounds and sores.

A bread poultice is very quickly and easily made. A basin is scalded and some boiling water placed in it. To this is added some breadcrumbs. The mixture is put to stand in a warm place, such as the hearth, for about five minutes. Then the unabsorbed moisture is drained off and the bread spread on linen. If the poultice is intended to soothe, it will be more effectual if made with milk.

Starch poultices are made by first mixing the starch (ordinary laundry starch is used) with cold water, stirring it to form a smooth paste. Then boiling water is added till the right consistency is arrived at, and the starch is spread in the ordinary way. Starch poultices are non-irritant in their action, and as soothing applications they are very useful.

Mustard Plasters. Mustard plasters are quite easily made by spreading ordinary table mustard in a thin layer on brown paper and covering it with tissue paper. The plaster must not be left on the skin very long as its effect is very irritating, and may produce blisters unless great care is exercised.

Medicated Baths. For various diseases different medicated baths are ordered. The preparation of such a bath is entrusted to the nurse, who should make careful note of the doctor's directions. In certain skin diseases and rheumatism soda and sulphur baths are sometimes ordered. In a soda bath two or three pounds of washing soda may be dissolved in the water; if bicarbonate is used a quarter of a pound will suffice. In a sulphur bath the amount used will depend on the doctor's orders, about 4 oz. of sulphate of potassium going to 30 gallons of water. Various kinds of salt baths

are ordered in some cases of rheumatism. Sea water is excellent for this purpose, but if not obtainable, the sea-salt can be dissolved in hot water, and this preparation has great value.

Oatmeal baths are soothing to patients suffering from skin complaints. A bag containing from half a pound to a pound is squeezed in and out of the water till the water feels soft to the hand. The same bag can be used to soften the water of two or three baths. A mustard bath, whether used as a foot bath or for total immersion, is often useful. For a cold in the head few remedies are more efficacious, and a child suffering from croup will be best treated with such a bath.

How to Administer a Cold Bath. A cold bath is sometimes ordered to reduce the temperature of a feverish patient. The patient suffering from hyperpyrexia (high fever) is so ill that if the doctor orders a cold bath he will probably be present to look after its administration. A tepid bath with water at a temperature of about 90° F. is prepared and the patient placed in it. Then the temperature of the water is allowed to fall to about 60° or 65° by the addition of ice-cold water and pieces of ice. The feverish patient's body will give out enough heat to raise the temperature of the water for some time, but in a few minutes he must be put back to bed again. He should be covered only with the sheet and perhaps a blanket over his feet. For some time his temperature will continue to fall.

The Hot Bath. When a hot bath is ordered, the patient is wrapped in a blanket and put into a bath at a temperature of 100° F. to 110° F. The temperature is kept constant by the addition of successive portions of boiling water, which should be poured cautiously down the sides of the bath. The bath should be covered over with a blanket to prevent loss of heat. Meanwhile the bed should be prepared with a large macintosh covering the lower sheet. Then, after the patient has been in the water about twenty minutes, he should be lifted out, blanket and all, on to the macintosh and rubbed down with a warm towel. A warm flannel shirt is slipped on, and he is wrapped in the warm, dry blanket; the macintosh is removed, and he is quickly covered up in bed. Such a bath is given sometimes to induce free perspiration. In that case hot drinks should follow, and hot bottles may be put in the bed. The uses of a hot bath are many. It may be intended to diminish pain, to relieve delirium, and to allay convulsions in a young child.

Vapour Baths. In administering a vapour bath, the patient should be enveloped in a blanket, and seated on a wooden chair standing in a foot-bath. The blanket should fall over the sides of the bath, leaving the patient's head free, but all other parts of his body exposed to the vapour from the hot water. His feet should rest on a fold of blanket on the side of the bath. Then the bath should be half-filled with boiling water. When the steam seems to be exhausted, hot bricks and fine clay balls can be dropped into the water to generate more steam. The patient should be exposed to this vapour for about twenty minutes. He should then be rubbed down quickly with hot towels, dressed in a flannel shirt, rolled in a blanket, and put into bed. A vapour bath is used for cases of rheumatism, gout, etc. The greatest care must be taken to avoid chills after these hot baths, or serious complications may arise.

To give a vapour bath in bed, the patient, enveloped in a blanket, lies under a bed-cradle, which supports the bedclothes. Over this framework rests a macintosh, and three or four blankets. Under the patient is another large macintosh covered by a blanket. The blanket which enveloped the patient is then drawn out, and the spout of a bronchitis kettle inserted between the blankets. The kettle should be resting on a properly-protected stove, and the steam will pass freely into the bed and act on the patient's skin. Great care must be taken not to scald the patient and not to burn the bedding or upset the stove. In about twenty minutes the kettle is withdrawn, the cradle removed, also the macintoshes, and the patient remains in blankets, carefully protected from all chance of catching cold.

Hot-air Baths and Hot Packs. The preparations for a hot-air bath are the same as for a vapour bath, and the patient is enveloped in a blanket. Hot air is then passed in from a specially-constructed lamp. The greatest care must be taken to avoid an accident. The lamp must be well guarded, and every care taken that the patient is not burnt. Hot-air baths are ordered for patients suffering from Bright's disease, and such a patient may be in a semi-conscious or unconscious condition. Such a patient might have his skin seriously burned by any carelessness on the part of the nurse, and such burns heal with difficulty.

A hot pack is used to induce perspiration much as a hot bath is used. It is easier for the home-nurse to manage alone, and, if skilfully given, is very efficacious. The patient's nightshirt is removed, and he is placed in bed on a hot blanket, under which is a macintosh. A sheet or blanket is rolled up lengthways, dipped in boiling water, and wrung out much as a fomentation would be, using a draw-sheet or very large towels as wringers. The patient is rolled on to his side in the bed, and the hot sheet and blanket laid beside him still only half unrolled. He is turned over to rest on this, and then the rest of the sheet is unrolled, and he is enveloped entirely in it with the blanket on top. He is then covered with another macintosh and additional blankets. Then he may be given plenty of hot drinks and hot-water bottles may be placed in the bed. This treatment should induce copious perspiration. In about twenty minutes the wet sheet, blankets, and macintosh may be withdrawn, and their place taken by a hot, dry blanket.

The same precautions against a chill must be taken as after a vapour bath. Generally the patient will be very drowsy after the pack. The best time to administer it, therefore, is in the evening, so that he may settle down to sleep undisturbed for hours.

Cold Packs. A cold pack is used to reduce the temperature. The only difference in administering a cold pack is that, instead of using a hot blanket, a sheet wrung out in cold water is used, and instead of heaping blankets on the bed, a single sheet is used as a covering. Sometimes pieces of ice are rubbed over the patient's skin. Every precaution must be taken in case faintness should attack him.

Ice is exceedingly useful in the sick-room. Some should be broken up and placed in readiness in a small dish. A thirsty patient will find small pieces very comforting to suck. Ice applied to a wound that is bleeding freely may staunch the blood flow. An ice-bag is prepared by filling a bag with pieces of ice, and suspending it over the patient by means of a bed-cradle. The entire weight of the bag should not rest on the patient; part of it only should rest against the head or limb, as ordered. The ice must be renewed from time to time as it soon melts.

Sometimes the ice is placed in pails—small ones, such as children use at the seaside—which are

suspended from a cradle over the patient. The cradle is covered with a sheet and left open at each end, so that a stream of ice-cold air passes over the patient. The patient should be dressed in a flannel nightshirt, and his feet placed against a hot-water bottle.

Cold-sponging. Cold-sponging is another means by which the temperature is reduced. The patient's whole body is sponged over with water at the ordered temperature. The face, neck, arms and chest should be sponged first; then the abdomen and legs, and, lastly, the patient's back. The sponging should be steady and very gentle. Then the patient should be dried, placed in a dry nightshirt, and left in bed covered with a sheet only, or perhaps one blanket. Throughout the process his feet should be kept warm, and he should be protected from draughts.

Inhalations. Inhalations of ammonia or of oil of eucalyptus, or of some terebene preparation is sometimes ordered. A teaspoonful of the particular medicament is placed in a wide-mouthed jug, a pint or more of boiling water is poured over it, and the patient inhales the vapour which rises. He holds his face over the mouth of the jug, and waste of vapour is prevented by holding a towel round the face.

The drugs used for the treatment of bronchitis are carbonate of ammonia, ipecacuanha, squills, and assafœtida.

Nursing Infectious Diseases. In infectious cases, the room chosen should be near the top of the house, and, if possible, no person beside the nurse should use the rooms near that of the patient. All unnecessary furniture must be taken from the sick-room, and all carpets and upholstered furniture and thick curtains banished. Such articles become impregnated with the source of infection, and can only be disinfected with the greatest difficulty. Light, washing curtains may be used, and the floor covered with Indian matting. The woodwork should be wiped over with a cloth dipped in some diluted disinfectant.

Over the patient's door a large sheet should be hung, wrung out in a solution of some disinfectant. One corner of the sheet should dip into a bowl of the same disinfectant to make good by capillary attraction the liquid lost by evaporation. The value of this precaution is often disputed, but it does probably filter the air which escapes from the sick-room, and so protect the other members of the family, and it certainly acts as a danger signal in the shape of a warning.

The Nurse's Health in Infectious Diseases. When nursing an infectious case, the nurse should pay scrupulous attention to necessary precautions and minimise her own risk of taking the disease, and that of other members of the family. She should not enter the sick-room until she has taken food, as she is more susceptible to infection when her stomach is empty. Should she cut herself accidentally, and notice any little wound or sore, she should cover it at once with adhesive plaster or a bandage. She should wash her mouth frequently with a suitable disinfectant, and try to avoid swallowing her own saliva. She should not lean over her patient more than it is absolutely necessary in nursing the disease. Every day she should take exercise in the open air, carefully changing her infected clothes for the purpose.

She should sleep for seven hours consecutively in every twenty-four, and this sleep must on no account be taken in the sick-room. The nurse must not take her meals in the sick-room, and any food that is discarded by the patient should be at once burned, as it would be a dangerous source of infection if eaten by others.

How to Nurse Sick Children. Children must always be watched carefully, because they cannot accurately describe a pain; and, in a child, a disease runs its course so rapidly that it becomes very important to detect its earliest stages. A child's body is more delicate than that of an adult, and disease quickly obtains a firm hold.

If the child seems cross and out of sorts, inclined to be fretful and peevish, in all probability there is something wrong with its health. These small beginnings of illness must be carefully noted and checked, if possible, as they may give rise to serious and dangerous results.

Points to Observe. The child who is sickening for a disease has often a capricious appetite, and its sleep is generally disturbed. Its position in bed should be carefully noted, as a premonitory warning of the presence of disease is given by unusual position. For example, lying with knees drawn up is a sure sign of abdominal trouble. The child instinctively knows that by drawing up its knees the pain is diminished, for the pressure on the abdominal organs is relieved by relaxation of the muscles. Again, earache or an incipient abscess may be indicated by the child pressing its head tightly to the pillow.

A dark shadow under the eyes and emaciation of the body are also unfavourable symptoms; the layer of subcutaneous adipose tissue which gives the rounded appearance to the limbs of a healthy child is quickly absorbed in the early stages of a disease: the child's skin becomes loose, wrinkled, and the muscles flabby.

Even a healthy child should not be allowed to sleep with its head under the bedclothes. The air in the bed is vitiated, and laden with particles from the skin and breath, and with carbon dioxide from the lungs. Moreover, this curled-up posture is very bad for the child's figure, and will undoubtedly result in round shoulders, and even curvature of the spine.

Much patience is needed in nursing a sick child. Its whims must only be gratified judiciously, and nothing is so bad as the method by which obedience is only obtained as the result of bribes. The conduct of the child when it is ill will differ but slightly from its normal behaviour when well. If it has been taught that obedience is necessary on all occasions, the chief difficulty in nursing will be obviated.

Nursing a Nervous Child. An excitable and nervous child must be treated with special care. A sudden fright or shock may result in complications of the disease. Many childish complaints are treated with a preliminary warm bath, but the hot steam arising from it is alarming to the little patient. In such a case, it is a good plan to spread an old blanket over the bath and lower the child on it into the water. The hot-water tap should never be allowed to run whilst the child is in the bath; many fatal accidents have resulted from the neglect of this simple precaution. The nurse should carefully ascertain that the water is at the required temperature by testing it beforehand with the thermometer. The hand is an unsafe guide; it is better to use the elbow if a thermometer cannot be procured. During the bath the attention of a nervous child can be distracted by some floating toy, a paper boat, or even a feather, or an imaginative nurse can delight her small patient with a fairy tale if her mind is not already overtaxed by her responsibility.

ENGRAVING IN MEZZOTINT & WOOD

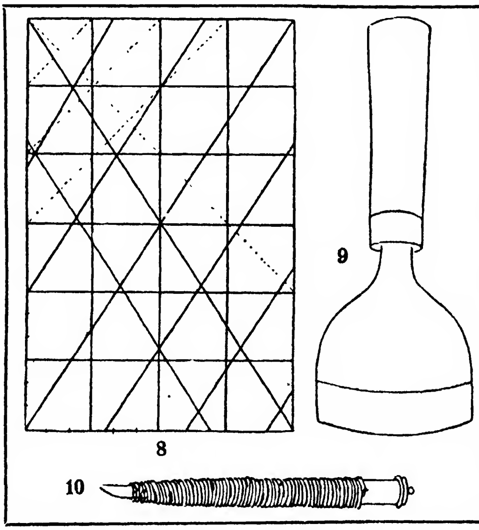
ENGRAVING continued from page 6111

The Most Popular Engraving Method. Mixed Mezzotint. Facing Copper-plates with Steel. The Schools of Wood-cutting and Wood-engraving

By EDWARD F. STRANGE

Of all the varying methods of engraving a metal plate, none is receiving more popular attention nowadays than the peculiarly British art of mezzotint—that is, so far as the productions of bygone engravers are concerned. The number of modern practitioners of the method is, however, small, and although some among them are no whit inferior in skill or taste to their predecessors, the vagaries of fashion are such that they receive but a paltry measure of support from their contemporaries. Their consolation is that they are undoubtedly working for the benefit of future generations.

This manner of engraving differs essentially from all others in that its practice entails the use neither of point of any kind nor of acid. The first essential is the laying of a ground; but this is, in itself, an integral portion of the actual graving to be done. Again, as with an aquatint, the need is to provide the whole surface of the plate with the means of retaining ink: but in this case it is done by roughening the plate with a tool. This is termed *rocking*. The tool used is of steel, somewhat resembling a broad chisel, but with its cutting edge shaped to the segment of a circle [9]. The outward face of this tool is regularly grooved to the extent, as a rule, of from 40 to 80 grooves to an inch. The curve is ground, from within, to an edge, which produces a point corresponding to each of the ridges between the grooves. It may be mounted with a short perpendicular handle, and so used, but for the preliminary laying of the ground, is better affixed at a right angle to a rocking pole, the opposite end of which is provided with a free slot travelling horizontally between guides fixed to a table.



MEZZOTINT ENGRAVING
8. "Ways" of rocking a mezzotint plat 9. Rocking T 10. Scraper

Rocking and Graving the Plate. The pole should be some 4 ft. long. The plate is held with one hand, while the tool is steadily and regularly rocked with the other, the motion causing it to pass in a straight line from one edge of the plate to the other, making a series of indentations as it goes, and at the same time ploughing up the copper to form a burr. In order to make sure that this roughening is equally distributed, the plate should first be marked out with guide lines for the rocker to follow, and these lines, termed *ways* [8], are arranged at various intervals and angles, by means of a scale. About 40 ways give a good ground, and continual re-sharpening of the tool is necessary during the operation. If the plate were now charged with ink and printed, the result would be a rich, velvety black of the finest quality attainable by any process of engraving.

The picture is produced by scraping away this ground with a broad-bladed double-edged scraper, terminating in a point [10]. It becomes necessary, however, at this stage, to bear well in mind what has been done to the plate. Highly magnified, the copper would present, in section, a series not only of elevations, but of depressions. The mere cutting away of the burr to the original level of the plate would produce, when printed, only a middle tint, as compared with the full depth of blackness given by the undisturbed ground. To obtain the highest lights, the hollows must also be cleared out, otherwise they would hold a considerable quantity of ink and print effectively. Between these two extremes of untouched burr and cleaned out indentations lie the possibilities of obtaining every shade and delicacy of tone in the whole gamut of monochrome.

The Charm of the Mezzotint. It will have been gathered from this description that line does not exist in pure mezzotint. Herein is one of the great difficulties of the art—that of obtaining adequate definition of form. At the same time, the universal softness necessitated by the process constitutes perhaps one of its most alluring charms.

It is usual in practice to transfer the outlines of the picture to be engraved by means of gelatine after the ground is laid. The work then proceeds from dark to light—care being taken to remove the ground gradually—keeping, so to speak, on the safe side until success is assured. The ink used is much the same as that used for an etching or aquatint. It must be thoroughly worked into the whole of the plate, and the superfluous ink then wiped off, particular attention being paid to the clearing of the high lights.

From the time of its invention, by Ludwig von Siegen (whose first plate was made in August, 1642), until the early part of the nineteenth century copper alone was used for mezzotint engraving. In 1820, W. Say produced a portrait of Queen Caroline, engraved on steel, and in 1822 the use of this material was perfected by T. Lupton, and for some time it had a considerable vogue.

But it was never quite satisfactory. The burr was slighter, the indentations shallower, and it was much more laborious to work; while the dead black ink and white paper used, lent themselves only to a limited range of effects, seen at their best in the engravings of David Lucas, after Constable. Moreover, the number of possible impressions was soon found to be little more than could be procured from copper, and since the modern process of steeling plates has been perfected there remains no good reason for the use of steel.

Combinations with Pure Mezzotint. So far we have treated only of pure mezzotint—that is, this method used by itself in the engraving of a plate. But the labour involved therein was so great that the process had hardly attained its full development before other methods began to be used in combination with it, for the purpose, not only of saving trouble, but of avoiding the difficulty of defining outlines already alluded to. R. Earlom was one of the first artists to give attention to this endeavour; he frequently employed stipple etching, both as a groundwork and in order to elaborate his detail. In the "Liber Studiorum" (1807-1819) J. M. W. Turner employed generally a combination of etching and mezzotint, using the first process to bite in the strong lines of his composition before handing over the plates to be completed by mezzotint engravers. In the hands of Samuel Cousins, what is called mixed mezzotint was pushed to its utmost limits. He and his contemporaries made use of a heavy roulette as well as of special rocking tools, to work up the steel, and also used stipple etching and even aquatint. But these practices do not add to the real artistic merit of an engraving, and it is significant that they were but the prelude to an almost complete decay of the art. In our own day the art of pure mezzotint is experiencing a certain revival. The student should study the works of Valentine Green [11], J. R. Smith, J. and W. Ward, and J. MacArdell.

11. GEORGIANA, DUCHESS OF WESTMINSTER
From a mezzotint by V. Green after Sir Joshua Reynolds, 1780

Steel-facing. The printing powers of etched or mezzotinted copper-plates are very limited. The former class may produce 200 or 300 good impressions, but the latter (and the same applies to drypoint) cannot be relied upon to give more than from 30 to 100 prints of the best quality, owing to the rapid wearing away of the soft metal in the press. An attempt was made, as we have seen, to overcome this difficulty by the substitution of steel for copper, but without success. During the last two decades science has come to the rescue, and has provided a means whereby the actual engraving having been done upon copper, and full advantage taken of its unrivalled adaptability to this purpose, it may be invested with the durability of steel. The following concise description of the process (by Mr. Frank Short, A.R.A.) is taken from a pamphlet published by the Board of Education for use in connection with the Victoria and Albert Museum, and may be accepted as authoritative:

"Copper-plates when ready for printing are often covered with an exceedingly thin facing of steel (or iron) by suspending them in an iron solution and passing an electric current through it. The copper is covered, almost instantaneously, with a coating of hard, bright iron. From three to twenty minutes may be needed to obtain a sufficient thickness of iron, according to the plate and the current employed. Many solutions containing iron may be used, but the simplest method is to fill the tank with water, in each gallon of which is dissolved 1 lb. of sal ammoniac. A large iron or steel plate (the anode) is then placed permanently in it and attached to the positive pole of a battery (or other electric current), and a small piece of steel (generally an old file) is temporarily suspended opposite to it attached to the negative pole, until the bath becomes sufficiently full of iron to cause a deposit on a copper-plate when placed in it.

"The plate to be steel-faced is suspended by a strip of copper, soldered temporarily to the back, which serves both as a support to the plate and to complete the circuit of the electric current by contact with a brass rod connected to the negative pole of the battery. The quantity of current passing must be proportionate to the surface of the plate to be steel-faced, and its intensity may vary from 1½ volts to 6 volts. It is essential that the copper should be chemically clean before it is put in the bath, and it is necessary to remove it from the bath every few minutes to wash and gently polish the surface with a paste of fine whiting and water applied with a flannel, in order to keep the coating clear and bright.

"The steel-facing can be easily removed when desired by placing the plate in a mixture of nitric acid and water (1 acid to 7 water), which instantly dissolves the steel, leaving the copper untouched."

A good many wild statements have been made as to the effect of this process, and these need to be corrected. In the first place, it not only does not result in any loss of quality in the print, but it is impossible for the most accomplished expert to decide, from an inspection of proofs, whether they have been taken before or after the plate was steel-faced. Secondly, it does not prolong the life of the

12. CHRIST BEFORE HEROD
Woodcut by A. Durer, 1509

plate to the exent that has been claimed. It only makes it possible to produce some few hundred impressions—not thousands—of the best kind.

Wood Engraving. The old and beautiful art which made use of wood as a material for the printing of the artist's design has almost vanished under the stress of the competition set up by modern photographic processes. But it is so simple, and capable of effects so fine and characteristic, that many hope for its revival.

At the outset we have to indicate an essential difference between the wood block and that made of metal. In the former the printing is done by the upper surface of the block, exactly as with type. The process is, in fact, *relief printing*, as opposed to the *intaglio printing* of the metal plate, in which the paper is forced by great pressure into hollows excavated in the metal. As a consequence, wood blocks can be inserted in type without difficulty, and the paper shows no sign of that depression which is known as the plate-mark.

The Dürer Wood-cutting School. There are two methods of using wood for engraving. That employed by the great school of Albert Durer [12], and for many years afterwards, was executed upon blocks cut plankwise—that is, parallel with the grain. A wood of comparative softness, such as that of the pear-tree, was chosen. The drawing having been made or traced upon the smooth surface, the lines thereof were outlined with a knife, and the superfluous wood cut away with convenient tools, so as to leave the design intact. To this method it has been found convenient to restrict the term "wood-cutting." It is, in all essentials, that employed by the Japanese in their exquisite colour prints, and by many modern artists.

The Bewick Wood-engraving School. At the end of the eighteenth century it was found that boxwood, from its extreme hardness and closeness of grain, was especially suitable for a use to which the term "wood-engraving" is well applied [13]. The blocks were cut, not with the grain, but across it. The drawing was made upon the block, on a surface prepared for the purpose with Chinese white, and the engraving executed with burins of several sizes, practically the same as those employed by the line engraver on metal. It will be evident that the driving of the burin through the wood produces a white line, the ink being held by those portions of the block untouched by the tool; and this fact was made use of by Bewick and the best of the nineteenth century wood-engravers to produce their effects. Prints by these artists will be seen, on close examination, to consist of a series of white lines or dots, each made with deliberate purpose of expressing drawing. But the burin was also used for facsimile engraving, with a result similar to that of the knife, developing in this respect into a laborious reproduction of the exact lines of the artist's work, as compared with the individual translation of it secured by the white-line method.

The student should refer to the work of Bewick as exemplifying the latter; that of Charles Keene in "Punch" is an admirable exposition of the former. Millais and Keene, indeed, largely used the free line, but most of the other artists of that splendid epoch of book illustration made their drawings in wash or closely stippled pen drawing, leaving to the engraver a considerable latitude in the interpretation of tone. This he did by "cross-hatching"—picking out the spaces between the inter-sections of crossed lines; and to the general adoption of this mechanical device much of the inferiority of modern work is due.

CORLISS AND MARINE ENGINES

Corliss Valves. Examples of Engines. Cylinders. Marine Engines. Examples. Details. Leading Dimensions

By JOSEPH G. HORNER

CORLISS engines, deriving their name from that of the American, George H. Corliss, their inventor, have been modified in many ways by engineers in England and on the Continent. Their valves were a great advance on the old slide valves when engines of large dimensions were concerned, and have enjoyed an immense amount of success. But it is at least doubtful if they will not in time be superseded by the engines with drop valves and with piston valves. The general outlines of a Corliss engine are seen in **58**, which shows a pair of compound horizontal mill engines, of 1,800 indicated horse-power, by Wood Bros., of Sowerby Bridge. The engines are used for mill driving, the fly-wheel being grooved for cotton ropes, sets of which drive to different rooms in the factory.

The special feature of the Corliss engines is the shape and disposition of the valves. They are long valves, cylindrical in section where they fit their seatings, and their motion is only that of partial rotation. Figures **59** and **60** show the steam and exhaust valves respectively for **58.** They admit steam through passages nearly as long as the diameter of the cylinder. The passages for steam and for exhaust are distinct and separate, one for steam, and one for exhaust, at each end of the cylinder.

The details of operation, however varied, have two features in common: either a *wrist plate,* or its equivalent in lever arrangements, with dash pots, and pistons, or springs. The first imparts the partial rotary movement to the valves: the second close the valves sharply immediately following release, by detents.

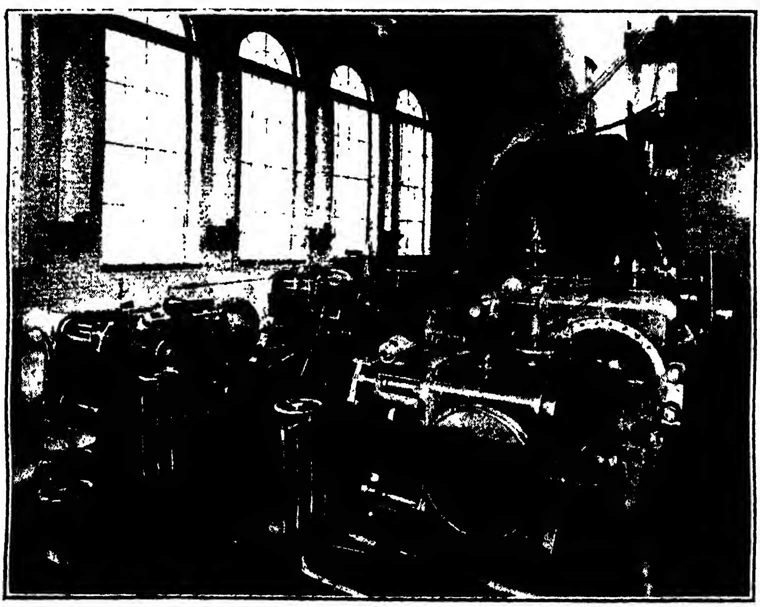
The gradual opening and closing of the common slide valve is not an ideal arrangement. The rapid and full opening to steam and to exhaust, and sharp closing of the same in the Corliss valves are more economical, preventing both excessive wire drawing and back pressure, and avoiding excessive clearance. The valves are simpler than balanced slide valves are, and work with less absorption of energy.

Robey Engine. Figure **61** illustrates a Corliss engine by Robey & Co., Ltd., in external elevation and plan, from which a good idea can be gathered of the design which is most commonly adopted—that of a wrist plate.

The valve gear is worked primarily from the eccentric A. Its rod oscillates a lever B, which is pivoted at *a*, so imparting a to-and-fro movement to the rod above, which rocks the wrist plate thus through an arc of a circle on its pin. Pivoted to this plate with pins are levers EE, which actuate the steam supply valves, and the levers FF that operate the exhaust valves. The valve stems of the steam valves are seen at *cc*, in the plan view, within their bonnets. The function of the wrist plate is to impart a fixed amount of movement to the valve spindles. But this movement is arrested, or *tripped*, at a certain stage, corresponding with the moment of cut-off, at which instant the steam valves are sharply closed by a piston in the dash pot G. The governor J acts on the steam valves through the rod K. The trip levers *dd* effect the connection of the valves by the notch in *d* fitting over the catch *e*, and the release by the arm of the lever coming in contact with the projection *f*.

The designing of the details of Corliss valve gears involves much graphic construction, supplemented by trials. The different types are known by different names, besides which manufacturers have introduced many minor alterations.

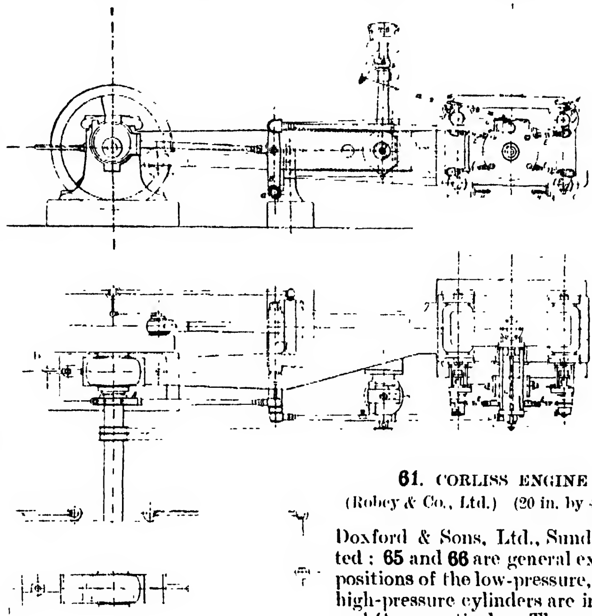
Cylinders. Figure **62** shows the cylinder of the Robey engine in longitudinal and transverse sections, which is an excellent illustration of the way in which a large cylinder is built up. AA and BB are the seatings for the steam and exhaust valves. The cylinder is built up of the plain body C, the ends DD containing the seatings, and fitting to the body with flanges, E is the back cover, and



58. COMPOUND CORLISS CONDENSING ENGINES—1800 H.P. (Wood Bros.)

F the hard liner, between which and the body is the jacketed space. The bore is 20 in., and the distance between covers 4 ft. 11¾ in., the stroke of the engine being 40 in.

Another cylinder is shown in **63** by the firm of H. Bollinckx, of Brussels, who make a speciality of these engines. The steam and exhaust seatings are cast partly in the end covers A, B, and partly in the jacket C at one end, and partly in the body D at the other end. The fitting of the body and jacket will be noted. At the end *a* there is a rigid connection between the two by a flange and bolts at the other end, *b*, the parts are free to slide under varying expansions with differences of temperature. The end covers are jacketed connections being made as seen between the covers and the body jacket.



61. CORLISS ENGINE
(Robey & Co., Ltd.) (20 in. by 40 in.)

Fleming Engine. A special type of Fleming Corliss engine by the Harrisburg Co. is shown in longitudinal section in **64**. It embodies a departure from long-established practice. Hitherto, Corliss engines have mostly been of long-stroke design. This is of short-stroke type, following in this respect designs of vertical high-speed engines.

The engine is a tandem compound, and both cylinders are fitted with Corliss valves. Two eccentrics are provided. One actuates the two steam admission valves, the other the two exhaust valves. The motion of the valves is transmitted through bell cranks and independent rocker arms. The bell cranks are coupled together with adjustable links. To the short arms of the bell cranks a link is attached, which transmits their movements to a valve arm secured to the projecting valve and stem (not indicated). The effect is that the valves have an accelerated rate of movement at the points of opening and closure. The exhaust valve arms are connected with a common link.

Marine Engines. The term *marine engine* is too vague to convey much beyond a general idea of the type. It is now used always in the case of ocean-going steamers to denote the inverted cylinder type. But the compound engines of a yacht have little more than this in common with the engines of a liner or a battleship.

A triple expansion marine engine by the Pallion Engine Works of Wm. Doxford & Sons, Ltd., Sunderland, is illustrated: **65** and **66** are general external views. The positions of the low-pressure, intermediate, and high-pressure cylinders are indicated by A, B, and C, respectively. They are carried on cast-iron frames DDD, which are supported by the base plate E. The frames D have slipper faces formed for the crossheads F, whence the connecting rods G drive to the crank shaft H, which has its bearings in the base plate E. The eccentric rods J, K, L actuate the valves for the low, intermediate, and high pressure cylinders respectively. The first two are double-ported slide valves. The last is a piston valve. The rods and eccentrics are duplicated for reversals for driving ahead or astern. The shifting links are indicated at M, the drag links at N, and the weigh shaft at O. The mass of these is so great that a simple hand lever would be useless. A hand wheel P and worm gear Q therefore operate the weigh shaft through the rod R and its lever.

The surface condenser S is built into the standard framings, with economy of space. The air and circulating pumps indicated at T are bolted to it, and their piston rods are actuated by the connecting rods U and levers V from the crosshead of the low-pressure cylinder by the pin W and connections XX: at Y is seen the turning gear for giving the engines initial movement. At Z is a starting engine, driving to a crank for effecting reversal for ahead and astern movements, and being

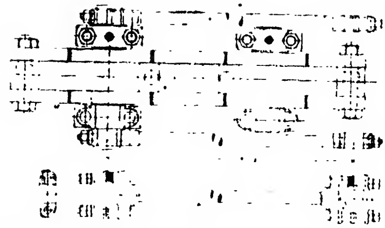
69. ECCENTRIC ROD AND LINK OF MARINE ENGINE



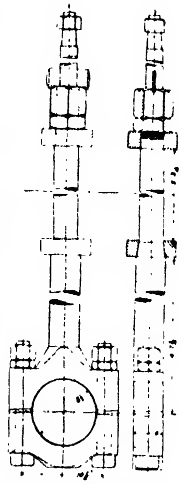
70. REVERSING LINKS OF MARINE ENGINE

auxiliary to the hand gear P, Q, R. The numerous small handles and levers are for passing live steam into the cylinders to warm them up, and for operating drain cocks, etc. These are usually located close to the reversing hand wheel and engine. From this general description we may pass to consider some of the principal details, which, however, can be only partially illustrated in a portion of an article, owing to the enormous amount of items in such an engine.

Details. The three cylinders are cast separately, and bolted together by flanges. They measure respectively 27½ in., 45½in., and 75 in. in diameter, and the piston stroke is 4 ft. 6 in. The high-pressure only is fitted with a liner. The casing for the piston valve is cast with this cylinder. The valve chests for the double-ported valves of the intermediate and low-pressure cylinders are formed in their castings. Feet are cast on each cylinder for bolting it to its A standards. The exhaust pipe, AA, to the condenser is bolted to the low-pressure cylinder. In these large engines the valves, pistons and covers are massive ribbed castings, very different from those in the smaller engines we have hitherto illustrated. Figure **67** shows the piston and cover of the low pressure cylinder. Covers and pistons are hollow, to ensure rigidity and strength without excessive weight, for the pressure on pistons and covers amounts to many tons. Junk rings and spring rings are fitted to the pistons. Lifting screws are fitted to enable the crane to lift covers and rings out for examination and repairs.

The piston rods [**68**] measure 7½ in. diameter, and the crossheads are 2 ft. 4 in. in length, by 1 ft. 5 in. in width. White metal facings are used. Details of the valve gears are shown in **69** to **71**. In **69** M is the link, similarly lettered in **65** and **66**: A is the sliding block which is embraced by the end of the valve rod [**71**]: J, K, L are the eccentric rods; NN the drag or reversing links; compare with **65** and **66**.

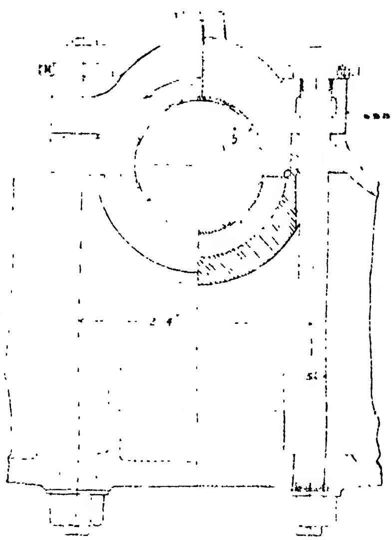
The enormous dead weight of the reciprocating masses is largely counterbalanced by the three-cylinder arrangement, in which the cranks are set 120° apart. The crank shaft, which is 1 ft. 3 in. in diameter, is built up in the manner shown in **73**. Lengths of shaft with flanges are coupled and bolted as seen in the detail at A. The crank webs, B, are fitted over the opposite ends, and over the crank pins. These are shrunk fits in the first place—that is, the parts are turned and bored with a slight excess in size of the turned portion, and the webs are then warmed, slipped over, and tighten in cooling. Turned keys are afterwards inserted to prevent possible loosening in working.



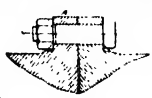
71. VALVE ROD OF MARINE ENGINE

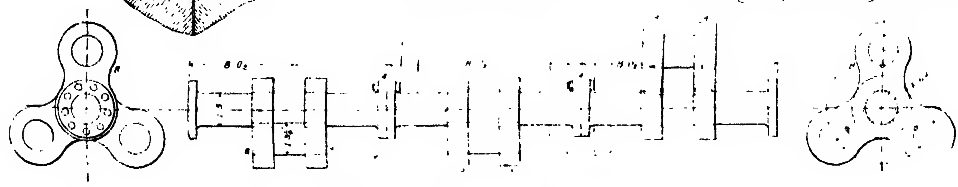
The frames or columns DD [**65**] are massive hollow castings, though having a quite solid appearance from the outside. Suitable facings are provided on them for the reception of the cylinders, and feet for the bedplate, and manholes. The bedplate, or soleplate, E, is a hollow casting in one piece, and having the shaft bearings, six in number, cast with it, shown in detail in **72**, to receive the frames.

The condenser, S [**65** and **66**], is shown separately in **74** along with the columns with which it is cast. The circulating tubes are inserted by ferruling into the tube plates bolted within the main casting. The distance between the tube plates is 14 ft. There are 1,868 tubes, ¾ in. diameter outside, giving a cooling surface of

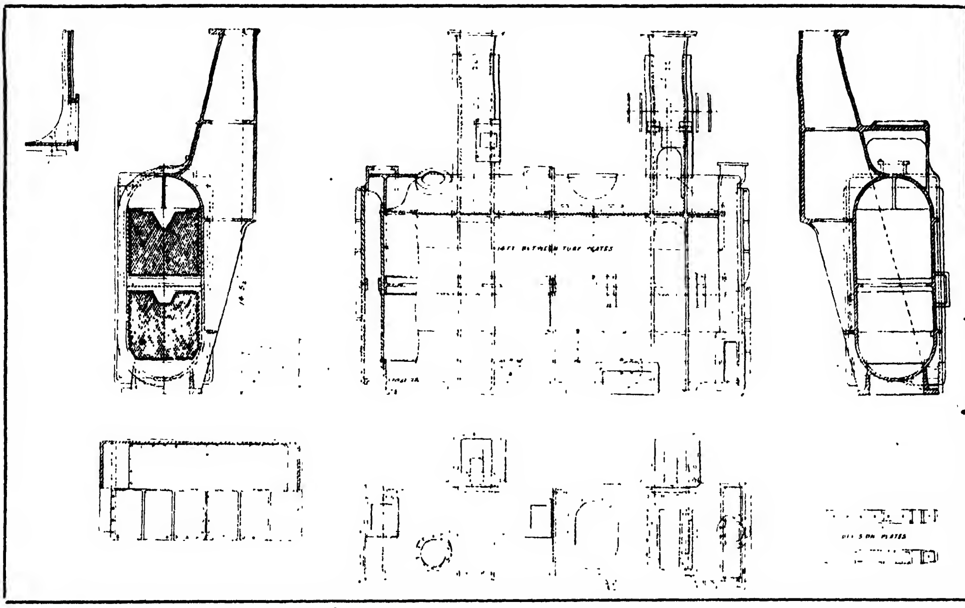


72. MAIN BEARING IN SOLEPLATE OF MARINE ENGINE





73. THREE-THROW CRANK OF MARINE ENGINE



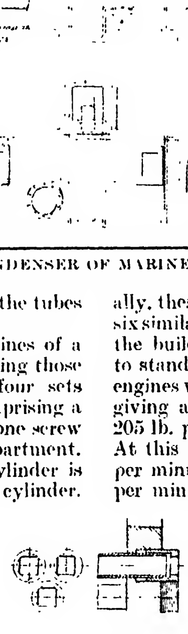
74. CONDENSER OF MARINE ENGINE

5,754 square ft. The method of fastening the tubes is shown in 75.

Examples of Engines. The engines of a big liner are of immense proportions. Taking those of the Kaiser Wilhelm II., there are four sets of these, each complete in itself, each comprising a quadruple expansion set. Two sets drive one screw shaft. Each set is fitted in a watertight compartment. A peculiarity is that the high-pressure cylinder is placed tandem above the intermediate cylinder. The diameters are as follows: High-pressure, 950 mm. (37·40 in.); first intermediate 1,250 mm. (49·21 in.); second intermediate 1,900 mm. (74·80 in.); low-pressure 2,850 mm. (112·21 in.). The common stroke is 1,800 mm. (70·86 in.). The ratio of cylinders is 1, 1·73, 4·9. Each engine set has its own condenser, with 11,733 square ft. of cooling surface, twin air pump, circulating pump, feed pump, and feed heaters and various pumps. So immense is the installation that the steam cylinders in the vessel total to about 140.

Engines of Battleships. The engines of the Japanese battleship Katori, built and engined by Messrs. Vickers, Sons & Maxim, Ltd., consist of four cylinder triple expansion engines, of which there are two sets. Each set has one high-pressure cylinder, 35 in. in diameter, one intermediate of 56 in., and two low-pressure cylinders, each of 63 in. diameter, with a 48-in. stroke. The engines work at 200 lb. initial pressure, the boiler pressure being 230 lb. The valves on the high-pressure and intermediate cylinders are of piston type, those on the low-pressure are double-ported flat valves. The condenser has a total cooling surface of 17,000 square ft.

The following relates to the engines of the armoured cruiser Duke of Edinburgh. Incidentally, these are of interest because these, with those of six similar cruisers of which the Admiralty sanctioned the building, have their six sets of engines made to standardised gauges, templets, and jigs. These engines were designed to develop 23,500-horse power, giving a speed of 22·33 knots. Steam is used at 205 lb. pressure when at the main regulating valve. At this pressure the engines make 135 revolutions per minute, equivalent to a piston speed of 945 ft. per minute. The cylinders are ranged thus: The high-pressure has one low-pressure adjacent. On the other side is the intermediate pressure cylinder, and beyond that the second low-pressure cylinder. These four cylinders constitute a set, and two such sets are placed in separate watertight compartments on opposite sides of the vessel. The diameter of the high-pressure cylinder is 43½ in., that of the intermediate 69 in., and the two low-pressure cylinders are 77 in. in diameter. The stroke is 42 in. To facilitate balancing, the combined horse-power of the two low-pressure cylinders is equal to that of the high-pressure, and of the intermediate pressure cylinder separately. In these engines all the cylinders are steam jacketed. The liners for the high-pressure and intermediate are of forged steel, but those for the low-pressure cylinders are of cast iron. Cast steel is used for pistons, and cylinder covers. The high-pressure cylinder is fitted with one piston valve, the intermediate cylinders with two. Flat slide valves are used for the low-pressure cylinders with relief wings at the back. Starting valves are provided to admit steam directly to the intermediate and low-pressure cylinders. The condensers serve for the main and auxiliary engines. There are two in each engine-room, each with a cooling surface of 7,009 square ft



75. FASTENING OF CONDENSER TUBES

Continued

SHORT DICTIONARY OF PRIME MOVERS & STEAM BOILERS

ACTUAL HORSE-POWER—Horse-power obtained by the indicator, minus the power absorbed by the engine friction.

Adhesion—Specifically, the measure of the weight resting on the wheels of locomotives.

Air Pump—A pump employed in all condensing engines for removing the mixed air and water from the condenser.

Asbestos—A fibrous mineral, which, owing to its heat-resisting character, is prepared for use in engine packings and joints.

Atmospheric Engine—An early type, in which the pressure of the air moved the piston downwards against a partial vacuum.

Atmospheric Line—The line on an indicator diagram which divides the steam area from that of vacuum.

BACK PRESSURE—Pressure opposed to the movement of the piston in a cylinder, due to steam not wholly exhausted.

Balloon Boiler, or Haystack Boiler—An obsolete form, of a dome shape, externally fired.

Barring Engine—A small engine used for starting a very large engine.

Beam Engine—A vertical engine having the piston-rod operating one end of a pivoted beam, and the connecting rod at the other.

Bed Plate—The base, usually a casting, which carries all the mechanism of an engine.

Blast Pipe—In a loco. boiler, the pipe through which the steam exhausts into the chimney, so creating a sharp draught in the fire-box.

Blow-off—The periodical discharge of steam, water, and sediment from a boiler.

Boilers—The steam generators for engines. Internal combustion engines require no boilers.

Brake Horse-power—Horse-power as measured by a friction brake.

CALORIE—The French unit of heat, or that which will raise 1 kilo. of water through 1° C. between the temperatures of 0° C. and 1° C.

Carnot's Principle—Postulates the law that the work done by a heat engine is wholly a question of temperature.

Central Valve Engine—An engine in which the distribution of steam is effected by openings in the piston-rods.

Cheval-Vapeur—French horse-power, or 4,500 kilogrammes lifted 1 metre high per minute, equals 0·9863 English horse-power.

Chimney—The function of a chimney is to produce a draught in the furnaces and flues of a boiler. It acts by virtue of the difference in the specific gravities of the hot air within and the cold air without.

Circulating Pump—A pump which forces the cooling water through the tubes of surface condensers.

Clark's Process—The best known process for softening the feed-water for boilers by the addition of lime thereto.

Clearance—The space left between the face of a piston at the termination of its stroke and the inner face of the cover, to prevent actual contact. Freedom to exhaust in an engine cylinder.

Clinkering—Cleaning the grate bars of boilers periodically.

Closed Ashpit—Signifies that the ashpit alone receives air under pressure.

Closed Stokehold—The stokehold enclosing the boiler front of a marine engine which receives the supplies of air through fans only.

Cold-water Test—The hydraulic pressure test applied to steam boilers with cold water.

Compound Engine—An engine having two or more cylinders in which steam works expansively in succession.

Condenser—The vessel in which the exhaust steam from an engine or engines is condensed to water.

Condensing Engine—One in which the exhaust steam goes into a condenser instead of into the atmosphere.

Connecting Rod—The rod which connects the piston and its cross head to the crank of the flywheel shaft.

Corliss Engine—One in which separate valves are used for the entering and exhausting steam.

Cornish Boiler—A horizontal boiler with a single furnace flue.

Cornish Engine—A special type of beam engine, used first in the Cornish mines.

Corrugated Furnace—A type of boiler furnace which is stiffened against collapse by alternating ridges and depressions.

Crank-pin—The pivot on which the free end of the connecting rod takes its bearing, being the end opposite to the crank shaft.

Cushioning—The elastic counter-pressure against a piston, bringing it to rest by the steam admitted through the opening to lead.

Cut-Off—Arresting the supply of steam to the interior of a cylinder.

Cut-off Valve—A supplementary slide valve on the back of a main valve for working steam at high expansion.

Cylinder—Specifically the vessel in which the movements of an engine piston are coerced.

DAMPERS—Sliding, or swivelling plates which regulate the draught through boiler flues.

Dead Centres—When the axis of the piston-rod, the crank-pin, and the crank-shaft are in one plane the engine is on dead centres.

Dead-weight Safety Valve—One in which the loading is done directly by the imposition of annular weights.

Double Acting—Expresses the case of pistons which are subjected to pressure on opposite sides alternately.

Dry Steam—Steam which is only saturated with moisture by contact with the water from which it is generated.

Duty—The duty of an engine is the number of foot pounds obtained by the burning of a bushel of good coal. The term is nearly obsolete.

D-valve—The form of slide valve which has a section nearly like that of the letter **D**.

Dynamometer—A mechanism by which the power given off or absorbed by a prime mover or machine is measured.

ECCENTRIC—The agent by which the rotary motion of the crank is converted into the reciprocating movement of the slide valve.

Eccentric Sheave—The body of an eccentric, keyed on the crank-shaft.

Eccentric Straps—The bands which encircle the sheave, and transmit its motion to the eccentric rods and slide valve.

Economiser—A nest of pipes in which the feed-water for boilers is heated by the waste gases from the boiler.

Elastic Force—The expansive, or heat energy of a gas.

Enclosed-type Engine—Stationary engines having the working parts wholly enclosed, and running in an oil bath.

Evaporative Power—It is usual to estimate the value of different fuels by the relative quantities of water which they will evaporate.

Exhaust Steam—The waste steam from an engine cylinder.

Expansive Working—A definite volume of steam or gas doing work on a piston by the force of its own expansion.

External Firing—The application of heat outside a boiler shell. Now obsolete.

FEED PUMP—The pump which supplies feed-water to boilers.

Feed-water Heater—A type of economiser in which the feed is heated before being passed into the boiler.

Ferrules—Rings used for fastening the tubes of boilers and condensers into their plates.

Final Pressure—The pressure of steam in a cylinder in the last stage of its expansion.

Fire-bars—The grate bars in a boiler furnace.

Fire-box—The furnace of a locomotive or a vertical boiler.

Forced Draught—Air for combustion in steam boilers which is introduced under pressure by fans.

Furnace Flues—The furnaces of horizontal boilers, placed within the shell.

Fusible Plug—A plug of easily fusible alloy, inserted in the top of a boiler furnace, which melts and lets the water out if the water runs dangerously low.

GAS ENGINE—Any engine using gas, which may be town, or producer, or blast-furnace gas.

Gaskets—Packings of hemp rope used in stuffing boxes.

Gauges—Instruments for indicating pressure of steam, and vacuum, and water levels.

Governor—A device which automatically reduces variations in speeds of prime movers.

Grate Area—The superficial area of the fire-grate of a boiler.

Guides—Flat bars, or cylindrical tubes by which the movements of the crosshead are coerced.

HEAT ENGINE—Any prime mover which is actuated by heat contained in a gaseous fluid.

Heating Surface—The area of a steam boiler which is exposed to flame and hot gases on one side and water on the other.

High-pressure Engine—Any engine which uses steam at a pressure higher than the ordinary at a given period. The high pressures of a few years ago would not be classed as such now.

High-speed Engine—One which has a high rotative or a high piston speed in comparison with ordinary engines. The term is therefore relative.

Horse-power, or H.P.—33,000 lb. lifted 1 ft. high per minute.

Hot-air Engine—One in which atmospheric air is used, which is alternately heated and cooled.

Hot-water Test—The hydraulic pressure test applied with hot water to steam boilers.

Hydraulic Engine—One, the motive-power of which is water under high pressure.

INDICATED HORSE-POWER, or I.H.P.—The horse-power of an engine obtained by an indicator.

Indicator—An instrument for recording on a card the varying pressures of steam in a cylinder.

Indicator Diagram—The diagram traced by an indicator.

Induced Draught—Boiler draught induced by a fan placed in or near the chimney in the course of the flues.

Induction Port—The opening of the passage through which steam is admitted to a cylinder.

Ignition—The act of firing the charge in the cylinder of a gas engine.

Injector—A device for supplying feed-water to a boiler.

Internally Fired Boiler—One which has its furnace within the shell or water casing.

JACKETING—Surrounding an engine cylinder with a chamber supplied with steam.

LANCASHIRE BOILER—A two-flued horizontal land boiler.

Lap—The distance by which the edges of a slide valve when in middle travel overlaps the induction ports.

Latent Heat—The heat which disappears during the vaporisation or the fusion of a substance, without raising the temperature.

Lead—The distance by which the edge of a slide valve opens the exhaust port at the termination of the piston stroke.

Liner—The lining tube of hard metal fitted within many engine cylinders.

Link Motion—The arrangements of slot link, eccentrics, and rods used for actuating the movements of slide valves.

Live Steam—Steam as it comes from the boiler.

Lubricators—Vessels which contain liquid or solid lubricants for the supply of bearings.

MAIN BEARINGS—The bearings of the crank shafts of engines.

Mean Pressure—The average of the entire range of steam pressures in a cylinder from the moment of inlet to that of final exhaust.

Metallic Packings—The steam-tight joints made in stuffing boxes with elastic rings of metal.

NEWCOMEN'S ENGINE—The pattern on which the early steam engines were built. It was operated by atmospheric pressure.

Nominal Horse-power (N.H.P.)—A commercial term, a survival of an early practice, of little value under changed conditions.

Notching-up—In link motions, pulling the link nearer to the centre, with resulting earlier cut-off and higher expansion.

OSCILLATING ENGINE—A nearly obsolete type, in which the oscillation of the cylinder was made to operate the slide valves.

PACKINGS—Materials used in stuffing boxes for rendering piston and valve rods steam-tight in their holes.

Piston Speed—The speed of movement of a piston measured in feet per minute.

Piston Valve—A sliding valve which is of cylindrical section.

Prime Mover—A machine which utilises the forces of Nature for the service of man.

Priming—The mixing of particles of water with steam.

Producer Gas—Gaseous fuel generated by the combustion of solid fuel in gas producers of various kinds.

QUADRUPLE EXPANSION ENGINE—One in which the steam is expanded through four successive cylinders before exhausting to the condenser.

RECEIVER—The steam chest, pipe, or special vessel through which steam passes from one cylinder to the next in compound engines.

Return Tube Boiler—The marine, or Scotch boiler, in which the smoke tubes return over the top of the furnace to the front of the boiler.

Reversing Rolling Mill-engine—A special design used for rolling steel plates and sections, the direction of movement being reversed between each pass.

Right-hand Engine—One in which the flywheel stands to the right, when viewed from the front of the engine.

SAFETY VALVE—A valve on a boiler which opens when a definite steam pressure is exceeded, so relieving the steam pressure.

Saturated Steam—Steam in contact with water of the same temperature.

Scale—Deposit which hardens on the water side of the plates of steam boilers.

Setting of Boilers—Fixing land boilers over their flues, and seatings of brickwork.

Slide Valves—Valves occurring in numerous forms, the function of which is to control the supplies of steam to cylinders, as distinguished from lift or drop valves and rotating valves.

Slipper—Slipper bars are guide bars; a slipper block is a piston crosshead.

Slot Link—The link through which variable expansion, and reversals are effected.

Smoke—Particles of solid carbon suspended in unburnt gases, and vapour of water. Its proper combustion is the object of many devices in boiler engineering.

Soda—Used for preventing scale in boilers.

Split Draught—The arrangement of flues in Lancashire boilers in which the products of combustion are divided at the back, and pass round to right and left.

Stationary Engine—One fastened to foundations.

Steam—The vapour of water, which, by virtue of its elastic energy, communicates motion to a piston or rotor.

Steam Chest—*see valve chest.*

Superheated Steam—Steam made hotter than the temperature at which it is generated.

Surface Condenser—One fitted with tubes in the steam space, and through which the cold water circulates. It differs in this respect from the jet condenser, which receives one jet of water.

TAIL ROD—A rod in continuation of a piston, or valve rod, but on the opposite side. Its function is to steady the movements of the piston, or valve.

Tandem Engine—A compound engine, the cylinders of which are in the same longitudinal axis.

Thermal Unit—The amount of heat required to raise 1 lb. of water 1° F. is the British Thermal unit, and is equivalent to 772 foot-pounds.

Three-cylinder Engine—Specifically an engine in which the cylinders are arranged round a circle, with their axes 120° apart.

Throttle Valve—A valve which opens and closes the supply of steam from a boiler to an engine.

Throw—Twice the radius of an eccentric or a crank.

Tractive Force—The power exercised by the pistons and driving wheels of a locomotive to move a train.

Travel—The length of movement of a piston or a valve.

Triple-expansion Engine—One in which the steam is expanded from one high-pressure into two low-pressure cylinders in succession.

Trip Lever—A lever which lifts drop valves through a certain distance, and then allows them to close sharply.

Try Cocks—The steam and water-cocks on a boiler which indicate the highest and lowest water level allowable.

Tube Expander—An appliance used for tightening the fire-tubes in multitubular boilers.

Tubes—Tubes of brass, steel, iron, or copper are used in boilers to convey the heat from the fire-box through the water to the smoke-box.

Tube Surface—The total area of the exterior surfaces of condenser tubes.

Tubular Boiler—Any boiler provided with nests of tubes to increase the heating surface.

UNDERTYPE ENGINE—A fixed engine with a locomotive type of boiler, in which the engine is fixed beneath the boiler.

Unit—A standard for calculations—as the unit of heat, of work, of mass, of strength, or of stress.

VACUUM—The amount by which the pressure of a condenser is below that of the atmosphere. It is measured in pounds, or in inches of mercury.

Valve—The agent by which the opening of steam and exhaust passages is controlled. It may be a slide valve, flat, or of piston type, or a drop, or a partly rotating valve. Or a main, or a cut-off valve.

Valve Chest or Steam Chest—The casing which encloses a slide valve.

Valve Diagrams—Diagrams made to show graphically the cycle of action of valves.

Valve Setting—Adjusting valves in relation to the crankpin and the eccentric sheave.

Variable Expansion—The expansion of steam in a cylinder caused by alterations in the opening of the throttle, or in the point of cut-off of the valves.

Varying Travel—The travel of a slide valve which is varied momentarily by expansion gear, instead of being constant by a fixed eccentric only.

Vertical Boiler—A cylindrical boiler having its axis set vertically.

Vertical Engine—An engine having the axis of its cylinder set vertically.

WAGGON BOILER—An obsolete form, deriving its name from its cross section. It was externally fired.

Wall Engine—A steam engine, the bed-plate of which is bolted to a factory wall, the axis of the engine being vertical.

Waste Heat—Residual heat from furnaces which, formerly lost, is now frequently utilised in warming feed water, or brickwork, or air and gas.

Water Pressure Engines—Engines of rotary or reciprocating types which are operated by water under pressure.

Water-tube Boiler—A steam boiler in which the fire plays around nests of small water-tubes variously arranged.

Weight Shaft—The shaft which carries the lever for lifting and lowering the slot links of valve gears.

Wheel Draught—The arrangement of flues in Lancashire boilers, in which the products of combustion pass round the boiler in one direction.

Winding Engine—A hoisting engine designed specially for hauling mine waggons up inclines.

Windmill—A wind engine, the chief use of which now is to drive well pumps in country districts.

Wire Drawing—Steam is wire-drawn when passages are made too small to permit it to enter with freedom into the cylinder.

Wire Gauze—Finely-woven wire used for making steam-tight joints between flanges.

Woolf Engine—An early compound engine in which the crank-pins were set 180° apart.

Wrist Plate—The rocking disc which transmits motion to the valve spindles of Corliss engines.

BONE AND IVORY CARVING

Prehistoric Forms of Carving. Working in Ivory. A Lost Art. Horn and Shell Carving. Shell Cameos

Group 2
CARVING
4

Continued from page 6138

By F. WELLESLEY KENDLE

THE presence of carved and engraved bones amongst the tertiary deposits of Europe and America constitutes the strongest link in the chain of evidence that connects man with this remote period [59 and pages 2479 and 2480].

Bone Carving. On account of the hardness of its outer layers and the cancellous structure of the inner, deep carving is not suitable to this material. Having sawn the bone into convenient slabs, rough out the design with the parting tool and very quick gouges: rough carve with flat gouges and firmers, finishing with the assistance of rifflers and files; sandpaper then comes into play to remove scratches and tool marks, the whole being finally polished with the help of putty powder.

Bone is easily dyed; it is even possible to impart a red colour to it during the lifetime of the animal by feeding it with madder (*Rubia tinctorum*). Bone is used as a cheap substitute for ivory for knife-handles, chessmen, thimbles, and other small articles: but it soon discolours, and the comparative coarseness of its grain renders it useless for the production of delicate objects.

Ivory Carving. The antiquity of this handicraft is also undoubted, for, like bone carving, it dates back to prehistoric ages. A contemporaneous portrait of a mammoth [60] carved most realistically upon a fragment of fossil ivory has been unearthed in the Madeleine cave, Dordogne. Coming to more modern times, specimens have been preserved that teach us that the art has been largely practised by nearly every known civilised nation.

Ivory is a fine-grained, hard, dentine-like substance composing the tusks of both the African and the Indian elephant, together with those of the walrus and the narwhal. The molars of the elephant yield a less dense variety and those of the hippopotamus a peculiarly hard kind, which was used by dentists. All the above are known as green or live ivory, distinguishing them from the white, dead, fossil, or Siberian ivory obtained from the remains of the extinct mammoth. The density, toughness, elasticity, durability, colour and beautiful figure of ivory, its absence of appreciable grain, and its capacity for receiving a high degree of finish, eminently fit it for the carver's hands.

The Tools for Ivory Carving. The tools used for carving ivory are similar in character to those of the wood-carver, but smaller and stouter, with less tapered edges, like turning and engraving tools. The design is drawn upon the ivory in Indian ink, as much as possible of the surface is removed with the saw, the pattern is grounded out, and the contours roughly hacked into shape. The ordinary cutting stroke is too tedious to be of practical service. Waste is removed more quickly by holding the tool upright and advancing first one corner of it and then the other in a zig-zag fashion, exerting firm pressure the while, nibbling the ivory away little by little. Drills and tiny points are next used for the deeper portions, and files for the shallower. Indeed, the file is such an important tool that "ivory filing" would be a more appropriate term for the art than "ivory carving." Ivory is more cheaply worked by worrying away its substance with revolving burrs and drills, afterwards finishing as described below.

Polishing, Engraving, and Repairing. The work is polished in three successive stages: (1) No. 0 glasspaper; (2) putty powder, pumice, or fine siliceous earth; and (3) a revolving brush fed with whiting and water.

Ivory may be easily engraved, the pattern being rendered visible by rubbing in Indian ink or indigo, and papering the surface to bring up the lines clearly and sharply.

Broken ivories can be repaired with fish glue, provided the broken surfaces are not greasy, in which case, cleanse them with sulphuric ether, alcohol, or benzene. Warm both fragments, apply as little glue as possible and exert firm pressure till thoroughly set. Ivory dust or shavings mixed with fish glue may be used for building up bruises, chips, or deep scratches.

Ivory carvings are apt to discolour unless exposed freely to both light and air.

Imitation and the Forgotten Moulded Ivories. Very fair imitations of old ivories may be made by covering carved wood with three or four coats of very pale chrome enamel, re-stamping the groundwork, and flooding the depressions with Vandyke brown; or by making casts in a creamy yellow plaster of Paris, boiling them in spermaceti or hard paraffin, stippling the ground and lining the furrows with brown, finally adding fine black, wavy strokes with Indian ink to simulate the cracks of the original.

Ivory may be made plastic by dissolving its earthy salts with phosphoric acid; on the other hand, when brittle and friable from age, it may be toughened by boiling in gelatine.

There is little doubt it was at one time possible to soften ivory so as to allow of its being squeezed or moulded into sheets of considerable size. Unfortunately, this is a lost art, for none of the recipes which have been preserved have proved successful in the hands of modern chemists.

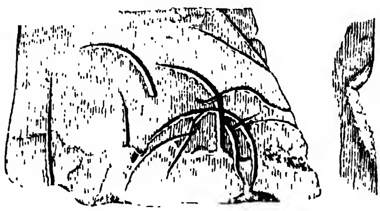
Ivory Substitutes. The curiously hard seeds of the *Phytelephas macrocarpa* are used as a substitute for ivory; the absence of the characteristic "engine-turned" figure of genuine ivory at once proclaims this substitute.

An artificial ivory known as bonzoline is supposed to be a mixture of celluloid and some very fine mineral earth.

The delicately fretted ivory fans made in Paris, and supposed to be of Eastern origin, are produced by drilling the design through a solid block of ivory and then sawing it into leaves.

Horn Carving. Ox and buffalo horns are chiefly used for this purpose, though rhinoceros horn is occasionally ornamented as a curio. Ram's horn is so decorated by Nature that further treatment is superfluous. Horns of deer are really deciduous bones, and with the exception of their being utilised as knife and cutlery handles, are generally better adapted as decorative objects when uncarved and arranged in pairs.

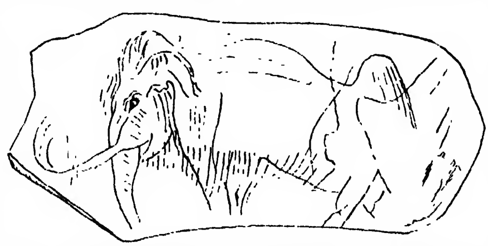
Horns may be carved with ordinary wood-carving tools, but owing to the smoothness, roundness, and natural greasiness of the surface it is not always an easy matter to get the tool to bite. Fortunately, horn can be softened by boiling. The carver therefore overcomes the difficulty by letting a jet of steam play on the horn, though he has to be careful not to allow it to remain subjected to a high moist heat for long at a time, lest the natural cement, which binds together the bundles of fibrous hairs of which it is constructed, should be decomposed.



59. RIB OF BALÆONOTUS SCORED WITH FLINT KNIFE

(A magnified section of a cut is shown to the right)

Working Difficulties. The carver also has to exercise considerable ingenuity in fixing his work firmly. Sometimes he will be able to keep it steady in a vice well padded with leather: at others by wedging it on both sides with wooden knees, and fixing cross-pieces above it. Or he may stand it upright and screw it to the bench, or fit the thin extremity into a block of wood or cement which can be held with a holdfast while the thick end is clamped to the table with a "long dog" [page 5810]. By this manœuvre a quarter-face can be worked at a time. There are no technical difficulties to be overcome in horn carving when once the outer skin has been pierced. A sharp knife is capable of doing most of the roughing out since the contour of a horn permits its use in almost any position.



60. CONTEMPORANEOUS PORTRAIT OF A MAMMOTH

(Carved on mammoth ivory)

An effective and permanent decoration is to stain the groundwork black with nitrate of silver, brown with chloride of gold, or yellow with nitric acid.

Horn may be made as plastic as putty by boiling it with quicklime, in which state it can be moulded into any desired shape, regaining its temper on being subjected to a continuous stream of cold water.

Shell Carving. The principal shell used for carving is that of the *Meleagrina margaritifera*, the Indian pearl mussel.

Mother-of-pearl, as it is called, is easily carved and turned, provided due allowance be made for its structural peculiarities. It consists of layer upon layer of a brittle, chalky material, packed closely together like the leaves of a book. If flaking is to be avoided, all cutting strokes must be made in directions radiating downwards and outwards from each high point of the relief. No special tools are required beyond sharp cutting scrapers of assorted sizes. Its brittleness handicaps the carver considerably, low relief and coarse fretting being the only decorations applicable.

Shells Displaced by Porcelain. Shell cameos, which were so fashionable for nearly 400 years, are now but rarely produced: indeed, the art of cutting them seems to have died out since Wedgwood imitated them so successfully in porcelain. The various and contrasted colours of the component layers of several species of shells suggested to the Italians of the Renaissance the possibility of substituting them for the stratified gems used for cameos. The shells most favoured for this purpose are given in the table

The deep layer is utilised as a background upon which to show up the design proper, wrought in the middle layer, the outer coloured portion serving to accentuate parts of the picture, and as a frame.

Cutting Cameos in Shell. Cutting shell cameos is tedious work, owing to the microscopic detail of the designs from which they are mostly copied. The finest bits and points are employed as the cameo reaches completion. Great care has to be exercised, not only in the first polishing, but also in subsequent cleansings, to avoid ruining the sharpness of the pattern, the chalky layer from which it is cut being very tender and friable.

SHELLS FOR CARVING

Name.	Colour of deep layer.	Colour of middle layer.
Bull-mouth (*Cassis rufa*) ..	Reddish or orange	Creamy white
Black-helmet (*C. tuberosa*) ..	Onyx brown ..	Pure white
Horned-helmet (*C. cornuta*)..	Brown or grey ..	Dead white
Queen's-comb (*Strombus gigas*)	Pink	Pinkish white

CARVING *concluded*

PROGRESS OF EUROPEAN STATES

Continued from page 6202

Russia—continued. Prussia and Frederick The Great. Italy from the Middle Ages to the Present Day. Spain and Holland

By JUSTIN McCARTHY

WE may resume the history of Russia with the death of Alexander I., in 1825, and the succession of Nicholas I., who was crowned at Moscow in 1826. For a time the history of Russia was mainly made up of wars against Persians or the remorseless crushing of Poland's efforts to win her freedom from Russian oppression, of futile alliances made with this or that European State for the purpose of strengthening Russia's power. The army was greatly increased by compulsory enlistment during this period, and there is the more satisfactory statement to be made that the general extension of the railway system in Russia was also a product of this reign.

The Crimean War. In 1853 began the Crimean War, in which England, France—then under the Empire of Napoleon III.—and Sardinia, at that time merely one of the States of a disunited Italy, made war on Russia in defence of Turkey. The war lasted until 1856, and its events and its conclusion are told in another place. While the war was still going on the Emperor of Russia issued a decree for the total emancipation of the serfs, 23,000,000 in number, throughout the whole Empire. This was put into force, and was carried to completion within two years.

The Emperor Nicholas I., who had begun his reign in 1825, was succeeded by Alexander II. in 1855. Russia's story for some time following was merely the struggle for something like political liberty and citizenship made by the great majority of the working population, and the efforts of the existing authorities now to conciliate by partial reforms and now to suppress by reckless force those ever-renewing efforts.

The knowledge of the development in political liberty which was going on through so many other parts of Europe was beginning to spread itself throughout Russia, and the people of Russia could not be prevented from making manifest their resolve to obtain something like political freedom.

The Czars and Russian Freedom. The effects of this contest between opposing orders and conflicting interests made itself evident in successive revolutionary conspiracies, and even in murderous outrages on the part of the unemancipated, and of ruthless punishments inflicted by the rulers. There appears to have been, on the part of more than one of the Russian czars, a sincere desire to render something like justice to the unemancipated classes, and to establish something like the representative principle of government throughout the Russian dominions. During the reign of Alexander II. some reforms were introduced, but they did not suffice to satisfy the demands of those for whom they were intended, and, indeed, they seem to have aroused only a fury of disappointed aspiration among the great masses of the Russian people.

One result was the foundation and the spread of the Nihilist conspiracy, the underlying principle of which seemed to be that everything was wrong in Russia and in most other lands, and that nothing but a total reconstruction of society could effect any lasting benefit for the world. Many of the Nihilists were sincere, but there were large numbers who had nothing in their mind but the destruction of all existing organisations, and who would have held back from nothing to gain their ends. In February, 1881, the Czar made known to his council a plan for the promulgation of a political constitution, but within a few days after this event he was killed by a bomb thrown at him in one of the public streets. He was succeeded by Alexander III., who was married to a daughter of the King of Denmark, sister of Queen Alexandra. He reigned from 1881 to 1894, and the work of Nihilism still continued. Many attempts were made upon his life by Nihilist conspirators, and it is believed that the shocks to his system of these repeated attempts led to the illness which caused his death.

The Hague Conference. Nicholas II., who succeeded him, and who was married to a granddaughter of Queen Victoria of England, made a marked advance in the constitutional policy approached by his predecessor. He showed himself distinctly in favour of a constitutional system from the beginning of his reign, made many concessions towards his Polish subjects, and proved himself an enlightened and conscientious advocate of the cause of peace among the States of the world. On August 28th, 1898, his government made known to the Courts of Europe his famous plan for the assembly of a conference of all Powers for the consideration of means to put an end to the incessant increase of armaments, and to occupy itself "with the grave problem of universal peace." This proposal led to the formation of the Hague Conference of 1898. That conference, however, proved disappointing in its results as the question of international disarmament was not actually brought forward; but the mere fact of such an arrangement having been proposed by Russia is in itself of great importance. The further consideration of the whole subject was not abandoned, but was postponed to a second sitting of the conference at the same place and for the same purpose.

Some time after this the Czar actually convened an assembly of the Duma, or national Parliament, a novel institution for Russia; but this first assembly did not appear to give full satisfaction to its author, and was suddenly and inauspiciously dissolved. Then

followed a number of outrages startling even for Russia, a series of murderous and fatal attacks on Ministers of State, governors of departments, and other public functionaries, followed by fierce and sanguinary efforts at repression. The Czar did not seem to lose hope or heart, and he soon announced that the convocation of a new Duma, with even more expanded representative power, was soon to take place. Meanwhile, however, the attention of all the world was drawn away from Russia's internal troubles by the outbreak of the war between Japan and Russia. There had been arrangements going on with regard to the rival claims of Japan and Russia concerning Manchuria and Corea, and the Japanese, at last becoming impatient of delays, declared war on February 6th, 1905.

The Coming Up of Japan. Then it became apparent to the whole world that a new Power was coming up in the East to shake the balance of controlling influences in the West. In the work of war the Japanese proved superior even to Russia with her vast military resources, and the Russians were compelled, after successive defeats, to make peace on Japan's terms, Japan only yielding so much of her original demands as was put in the form of a claim for money indemnity. Even this moderate concession created much popular indignation in Japan, where the public feeling, over-excited by continuous success, seemed disposed to insist that she should have abated nothing of her claims. The peace was brought about to some extent by the influence of President Roosevelt and the Government of the United States, who strongly urged upon Japan and Russia the world-wide importance of their coming to terms of settlement. The second Duma was summoned on March 5th, 1907, but the condition of Russia at the time of writing is anything but satisfactory.

PRUSSIA

Prussia as a separate State may be said to have had its beginning in 1511. The Margrave Albert of Anspach, of the family of Hohenzollern —a family of Frankish descent which had already become powerful in Prussia—and a kinsman of the King of Poland, was elected their Grand Master by the Knights. Prussia was not immediately freed from Polish rule, but in 1525 the Grand Master was acknowledged Duke of Prussia, and under his rule the country advanced in prosperity. He improved the existing laws and established schools, and during his reign the University of Königsberg was founded. Duke Albert became a Lutheran, as did many of his followers. His son was insane, and the Elector of Brandenburg, after being Regent, was, on the death of Duke Albert in 1618, made ruler of the Duchy. The House of Hohenzollern-Brandenburg have from that day been the rulers of Prussia. In the reign of his successor occurred the Thirty Years War by which the country was much disturbed, and the population and the finances of it diminished rapidly; but under his son Frederick William, known as the "Great Elector," Prussia attained a high position among European States and became prosperous in every way. Frederick increased the finances and established an army of 38,000 men. Under his successors, Frederick I. and Frederick William I., Prussia still advanced, and in 1701 became a kingdom. Frederick William is best known as the father of Frederick the Great, the most famous of all Prussian monarchs; he also did much for his kingdom, and by his rigid economy left the treasury in a flourishing condition and established a powerful army.

Frederick The Great. Frederick II. succeeded his father in 1740. He reigned for forty-six years, and under his rule Prussia became one of the great Powers of Europe. Frederick the Great was born in Berlin, January 24th, 1712. His mother was Sophia Dorothea, daughter of George I. of England. His early years were made so unhappy by his rigid military training and his education, which was equally rigid, that he tried, when only eighteen, to escape to England. His father was angry at this and would have sentenced his son to death but for the intervention of the Emperor. He did actually have Lieutenant Katte, whom he suspected of complicity, executed in his son's presence, and Frederick was imprisoned. The young Prince now saw that resistance was hopeless: he did everything in his power to conciliate his father, and in 1733 married the Princess Elizabeth Christina because his father wished it. He did not come to the throne for seven years after his marriage, and for those years he lived at Rheinsberg and gave much of his time to the study of music and literature, especially French literature. He also took great interest in the philosophical questions which were at that time much discussed by people of learning and culture, and he corresponded with Voltaire. But it is certain that he also gave much thought to the question of the expansion of his dominions—the Prussian Kingdom of which he was so soon to be the ruler, and whose territory he left twice the size it was at his accession.

The Seven Years War. One of his first acts, when he succeeded in 1740, was to make war on the Austrians, whom he defeated at the Battles of Mollwitz and Chotusitz in 1741 and 1742. He made an alliance for fifteen years with France, and this compelled Maria Theresa, whose accession in 1740 had separated Austria from Prussia, to cede to him Lower and Upper Silesia. By another war in 1744 he acquired still more territory, and after this there was a period of peace which lasted eleven years, and enabled Frederick to turn his attention to reforms in his dominions. In 1756 occurred the third Silesian war, better known as the Seven Years War. In this famous war, in which Frederick was the aggressor, he was in the end completely victorious, and showed himself to be a great military genius. The war ended with the Peace of Hubertsburg in 1763. In 1772 he shared in the first partition of Poland, of which he added a large part to the dominions of Prussia In 1778 he engaged in another war and acquired the Franconian Duchies. He also established the famous "Fürstenbund," or League of Princes. This was one of his last acts, for he died at Potsdam on August 17th, 1786.

ITALY

There is not much to tell of the history of Italy from the middle of the sixteenth to the end of the eighteenth centuries. By the Peace of Cambrai, in 1529, Charles V. of Austria became practically lord of Italy, and, thirty years later, his son Philip became, by the Peace of Cateau Cambresis, almost undisputed ruler. Venice alone remained really independent. Genoa, Lucca, and San Marino were independent in name only. Piedmont was given to Philip's cousin, the Duke of Savoy, who had regained Savoy and Nice. The Order of the Society of Jesus was founded in 1540, and the famous Council of Trent, established in 1545, defined the doctrines of the Church of Rome. Venice, formerly under the rule of her own Patriarch, now acknowledged the supremacy of the Pope of Rome.

But the days of Venice's greatness were over; much of the territory that had been hers was now in the power of the Turks, and notwithstanding the victory of the Battle of Lepanto, in which the Christians under Don John of Austria had defeated the Turks, Venice had been compelled to cede Cyprus to the Ottoman power. The conquest of the Peloponnesus in 1684 was the last triumph of the Venetians, and the Peloponnesus was recaptured by the Turks thirty years later. Other events of this period were two risings in Sicily and the revolt led by Masaniello in Naples—an event much celebrated both in poetry and romance. Masaniello was a Neapolitan who in 1647 organised a rebellion against Spanish rule for the remission of taxes. The rising was successful, but Masaniello was soon afterwards assassinated.

Italy Divided Among the Powers. The great days of Spain were also over, and after the war of the Spanish Succession, Italy was again divided among the European Powers. To the House of Savoy the Island of Sicily was given, with Victor Amadeus II. as King. He proved a good ruler, but in 1720 was compelled to give Sicily to Charles VI. of Austria in exchange for Sardinia, which remained under the rule of the House of Savoy until 1861. By the Treaty of Aix-la-Chapelle, Italy was once more broken up. The House of Savoy had Sardinia, Piedmont, and some other parts of Italy; the Austrians had Milan and Tuscany; Charles III., the Bourbon, was King of the two Sicilies, and his brother Philip was Duke of Parma. The Papal Territory included the centre of Italy as far as Venice, which remained a republic until 1797. Modena and Genoa were under the protection of France, and in 1755 Genoa gave the island of Corsica to that country.

For a time there was peace in Italy—peace, at least, from war—under the despotic sway of the Bourbons, who now held most of the peninsula. Of these rulers of Italy, Peter Leopold, Grand Duke of Tuscany, was far the most capable. He suppressed the Inquisition and made many improvements in the condition of his territory. In 1790 he became Emperor of Austria.

After the days of the Napoleonic wars and the fall of Napoleon, the national feeling of Italy began to concentrate itself more and more on the re-establishment of that Italian unity which had long been but a memory of the past. The practical working out of this purpose was mainly due to the efforts of Count Cavour, a great Italian statesman, Mazzini, a great and popular and patriotic agitator, and Garibaldi, a gallant, single-minded and brilliant soldier. Mazzini and Garibaldi were both Republicans by principle, and were strongly opposed to the system which divided Italy into a number of small kingdoms, and thus left the country under the influence of powerful rival sovereignties like France, Austria, and Russia.

Mazzini and Garibaldi. Cavour had risen high in public life in Sardinia when that kingdom had become a constitutional State, and his genius and influence had done much to draw the attention of Italy towards Sardinia as the Italian Power destined to take the leading place in the movement for Italian unity now making itself felt throughout the whole country. Both Mazzini and Garibaldi were willing to accept the rule of one constitutional sovereign, provided the country could, by means of that system become one united and independent Italy. Victor Emmanuel II. was then King of Sardinia, and his State was regarded by most of the Italian peoples as the rising hope of Italy's accession to national independence. Count Cavour became Prime Minister of Sardinia in 1852. The wars between France and Austria, under the rule of Louis Napoleon as Emperor, brought sudden support to the policy of Cavour.

Garibaldi headed an armed rising against the King of Naples, a kingdom still governed according to the most old-fashioned systems of tyrannical rule, and Victor Emmanuel, at the head of his army, supported the rising against the King, whose rule was detested by the vast majority of his subjects. On November 7th, 1860, the King of Sardinia entered Naples in triumph, and was welcomed as sovereign. On February 26th, 1861, the first Italian Parliament assembled, and Victor Emmanuel was declared King of Italy, and on March 31st, in the same year, the kingdom was recognised by Great Britain.

The capital of Italy was then transferred from Turin to Florence. Garibaldi made several attempts to capture Rome from the Papal dominion and make it the centre of the Italian power, but these attempts had to be resisted and suppressed by Victor Emmanuel, although he and his people were in thorough sympathy with the desire to make Rome the centre of united Italy, so far as political life was concerned.

Rome Ceded to Italian Rule. France had been occupying Rome for some time, but after the fall of the French Empire, in 1870, the French occupation of Rome came to an end, and on September 20th of the same year the King entered Rome and was proclaimed sovereign of United Italy, the political power of the Papacy thus coming to an end. King Victor Emmanuel died in January 1878, and was succeeded by his eldest son, King Humbert I., who was born in 1844, and from that time the kingdom of Italy has held its place among the States of

Europe. Pope Pius IX. died a month after King Victor Emmanuel and was succeeded by Leo XIII. King Humbert I. was assassinated on July 20th, 1900, at Monza, by Angelo Bressi, a Tuscan, and was succeeded by his son, Victor Emmanuel III., the present King. Pope Leo XIII., a great statesman as well as a great ecclesiastic, died in 1903, and Pope Pius X. was elected to the Papal Chair

SPAIN

The story of Spain, from the opening of the new era when the restoration of royalties had followed the fall of the Napoleonic Empire, is made up chiefly of dynastic and other internecine struggles. There were always rival family claims for the throne of Spain, which led to continuous domestic wars, and there were also continuous struggles among political parties and factions. There were arising in Spain great parties of men—in fact, large sections of the population—who were tired of the dynastic quarrels, who could not recognise any Divine right amongst the families who disputed for the crown, and were craving for some system of government more in accordance with modern ideas.

In 1817, the rule of despotism had again set in for Spain, but the representatives of despotism were in strife among themselves, and there was war, not so much between despotic power and liberty as between one Power claiming to be despotic and another which contended that itself, and it alone, had "the Divine right to govern wrong." In the meantime, the growing light of civilisation had guided some important reforms in the Spanish system, one of which was the abolition of the slave trade. Spain had some costly struggles brought upon her by her efforts to regain her power over Morocco. The war in which, unwisely and unfortunately for herself, Spain engaged with the United States, is described in another place. The sovereigns who ruled in Spain during the period now under our survey were Isabella II., Amadeo I., Alfonso XII., Maria Isabella, and Alfonso XIII., enthroned 17th May, 1902.

THE NETHERLANDS

The death of William the Silent, in 1584, was a great misfortune for Holland, for the country had been delivered by him from Spanish rule. The Union of Utrecht, in 1579, and the declaration of 1581, in which the Dutch renounced allegiance to Philip II. of Spain, had already made the Netherlands free. Maurice of Nassau carried on his father's work, and the Dutch won many victories at sea. Parma succeeded in taking Antwerp, but his fleet was prevented by the Dutch from joining the Spanish Armada in 1588. Parma died in 1592, and Philip II. in 1598, leaving the Netherlands unconquered: and, though Philip II. still called the Dutch "rebels," their successes at sea enabled them to make their own terms, and in 1609 he signed an armistice with them for twelve years.

Unfortunately, this time of peace was spent in religious and political struggles between the followers of Gomarus and the followers of Arminius, which ended in the defeat of the Arminians. Grotius and others had to fly, and Olden Barneweldt, the Grand Pensionary, was beheaded in 1618. But the Republic progressed all the same, and Frederick Henry, who succeeded his brother Maurice of Nassau in 1625, compelled Spain, by the Treaty of Munster, to recognise the independence of the Dutch Republic.

A Century of Prosperity. From this time Holland, for at least a century, progressed steadily in power and prosperity, and gave many great men to the world.

Holland had wars with England both in the time of Cromwell and during the reign of Charles II., and among the great admirals who commanded her fleets were De Ruyter, Tromp, Van Galen, and Evertsen. There were also wars with France in the reign of Louis XIV. in which Holland was defeated. De Witt, who had strengthened the navy, had neglected the army, and he became so unpopular in consequence that he was killed by a mob at the Hague in 1672. William of Orange, who became William III. of England, was chosen as Stadtholder by the people, and under him the country again became prosperous and successful. He married Mary, daughter of James, Duke of York, and was thus allied with England, and Louis XIV. had to sign the treaty of the Peace of Nimeguen in 1678. The Revocation of the Edict of Nantes drove many Huguenots to find a new home in Holland, and they helped the Dutch in their wars with France. After the death of William in 1702, Holland again became a Republic, and the Treaty of Utrecht in 1713 ended, for the time, the greatest epoch in her history.

The French in Belgium. In 1747 the Stadtholdership was re-established. In 1793 the National Convention made war on Holland, and French troops overran Belgium in the following year. The Patriots of the United Provinces, combining with the French, compelled William V. to fly to England. The "Batavian Republic" was succeeded, after many changes, by the reign of Louis Bonaparte; but this only lasted from 1806 to 1810. Holland then became part of the French Empire, but on the fall of Napoleon it again became a kingdom under the rule of the House of Orange. Belgium seceded from Holland in 1830, but nine years later the two countries made peace. Holland was ruled in succession by William I, II., and III., and during the reign of William III. some important changes were made in the laws. In 1862 the Bill for the Emancipation of Slaves was passed; in 1869 capital punishment was abolished, and in 1872 a new Treaty was made between Holland and England which defined and limited the sphere of influence and action of the two countries in the Indian Archipelago and removed some restrictions of a former treaty.

William had no son, and his daughter by his second marriage, Wilhelmina, the Princess of Orange, was chosen as his successor, Queen Emma being appointed Regent. William III died in 1890, and Princess Wilhelmina, who was then ten years old, became Queen of Holland.

COPPER AND ITS ALLOYS

Copper Ore and Its Treatment. Electrolytic Copper. Alloys of Copper. Brass and Bronze. Working of Brass and Bronze

Continued from page 6179

COPPER, the symbol of which is Cu, and the atomic weight 63·1, was one of the earliest metals discovered by man. The Copper Age followed the Stone Age, and preceded the Bronze Age. Copper weapons have been found in Egypt at a depth which, assuming the present rate of deposit as fairly constant since it was left there, gives its time of manufacture as not less than 10,000 years ago. The occurrence of large copper masses in the metallic state, the colour of which renders it easily recognisable, drew early attention to copper.

Physical Properties of Copper. The colour of copper is a characteristic red, with a tendency towards purple when cuprous oxide is present. It is only a little softer than nickel and iron, of the useful metals. Its tenacity and extensibility give it great industrial value; it can be rolled, beaten, and drawn into very fine leaf and wire. The specific gravity of the ordinary copper of commerce is from 8·2 to 8·5, rolled and hammered copper having a higher specific gravity than cast or crystalline copper. Electrolytic copper is 8·95. Roberts-Austen gives the specific gravity as 8·82. The precise melting point of copper has not been determined, but is between 1,050° and 1,100° C. Molten copper is of a sea-green colour, and of great fluidity. The thermal conductivity of copper is 736 (silver = 1,000) and the electrical conductivity 97·61 (Roberts-Austen) (silver = 100). Copper can be welded only with difficulty, and then only at a bright red heat.

Chemistry of Copper. Copper is unaffected by atmospheric exposure at ordinary temperatures, but under the influence of damp or of carbon dioxide it becomes coated with *verdigris*, an impure acetate of copper. When heated to redness in air it develops copper scale, a dark layer consisting of cupric oxide on top and cuprous oxide below.

Copper is immune from attack by water free from air, and by lime water, hence the value of copper for kettles and other utensils, for boilers and for boiler tubes. It dissolves easily in ordinary nitric acid and aqua regia, but only slowly in sulphuric and hydrochloric acids. It is remarkable, however, that the strongest nitric acid does not act on copper. Under an electric current copper may be separated from impurities and deposited on the cathode as pure copper, the application of this principle constituting the process of electrolytic copper refining, which we shall consider later on.

Sources of Copper. Within a half century the world's supply of copper has multiplied by ten, but the world's demands have grown quite as much as the supply, and the present high price of the metal is evidence that it is far from overtaking the demand. The main though not the only reason for this increase in consumption has been the growth of the electrical industries, with their huge demands upon the copper market. As the electrical industries grow and spread, so will the need for copper increase, so that there is no present likelihood of pause in an expanding consumption. The relative importance of the copper sources has undergone change during the last few decades. Formerly the world looked to Chili as the most important source of supply, but to-day the United States of America, with the enormous copper wealth of Montana and the Lake Superior district, supplies 60 per cent. of the world's copper requirements, with Spain a good second.

Copper Ores. Copper is found both in the native state and in combination. The largest deposits of native copper known are in the Lake Superior district of North America. New Mexico and South Australia also possess important deposits and the copper sand of Chili contains from 60 per cent. to 90 per cent. of metallic copper.

Copper pyrites, or *chalcopyrite* ($Cu_2S.Fe_2S_3$), known also as *yellow copper ore*, is the source of most of the copper supply of the world. It has a yellow colour with a black streak, a hardness of 3·5 to 4, and a density of 4·1 to 4·3. It is found at Rio Tinto, in Spain, and in every one of the five continents. Cornish ores, and the large deposits of Montana and Alabama, are of this variety.

Malachite ($CuCO_3.Cu(HO)_2$) is a beautiful streaked green copper ore which is much used for ornamental purposes. Its hardness is 3·5 to 4, and its density 3·7 to 4·1. It occurs in the Ural district of Russia, in Chili, and in Arizona and New Mexico. It contains, when pure, 57·33 per cent. of copper, but is seldom found pure, being usually associated with salts of lime and magnesia, oxides of iron and manganese and other substances.

Cuprite, or *red oxide of copper* (Cu_2O), is of a red colour with a red-brown streak, a hardness of 3·5 to 4, and a density of 5·7 to 6·0. It contains 88·8 per cent. of copper, and occurs in Montana in the upper sections of Butte City veins, in New Mexico, and in Russia.

Azurite ($2CuCO_3.Cu(HO)_2$) is of a beautiful blue colour with blue streaks, has a hardness of 3·5 to 4, and a density of 3·5 to 3·8. It is usually present with malachite, but in much smaller quantities. It carries 55·16 per cent. of copper.

Bornite, or *churesate* ($3Cu_2S.Fe_2S_3$), or *purple copper ore* (sometimes also called *peacock* ore) is of a brilliant purplish brown colour when uncovered, but exposure to the atmosphere speedily causes it to change, and it may become yellow or deep blue, green or purple. Its copper content varies from 40 per cent. to 70 per cent. Its hardness is about 3, and its density about 5. It is found in Montana, Cornwall, and Chili.

Chalcocite, or *copper glance* (Cu_2S), is of a streaked dark grey colour, has a hardness of 2·5 to 3, and a density of 4·8 to 5·8. It usually holds at least 55 per cent. of copper, and the deposits in Montana carry from 60 to 74 per cent. It is also found in quantities in Arizona, Colorado, and New Mexico, while smaller deposits are found in many other places

Treatment of Ores. The various ores of copper for metallurgical purposes may be classified into three groups. First there are the native copper ores, as found in the Lake Superior district, where the metal occurs in the form of metallic particles, and where the ore is concentrated mechanically, the resulting concentrate, or *mineral*, as it is termed, being melted down and toughened in refining

furnaces. Then the sulphide ores, the most important of which are copper pyrites, are subject to dry or wet processes, according to their nature and their copper contents. Dry methods are usually adopted with ores rich in copper and wet methods with poorer ores or with auriferous and argentiferous copper ores.

Chalcopyrite is a combination of copper with iron and sulphur, and the object in smelting is to separate the copper from these two and also, of course, to eliminate the gangue. The process depends upon the affinity of iron for oxygen and copper for sulphur. By calcination, or roasting the ores in heaps, or in shaft or reverberatory furnaces, they are freed from siliceous matter and concentrated, forming a copper *matte*, so-called. The matte is then smelted with a siliceous flux and oxide of copper is changed into a sulphide. Again it is fused with slag to oxidise the sulphide of iron and the result is a *white metal*, sometimes called *blue metal* or *fine metal*, with from 60 per cent. to 75 per cent. of copper. This is now melted in contact with air, and the oxide of copper formed reacts on the cuprous sulphide, forming an impure metallic copper (*blister* copper) and a slag rich in copper.

Copper Refining. The metal contains iron and other impurities, and has now to be refined. It is treated in a reverberatory furnace, and to remove the cuprous oxide poles of green wood are pushed into the bath, and charcoal or anthracite is sprinkled on the surface. When the metal has become pale and fibrous this refining is finished. The resulting copper ingot should show a flat surface. If it contain too much oxide it will be furrowed and is "underpoled," and if it be ridged on the surface it is "overpoled" and contains too little.

The modifications of this "reaction" process, as it is called, are numerous, and the varieties of furnaces and operations are very great. Each ore must be treated for its individual properties, and local conditions must also be considered. The "reduction" process is similar to the reaction process up to the "white metal" stage. The reduction process oxidises the sulphide completely, and reduces the mass by carbon. It is less economical than the other process.

The wet method of treating copper ore is followed for low grade ores. Copper sulphate is extracted from the roasted ore by bleaching with water, and the copper in solution is precipitated by the aid of another metal, usually iron, or by electrolysis. The great value of the wet process is that if the ore contain silver or gold these metals may be recovered.

Electrolytic Copper Refining. The electro-chemical treatment of copper ore has not yet been practised on a large scale, but electrolytic treatment of impure copper produces a copper of high purity, such as is required for electrical purposes. The principle of electrolytic refining of copper is simple. The electric current enters a bath of solution of sulphate of copper through an *anode* of impure copper and leaves it by a *cathode*. The action is that the anode is dissolved, but only the pure copper is deposited on the cathode, the remaining metals present as impurities, and also dissolved from the anode, not being so easily deposited as copper. We shall examine details of the process of electrolytic refining as practised in some of the largest works.

The first process in the electrolytic refining of copper is to melt the copper pigs or ingots so that they may be cast into the large flat plates which form the anodes in the electrolytic tanks. The charge of copper is melted in the *anode furnaces* as they are called, reverberatory furnaces used for this special purpose. Then the metal is worked by methods akin to those of puddling [see page 4635] for some hours, sometimes as many as thirteen or fourteen. This treatment dispels some of the impurities, and the copper is raised from usually 98·5 per cent. of purity to 99·5 of purity. Then the furnace is tapped, the metal is drawn off by the help of a ladle, and is poured into moulds which are mounted upon an endless chain. The copper plates which are to be used as anodes are 36 in. by 24 in. by 1 in. Each is made with two lugs on its upper edge, these being used to support the plate in the electrolytic tank. The plates are then put into frames holding 22 plates, the full charge for one electrolytic bath.

Electrolytic Bath. The tanks are filled with diluted sulphuric acid and sulphate of copper electrolyte, and are usually arranged in sets with a reservoir and pump to each set. They are arranged electrically in series, and the electrodes in each tank are parallel.

The thin cathode sheets used in the depositing tanks are themselves deposited in other tanks known as *stripping tanks*. The cathodes in the stripping tanks are pure rolled copper plates covered with grease or plumbago, upon the surface of which the new plates form, and from which they are afterwards easily detached. These new plates are beaten with wooden paddles and are hung by copper loops from copper rods which lie upon the edges of the depositing tank.

Now the electric current is passed through the bath, and the action is to transfer the copper of the anode plates to the cathode plates, upon which it is deposited. The charge is under treatment in the electrolyte for seven days, when the cathode plates have increased from 6 lb. to 8 lb. in weight to 75 lb. or 80 lb. Then they are removed and taken to the refining furnaces. The anodes, however, are not yet exhausted. New cathode plates are supplied and the process is resumed. The anodes last for six weeks.

The final process of refining is similar to that already described, when the green wood is plunged beneath the surface so as to remove the oxide by the carbon of the wood combining with the oxygen and escaping as carbon dioxide. The result of the process is a copper of 99·88 per cent. of purity.

Copper Castings. Casting copper so as to give good sound castings is not an easy matter, but it is a subject of some importance because several industries, particularly the electrical industry, are developing an increasing need for copper castings. The chief difficulties in casting copper are occasioned by impurities in the copper, by the formation of cuprous oxide while the metal is in a state of fusion, whereby blow-holes are caused, and by the great contraction during cooling, whereby the mould is not completely filled. The first-mentioned difficulty is overcome to some extent by the use of copper which has been electrolytically refined, and is therefore chemically pure. A common method of overcoming the cuprous oxide difficulty, in good practice, is by casting in chills or dry sand moulds, and by adding up to 5 per cent. of manganese at the time of casting. Manganese combines with the oxygen of the cuprous oxide, thus making the metal more uniform. Sometimes zinc or tin, up to $1\frac{1}{2}$ per cent., is added, and has the desired effect. For very thin or very sharp copper castings, the introduction of one-half of 1 per cent. of phosphorus has beneficial effects. It has a deoxidising effect, and increases the fluidity.

Copper Oxides. Numerous compounds of copper have a place in industry. We cannot go into great detail in every one of them, but we can pass them under cursory review and indicate their value and importance.

Cuprous oxide (Cu_2O), otherwise known as *red oxide of copper, copper suboxide,* and *copper hemioxide,* is found in the native state as cuprite or red copper ore [see page 6305], and as chalcotrichite. It may be prepared by heating finely divided copper in air below red heat and in several other ways. It is used as a pigment, and, in combination with black oxide of copper, constitutes one of the copper antifouling paints used for ship bottoms. It is also used in the manufacture of ruby glass.

Black oxide of copper (CuO), or copper monoxide, is found as *melaconite* or *black* copper in native deposits, prominently in the Lake Superior district. It is used in organic analysis. It is also used in the manufacture of green and blue glass [see page 4533].

Hydrated copper oxide ($CuO \cdot H_2O$) is used in paper staining. It is of a blue colour, but develops into green under atmospheric exposure. Schweitzer's reagent, which is used in the manufacture of Willesden paper, is a solution of cupric hydrate in strong ammonia. Treated with this solution cellulose gelatinises and is completely solved. When the solution has been evaporated, a gummy mass consisting of cellulose and copper oxide remains. In making Willesden paper the solution is allowed to dry on the paper, making it water resisting and binding the constituent fibres together, thereby increasing the strength. Ropes and netting are also treated by the same process. Thorpe quotes the alleged best method of preparing hydrated copper oxide: "Six parts of copper sulphate are dissolved in water and mixed with a solution of three parts of calcium chloride. The clear liquid is decanted from the precipitated calcium sulphate and is mixed with one and a half parts of lime, made into a cream with water. The greenish precipitate is collected, washed and mixed with one-fourth of its weight of slaked lime and as much pearlash, and to render the colour more permanent one-fourth of its weight of ammonium chloride and one-half of its weight of copper sulphate are usually added."

Chloride and Other Copper Salts. The *Brunswick green* of commerce is *cuprous chloride* (Cu_2Cl_2). It has a wide use as a pigment. It is found native as *atacamite.* It is prepared from copper turnings by moistening them with hydrochloric acid or ammonium chloride under atmospheric exposure, or it may be made by boiling copper sulphate in solution with a small percentage of bleaching powder solution.

Cupric chloride ($CuCl_2$) is used for methyl violet in calico printing and for oxidising cutch colours. It is made by heating copper in excess of chlorine or by dissolving oxide of copper in hydrochloric acid.

Sulphate of copper ($CuSo_4 \cdot 5H_2O$), or *blue vitriol,* as it is popularly known, is the most important salt of the copper. It has many uses. In agriculture it is used for dressing wheat and other seeds. The practice is to soak the seeds in a weak solution of the salt within twenty-four hours of being sown. It is also applied to vines, usually as a solution of from 10 per cent. to 20 per cent. It is also applied to timber, and prevents rot. Sulphate of copper is also used in cotton printing, chiefly with potassium bichromate or iron mordants, and with logwood for black dyeing.

It is made from metallic copper, usually scrap copper, which is heated in a reverberatory furnace, sulphur being afterwards added and the doors shut. After some time the doors are opened and the heat is increased so as to oxidise the sulphide with sulphate. The hot mass is withdrawn, immersed in sulphuric acid (diluted), and, after settling, is decanted, concentrated and crystallised.

Cupric sulphide (CuS) is also used in calico printing for fixing aniline black. It is made in one way by precipitating a sulphate solution with sodium sulphide.

Nitrate of copper ($Cu(NO_3)_2$) has a limited use in cotton printing and textile dyeing. It is made by dissolving metallic copper or the carbonate or oxide in nitric acid.

Verdigris and Other Pigments. *Acetate of copper* is used as a pigment and in indigo dyeing as an oxidising agent. *Verdigris,* erroneously referred to by many authorities as a carbonate of copper, is a mixture of basic copper acetates, the monobasic, dibasic and tribasic acetates being present in different proportions in different varieties of verdigris. The varieties of verdigris are used for oil and water colour paints, for the manufacture of emerald green and other copper paints, and in dyeing and calico printing. Green verdigris is manufactured commercially by placing copper sheets for some weeks between cloths moistened from time to time with pyroligneous acid or acetic acid. The verdigris forms as green crystals. Blue verdigris is made by allowing the refuse of the wine press—consisting principally of grape skins—to ferment, and by placing into this thin copper sheets. The copper sheets become coated with verdigris. They are allowed to remain in the mixture for about two to three weeks, and are afterwards left to stand and subjected to occasional moistening with water or wine during some two months. The verdigris is removed and squeezed into cakes.

Emerald green, referred to above and known also as *imperial green* and *Schweinfurth green,* is an *aceto-arsenate of copper.* It is a brilliant green of pleasing shade and is largely used. Wallpaper stained with this green is found to give off a peculiar odour when the wall is damp, and this is alleged to be poisonous. This pigment is manufactured by mixing boiling concentrated solutions of copper acetate and arsenious oxide. The volume is doubled by the addition of cold water, and the mixture is placed in bottles or flasks filled to the top so that premature crystallisation may not occur. Crystallisation takes place gradually, and is not complete for a few days. There are other methods of making the pigment, but that described yields the finest product.

Scheele's green is arsenite of copper. It was formerly in extended use but is now of little importance. It is made by adding arsenious oxide to a boiling aqueous solution of potassium carbonate; after filtering, this is added to an aqueous solution of copper sulphate and the arsenite of copper is precipitated.

Some basic *carbonates of copper* are known commercially as *verditer* green or blue and *Bremen* green or blue. They are used chiefly for paper staining. *Malachite* is a basic carbonate. Verditer is made commercially by grinding sea salt and blue vitriol with water and digesting the resulting paste in wooden boxes along with pieces of copper plates. When the chemical action is complete, hydrochloric acid is added with agitation. Caustic soda and water follow as an addition to the mixture, and the product is washed, filtered and dried.

Alloys of Copper. The most valuable of the alloys of copper are those with tin and zinc, the tin-copper alloys forming the important family of the *bronzes*, and the zinc-copper alloys giving us *brass*, both of which we shall consider at some length. With gold and silver, aluminium, nickel, and antimony, copper also alloys well [see pages 5856, 5983 and 5992], but with lead and iron it is unsatisfactory.

Successful alloys of copper depend greatly upon the absence of deleterious ingredients in the copper used. Cuprous oxide makes the metal red-short and cold-short, and the higher the proportion of cuprous oxide the more pronounced are these faults. It also causes castings of the metal with which it may be mixed to contract considerably. Sulphur in copper makes blown castings; silicon affects the ductility, pales the colour, and gives brittleness; nickel and antimony, singly or in combination, decrease the malleability; phosphorus increases the hardness and the fusibility.

Copper Alloyed with Gold and Silver. The British gold coinage is an alloy of gold and copper [see page 5851]. The colour of a gold-copper alloy shades into red, and green gold is an alloy of gold, silver, and copper. Silver-copper alloys are hard, strong, and tough, and give out a clear, penetrating sound when struck. Copper may be added to silver up to almost 50 per cent. of the alloy without changing the colour of the silver. Care must be taken in casting a silver-copper alloy, or "liquation"—that is, separation, may take place. In working articles of silver-copper, the frequent annealing necessary causes the copper to oxidise, giving the alloy a steel-grey colour. This colour is removed by the process of "blanching," so-called—that is, boiling the articles in dilute sulphuric acid (1 in 40). This process dissolves the surface copper and gives a surface of pure silver.

Bronze. Bronze is an alloy of copper and tin. It has been in use from prehistoric times, and in the early days it was more nearly a pure binary alloy than it became during the mediæval ages, when its value was usually impaired by a percentage of lead. Although tin is a soft metal by itself, it forms a very hard metal when alloyed with copper. If bronze is to be rolled into sheets, the percentage of tin must be small—not more than from 4 per cent. to 6 per cent.

Most of the bronze of commerce is not a mixture of pure copper and tin, especially when it is made with an admixture of old bronze, which usually contains other metals as impurities.

A small quantity of zinc in the alloy makes bronze castings sharp and tends to prevent blow-holes, but the zinc should not constitute more than 2 per cent. of the whole, or the appearance will tend towards that of brass. Lead in bronze is detrimental, especially when the alloy is to be cast; it increases the liability to oxidation, and as the lead tends to liquate from the bronze, the castings are unequal. Iron hardens bronze and gives a whitish colour; it is often introduced when the bronze is to be used for axle bearings. Nickel makes bronze harder, and decreases the toughness.

Properties of Bronze. The colour of bronze may be varied within wide limits by the different proportions of the constituent metals. Bronze with over 90 per cent. of copper is of a pure red colour. As the copper decreases, the colour passes through orange yellow to pure yellow at 85 per cent. of copper. A copper proportion between 50 per cent. and 35 per cent. gives a pure white bronze, and below this proportion the colour is steel grey, but as the copper becomes very low, the white colour reappears.

Tin reduces the ductility of bronze very much, and as low a percentage as 15 makes it impossible to hammer the alloy without fracture, even when it is hot. The maximum hardness of pure bronze is when it is made of 72·8 per cent. of copper and 27·2 per cent. of tin. As the tin increases above this proportion, the hardness diminishes, until, when the tin is two-thirds of the whole, the alloy is as soft as pure copper. Bronze, very rich in copper, is made very hard and very brittle by repeated forging. Cooling red-hot bronze rapidly makes it much less brittle and less dense, so that bronze bells rapidly cooled are deepened in tone. The higher the proportion of copper in bronze the higher is the point of fusion. Thus, bronze with 95 per cent. of copper melts at 2,520° F., while, when the copper is only 80 per cent., the melting point is only 1,868° F.

Bronze for Various Purposes. The general rules which should guide in the manufacture of bronze for various purposes have been given, but we may tabulate common formulæ of bronzes for various industrial purposes:

COMPOSITION OF BRONZES

Purpose.	Copper.	Tin.	Zinc.	Lead
Rail waggon axles	75	20	2	
Piston rings	84	2·9	8·3	4·3
Stamped articles	64	5·5	30·5	
Small castings	94	6·0		
Cocks..	88	10	2	
Steam whistles	80	17	2	
Articles to be hard soldered ..	87	12	1 part antimony.	
To resist atmospheric action ..	93	7		
Speculum for telescopes	66·6	33·3		
Very tough	32	3	1	
Valves and fittings (Admiralty mixture)	90	10	2·5	
Soft gun metal	16	1		
Gun metal for casting	9	1		
Maximum hardness for bearing metal	5	1		
Bell metal..	4	1		
Ordnance metal	91·6	8·3		

For bronze statuary, the composition of the alloy depends upon the colour desired. The following proportions are recommended by Brannt to give the shades indicated:

COMPOSITION OF STATUE BRONZES

	Percentages.		
	Copper.	Tin.	Zinc
Red yellow	84·42	4·30	11·2
Orange-red	83·05	3·92	13·0
Orange yellow	81	4	15
Pale orange	73	4	23
Pale yellow	70	3	27

Another authority states that the best statue bronze has the following composition: copper, 78·5 per cent.; tin, 2·9 per cent.; zinc, 17·2 per cent.; and lead, 1·4 per cent. If the proportion of zinc be too high in a statue bronze, the object loses the warm colour desired in statues, and when the zinc is too high the natural green tone, termed *genuine patina*, which a statue of the proper composition gains from exposure to the air, is not acquired, but one shading into black.

In making alloys into which tin enters, it is usual to put in one-half of 1 per cent. more tin than the final alloy is desired to carry, this quantity being lost by oxidation during the period of fusion.

Bell Metal. Bell metal is a variety of bronze, as it is essentially a copper-tin alloy. Occasionally, other metals are introduced in order to modify the tone. Common cheap bells are frequently made of brass or of steel. The low-priced bicycle bells are of this order, but gongs and house bells, clock bells, and sleigh bells, tower and church bells, are made from the bronze alloy known for centuries as bell metal. We refer under Manganese Bronze [see below] to claims for that alloy as a material for bells. It was formerly considered that a small percentage of silver improved the tone of a bell, but this view is no longer held, and the use of silver in bells is now discarded. The usual bell metal contains about 20 per cent. to 25 per cent. of tin. The following table gives the recognised formulæ for some bell metals.

COMPOSITION OF BELL METALS

	Copper.	Tin.	Zinc.	Silver.	Lead.	Bismuth
House bells	80	20				
Do. smaller ..	75	25				
Small hand bells ..	40	60				
French clock bells ..	72	26·56		1·44		
German do.	73	24·3	2·7			
Swiss do.	74·5	25			0·5	
Sleigh bells	84·5	15·4				
Gongs	82	18				
White table bells ..	17	80				3

A good bell metal is grey white in colour. In practice, the fracture determines the quality of the metal for the bell founder. If too coarse, the alloy must be made richer in tin; and if too fine, the tin is already too high, and copper must be added. Bells made from metals that have been frequently melted are not pure toned, this being caused by the oxide solution which has come into the alloy. But the art of the bell-founder embraces more than merely making a suitable alloy. The size, shape, and diameter of a bell, and the relation of its height to its diameter, have much to do with the sound that it gives out. Small bells are often cast in iron moulds, but large ones are always cast in the sand.

Phosphor Bronze. *Phosphor bronze* possesses very great strength, and can be rolled and hammered in a cold state. The name would indicate that it is a bronze carrying a certain percentage of phosphorus, but it is not always so. A more appropriate name would be *deoxidised bronze.* Phosphorus is used in the preparation of bronze, although the final metal may contain no phosphorus. Copper usually contains cuprous oxide in solution, and this oxide reduces the strength of any alloy made from copper containing it. By the introduction of phosphorus when the alloy is in a state of fusion, a complete reduction of the cuprous oxide is effected. The quantity of phosphorus can be gauged accurately in accordance with the cuprous oxide present in the metal. No phosphorus may remain in the alloy. A practice in making phosphor bronze is to introduce the phosphorus as phosphor copper or phosphor tin, or sometimes as both, these alloys having been prepared beforehand. To make phosphor copper heat four parts of superphosphate of lime, two parts of granulated copper, and one part of finely powdered coal in a crucible. Phosphor copper with 14 per cent. of copper will separate at the bottom of the crucible. Phosphor tin may be made by heating together three parts of anhydrous phosphoric acid, one part of carbon, and six parts of tin. Then, to make the phosphor bronze, 10 ounces to 12 ounces of this phosphor bronze or phosphor tin is added to each cwt. of molten bronze. The field of phosphor bronze is in articles such as hydraulic presses and propeller blades, where great strength is required. Sometimes lead or aluminium is introduced into phosphor bronze for specific purposes.

Silicon Bronze. *Silicon bronze,* which is an alloy of copper, tin, and silicon, or of copper and silicon only, has very high tensile strength, and has been much used for telegraph and telephone wires. Such wires have been erected with stretches of 1,000 ft. with no intermediate supports. Phosphor bronze has, however, largely taken its place. A formula recommended for silicon bronze specifies copper 97·12 per cent., tin 1·14 per cent., zinc 1·10; and silicon 0·05 per cent. The tensile strength of this alloy is said to be 600 lb. for 0·001 square inch section. Silicon bronze owes its properties to the fact that silicon, while reducing the cuprous oxide in the copper just as phosphorus does, seems to have a greater affinity for the copper than phosphorus has.

Manganese Bronze. *Manganese bronze* is, properly, not a bronze at all, but a brass; yet, on account of its name, we refer to it here. The following mixture is frequently used: copper 51 per cent., manganese copper (containing 20 per cent. of manganese and 8 per cent. of zinc) 40 per cent., and aluminium 1 per cent. The manganese copper, besides containing manganese, usually contains from 2 per cent. to 4 per cent. of iron. Manganese bronze possesses very high tensile strength. The alloy of the composition given above has a tensile strength of 36 tons per square inch and an elongation of 20 per cent. A higher percentage of zinc increases the hardness and tensile strength and diminishes the elongation, while a lower percentage has the opposite effect. The sphere of manganese bronze is in the manufacture of ordnance, propellers, pinions, and bearings, where its qualities make it desirable. As the tin constituent in the true bronze alloys is replaced by the cheaper zinc in manganese bronze, it is cheaper than the other special bronzes without showing inferior qualities as a special metal.

Manganese bronze finds some use as a bell metal instead of the usual copper and tin alloy generally used for the purpose. The advantages claimed by the advocates of manganese bronze for this purpose are that in comparison with the older composition it is more sonorous, has a mellower tone, and is not liable to be cracked. The usual bell metal is made very hard and brittle in order to improve the quality of the tone.

Aluminium Bronze. *Aluminium bronze* is an alloy of copper and aluminium, and contains no tin, hence the use of the word bronze is not quite accurate, although it has come to be accepted. The content in aluminium is never usefully higher than 10 per cent., but even up to this modest proportion colour and physical properties vary a good deal. With 5 per cent. of aluminium the colour is golden, at 7½ per cent. it partakes of a green-gold hue, and at 10 per cent. it is a bright golden colour. These alloys have great tensile strength, are exceedingly malleable in both the hot and the cold states, give sharp, clean castings, and admit a fine polish. The highest qualities of aluminium bronze are brought out by remelting it three or four times, and its strength may be further increased by hammering so that it may be made equal to steel. In casting aluminium bronze experience is necessary to good work. Its shrinkage is about twice as much as that of brass [see also page 5992].

Aluminium Brass. *Aluminium brass* is properly so termed, being an alloy of copper, zinc, and aluminium. Here also the percentage of aluminium is invariably low: if it be higher than 15 per cent. the alloy becomes red short and hard. An alloy containing 60 parts of copper, 30 parts of zinc, and 2 parts of aluminium can be worked mechanically by rolling, stamping, or forging, and has a valuable use for cartridge shells, because the aluminium imparts the property of resisting corrosion by the gases of the powder. It has been claimed that aluminium brass with from 1 per cent. to 3 per cent. of aluminium has much similar properties to aluminium bronze with from 5 per cent. to 10 per cent. of aluminium, and, of course, it is much the cheaper; but we question the evidence for this claim. Certainly aluminium brass is heavier and oxidises more easily. But the aluminium and zinc seem to form an intimate combination, and to develop properties even superior to the aluminium-copper alloys. The field for aluminium brass is in machinery parts and fittings in which exceptional strength is desired, such as valve seats, hydraulic and mining machinery, and propellers.

Bronze Powders. Most of the bronze powders used to coat metal, paper, wood, and other materials are made in Austria. A large number of different shades are procurable. Zinc and not tin is alloyed with copper to form the material from which they are made, so that the term *bronze* is technically incorrect. Powders which incline to white in colour have a high zinc content, and those that incline to red are high in copper.

Brannt gives the following compositions for some representative colours:

ALLOYS FOR BRONZE POWDERS

Colour.	Copper.	Zinc.	Iron.
Yellow	82·33	16·69	0·16
Pale green	84·32	15·02	0·63
Lemon	84·50	15·30	0·07
Copper red	99·90		
Orange	98·93	0·73	
Pale yellow	90·00	9·60	
Crimson	98·22	0·50	0·56

All the variety of shades are not, however, obtained by varying the composition of the alloy so much as by heating the alloy (after it has been finely pulverised), until a layer of oxide of the desired shade surrounds each individual particle.

In making the bronze powders the alloy is beaten into fine leaves by power hammers. These leaves are then forced through a fine sieve with the assistance of a scratch brush, oil being added at the same time, and the oil and powder passes through a grinding machine, which consists of one steel plate mounted with fine needles having blunt points revolving against another steel plate. The metal is here reduced to a very fine powder, and the oil is removed, first by putting the mass into water, where the oil floats off, and then by pressure.

Brass. Although the alloys of copper and tin—the bronzes—can claim antiquity, the alloys of copper and zinc, generally known as *brass*, can claim a much wider use industrially. Brass is properly a binary alloy, and should contain only copper and zinc; but pure brass is seldom made. The alloy is usually associated with tin, iron, lead and arsenic, those metals sometimes being present as impurities in one or both of the constituent metals, and sometimes again being added so as to modify the properties of the alloy. The two metals, copper and zinc, alloy within very wide limits. The higher the percentage of copper the more does the colour of the alloy tend towards gold, and copper also increases the softness and the malleability. As the proportion of zinc increases the colour becomes paler until it is a pale grey, and zinc increases the brittleness, hardness, and fusibility. A proportion of zinc up to 7 per cent. does not change the colour of the copper to an appreciable extent, but when the proportion comes above this quantity the tone is red-yellow. Then at 14 per cent. the colour has modified into pure yellow, and above 16 per cent. it goes into a mixed yellow, while at over 30 per cent. the red colour returns, and is at about its maximum when the two metals are present in equal proportion. As the zinc exceeds 50 per cent. the colour rapidly pales, passing through reddish white at 53 per cent., yellowish white at 56 per cent., bluish white at 64 per cent., and into lead colour as the zinc exceeds this limit.

Colours of Brass. The various phases through which the colour of brass passes as the proportions of the constituent metals vary may be given in the form of a table.

COLOURS OF BRASS

	Composition.	
	Copper. Per cent.	Zinc Per cent
Red	95	5
Reddish brown	90	10
Red-yellow	85	15
Reddish yellow	80	20
Light yellow	75	25
Yellow	70	30
Dark yellow	65	35
Reddish yellow	60	40
Golden yellow	50	50
Light grey .	40	60
Lead grey .. .	30	70
Darker lead grey	20	80
	10	90

The physical properties of brass, other than colour, are also much influenced by the proportions of the metals alloyed. A small proportion of zinc increases the fusibility without affecting the hardness; a high proportion increases the malleability when cold, but makes forging when hot impossible. Lead causes brittleness if it be present in brass in large quantities, but small quantities increase the ductility, making it better for turning and filing. A small proportion of phosphorus makes sounder brass castings, by increasing the fluidity and tenacity, and helps the alloy to resist atmospheric action. It also permits of tempering to some extent. The composition of commercial brass for many specific purposes is given in the following table [see also table of bronzes on page 6308].

COMPOSITION OF BRASS

Purpose.	Copper.	Zinc.	Tin.	Lead
Gas fittings	40	20	..	1
Sheet brass for stamping and turning	3	1		
Brass wire	67	33		
Soft brass for hammering ..	7	3		
Tough brass for engine work	100	15	15	
Brass for soldering..	8	3		
Sheathing brass	3	2		
Nails for sheathing	87	4	9	
Yellow brass	2	1		
White brass	10	80	10	
Red brass	16	2		
Brass for forging hot	33	25		
Pinchbeck	88	12		
Tombac	86	14		

The common quality of brass used in the foundry is termed in the trade *ash metal.* This is a general mixture suitable for cheap work, and is very wide in its quality. It is made by melting together scrap brass, borings and filings, sweepings and skimmings. These materials are riddled so as to free them from unnecessary dirt, and are washed, melted, and poured into ingots so as to be ready for use. Remelting improves brass, although there is loss of weight in any remelting, so that to remelt brass is more expensive than the mere cost of fuel and labour which it entails.

Standard yellow brass, so called, is an alloy containing two parts of copper to one part of brass. It is common to use this mixture already made as an ingredient in brass mixtures for casting, particularly for *red metal,* as it is called. A cheap red metal is made by alloying 36 parts of yellow brass (standard) with 46 parts of copper, 14 parts of lead, and 4 parts of tin. For highly polished red metal plumbers' fittings a common formula is 4 parts yellow brass, 16 parts copper, and one part each of lead and tin. For red metal to stand riveting the proportions of lead and of yellow brass are usually increased and the proportion of tin lowered. Thus, a good formula frequently followed takes 26 parts of yellow brass, 66 parts of copper, 5 parts of lead, and 3 parts of tin.

Brazing Metal. For the coppersmith the most commonly used alloy of copper is called *brazing metal.* Whatever may be the composition of the brazing metal—and this depends upon its purpose—it is always desired to retain to a great extent the malleability, fusibility, and colour of copper. If the zinc be higher than 20 per cent. of the alloy the red colour of copper is replaced by the yellow colour of brass. The chief use of brazing metal is in the manufacture of tubes [see page 5325]. Brazing metal may be made from copper and zinc only, but very small additions of lead and tin make the alloy more easily worked in the sheet. A common mixture is eight parts of copper to from one to two parts of zinc. The best qualities have only 6 per cent. of zinc. Sometimes 2 per cent. of aluminium is incorporated, and is, indeed, specified in some Government work, but although tubes made to this formula give a more rigid joint than ordinary brazing metal, the aluminium makes the alloy less easy to work. A special article on engineers' coppersmithing appears on page 3884 and the following pages.

German Silver. German silver is brass with a proportion of nickel, the amount of which ranges from 15 per cent. to 25 per cent. according to the quality of the alloy. A formula frequently used prescribes three parts of copper to one part each of zinc and nickel. German silver ought to be of silver whiteness and almost untarnishable if made from pure metals, but the presence of impurities such as arsenic and antimony in the constituent metals detracts from this result. A small proportion of tin—up to 3 per cent.—permits German silver to take on a high polish; lead or manganese in a similar proportion increases the fluidity and gives good castings, while iron increases the hardness and helps the whiteness. The usual method of making German silver is to make an alloy of nickel and copper, and another alloy of nickel and zinc, the latter being added to the former while both are in the molten state [see also page 5983].

Copper Amalgam. Copper amalgam is an alloy of copper and mercury; it has a wide field of industrial use. Its chief sphere is in the recovery of gold from the crushed quartz by the use of amalgamated copper plates [see page 5847]. The alloy is not obtained by the direct method—that is, by uniting the fused metals. There are several methods of preparing copper amalgam, and we may notice one of them. Zinc strips are immersed in a sulphate of copper solution and shaken vigorously. The copper, which deposits as a fine powder, is washed and triturated with a solution of nitrate of mercury. Hot water is poured on the copper, and mercury (seven parts to three of the zinc) is added. The mass is kneaded into combination, and a longer kneading makes it more intimate. Then the water is discarded, and the paste remaining can be shaped to any desired form. Copper amalgam has the curious property of becoming soft when placed in boiling water. It is also used to a limited extent in cementing metals together. The metals to be joined must be heated to just under 200° F., after which the amalgam, usually in the shape of wire, is applied and the parts pressed together.

Manufacture of Brass. The earliest method of manufacturing brass was to fuse copper with zinc-bearing ores, usually calamine [see page 6166]. The results of this method were by no means uniform, owing to the varying properties of the ores used, even with ores from the same bed. Thus, as with all rule-of-thumb methods, the men who practised this method had to be expert in their judgment, able to tell by colour and fracture that the desired point in alloying had been reached. This method has not yet quite disappeared, but it has almost done so, and its death knell has long sounded in the best modern practice.

The present day practice of the brass-founder is to heat the metals in crucibles placed in furnaces. Many attempts have been made to dispense with the need for crucibles in brass making, but all attempts to fuse the metals direct in special furnaces have been unsatisfactory and have resulted in a return to the crucible. The types of furnace vary with the kind of fuel used, and with the size and regularity of the output. We may consider a furnace of small size heated with coke, and taking one crucible, capable of making about 80 lb. of brass. The furnace is about 28 in. deep with a horizontal section about 15 in. square. The chimney must be not less than 15 ft. high, and is usually 10 in. square, the flue connecting it with the furnace being, say, 7 in. by 10 in. The crucible rests on a firebrick placed on the firebars. It is heated, usually, by being placed upside down in the furnace. Then it is placed upright and packed around outside with coke. The copper and zinc have meantime been weighed in their proper proportions, but not mixed. The copper, in small pieces, is placed in the hot crucible and melted. Then the zinc, or spelter, broken into small pieces and warmed, is added gradually and stirred. Zinc volatilises, so that the proportion of zinc in the final alloy is never so high as it was in the weighed metal. Every time brass is remelted the zinc content becomes less. The brassmaker allows for this loss by using more zinc, in a definite proportion, than he wishes the alloy to show. As the metals fuse, the surface is sprinkled with powdered charcoal, borax, or broken glass, so as to prevent oxidation. After all the zinc has been melted the crucible is covered over for a few minutes before being poured. If part of the charge is old brass, this is melted first, then the copper is added, and when the latter is fused the zinc is put in as already described.

Brass Furnaces. There are many so-called improved furnaces, each with specific claims to merit, offered for the use of brass founders, but the

common furnace has too strong a hold to be easily displaced. Tendencies during recent years have been towards liquid fuel instead of hard coke, and the value of many patent furnaces offered has consisted in their ability to utilise cheap oils as fuel. Gas is also used for brass melting, and may be the most economical fuel with a very small plant and where the work is intermittent.

Patterns for Brass Castings. Patterns have been discussed at some length in previous articles [see pages 2337 and 2453], and the general remarks and instructions there given apply to brass. The small size of most brass castings causes the use of metal patterns to a far greater extent than for iron castings. Metal patterns, generally, give cleaner castings than wood patterns, and brass castings often carry some finely-cut ornamentation for which wood would be unsuitable as a material upon which to work. Metal patterns for brasswork are usually made of brass, primarily because it is more convenient to make them of brass in a brass foundry, and also because brass patterns require no preliminary preparation such as rusting and varnishing as iron patterns do, an application of a black-lead brush being all the treatment required.

Moulds for Casting Brass. The condition of the sand is of great importance in brass casting. If the moulds are made of loam they must be thoroughly dried before use. Good moulding sand is better than loam, however. If the sand is too meagre it will give a rough surface, occasioning labour and expense in finishing. The addition of a little flour paste to the sand will obviate this trouble, and if the sand be too "fat," the addition of powdered charcoal will prevent bad effects. The pouring temperature must be carefully gauged. If the metal is not hot enough, sharp castings cannot be secured; and if it is too hot, porous castings will result, and there will be loss of zinc by oxidation. Casting from the bottom is desirable as thereby the air cannot rise through the casting and cause blow-holes.

Brass - founding. In brass-founding, the ordinary iron-founding practice is followed [see page 2862], but there are a few points where variation is required. The contraction of brass in cooling is greater than that of iron, therefore the patterns have to bear a different relation to the work. Small castings of brass—say, under 12 in. long—shrink $\frac{1}{8}$ in. in each foot, and over this size the contraction is $\frac{3}{16}$ in. Brass sets more quickly than iron, therefore the molten metal must reach home more quickly, and to secure this the gates and runners are usually made larger. The sand used for brass is generally more porous than it is for iron, and there is not so much venting. Much brass work is poured through the ends of the mould boxes instead of by the top, the boxes in the end pouring being made to be at an angle in a trough, the object being that spilt metal may be recovered from the trough instead of being lost in the sand. Vertical pouring, which is common with iron castings, is infrequent with brass, there being less risk of scabbing and of blow-holes in the latter case.

Casting Bronze on to Iron. Sometimes it is desirable that a piece of mechanism should be of iron or steel inside and of brass or bronze outside. We may take as a typical instance of such work the pump plunger, which may be wanted with an iron or steel centre and with the working part of bronze which will withstand corrosion. The bronze part could be cast separately and fitted on, but this method entails much labour and expense. A cheaper and thoroughly satisfactory job may be made by casting the bronze upon the iron as a centre if proper precautions be taken. Brass or bronze cast upon iron is more or less spongy or porous, and would, in most cases, be unsatisfactory as the working surface of a piece of mechanism. The method of overcoming this objection is by casting upon the iron or steel a layer of brass or bronze only half of the desired ultimate thickness of the brass or bronze. The centre, of iron and steel, should for preference be tinned, as the copper alloy will unite with the tin easily, but tinning is not essential. Its absence may cause a little sputtering as the metal is poured, but it will give as good a result as when tinning is practised. If the iron or steel be not tinned, it should be cleaned and polished. In casting, this iron or steel is used as a core, and the porous coating of brass or bronze forms a good surface upon which to cast a second and final layer of brass or bronze, which will not in this case have the tendency to be spongy. The second pouring is made when the first cast is cold and when, of course, the second mould has been prepared for it. The second cast should be given under a good head of metal so as to get a good dense casting. The two castings of brass or bronze should unite solid, and can be machined in the usual way for the finished mechanism.

Modelling. In brass castings, especially those of an ornamental nature, modelling in clay is practised in the preparation of patterns to a considerable extent. The clay model is reproduced in plaster of Paris, and from the latter tin sections are cast, or rather sections made with an alloy of three parts of lead to one part of tin. These sections, when built up together, form the working pattern for the moulder. Modelling is used in ornamental ironwork also, but we give it an extended notice in this section on account of its application in the brass foundry and because most textbooks neglect it.

Modelling is chiefly suitable for light and ornamental castings. The actual task of modelling in clay is the work where, more than in any other which falls to his lot, the workman may give expression to any artistic feeling he may possess. The general work of clay modelling has been discussed in another course [see pages 1349 and 1532], and the technical details there given permit us to be brief upon that part of the subject. The clay must be soft and pliable. It is prepared by grinding, and all stones and grit are removed. The tools necessary are few and simple. The most important are the ten fingers of the workman, and he supplements these by a few boxwood modelling tools and floats. The chief work is done with the fingers, which press and knead the clay into the form desired. The tools are used to impart the finer lines, to remove any excess of material, and generally to give the finishing touches. The work is nearly always in low relief, as high relief would be impossible without undercutting, which would not allow the finished article to leave the mould.

The work is usually done on a modelling board, stiffened at the back and coated on its surface with a few applications of shellac varnish. Thus the moisture of the clay does not penetrate into the board. This board is placed on trestles or on a bench, and the clay is placed on it and manipulated as already stated, the operator working to his drawing. If the work cannot be completed at one sitting, a damp cloth thrown over the clay will cause it to remain soft and pliable. The work finished, the clay is allowed to get somewhat firm,

after which it is removed from the board, which may be helped by pulling a piece of thin wire right down the board, meantime holding it across the full width of the board under the clay. If the impression of the clay model is to be taken in plaster of Paris, this is generally done before the clay leaves the board. The tin alloy pattern is cast from the clay on the plaster of Paris counterpart in the ordinary way, and the material, while hard enough for ordinary handling, is pliable enough to be bent and modified in shape and to have the ornamentation cut or deepened with ease and good result.

Brass Burning. In casting brass, it may be that the casting desired is too large for the capacity of the crucibles or of the furnace. The difficulty is overcome by *burning* or autogenous soldering [see following article]. The process consists in making the full-sized casting in two or more pieces; then, by placing these in their proper positions in a sand mould and by pouring molten brass so that it flows around the surfaces it is desired to join, a homogeneous casting as strong as if it had been cast in one piece is obtained. In preparing the brass castings for burning, the surfaces where the join is to take place are filed or scraped, so as to free them from scale. It is desirable that the new metal should be hot, therefore an excess of metal is allowed, the first part of the pouring flowing out through a gate and heating the surfaces as they pass over them; then the metal that remains finally comes upon the heated surfaces and the union is made.

Plate Brass. Brass which has to be subsequently rolled into sheets or cut into strips to be drawn into wire [see page 5171] must retain its ductility, hence special precautions are necessary in casting the thin plates which are to be subject to this special treatment. Sometimes iron moulds have been tried, but have never had extended favour due to the fact that the brass cools off too rapidly, although this defect might be overcome by heating the moulds before casting, and by allowing them to cool off gradually by the application of external heat.

In many places loam moulds and sand moulds are used, but granite moulds are also in extended use, and give good results if properly manipulated. A granite mould is made of two granite slabs, the lower one a little wider than the upper. Both have an even coating of clay covered with cow dung, and are kept at the proper distance apart by iron bars placed between them at their ends. The slabs are bound together with iron bands. Their normal position for pouring is at an angle of 45° from the horizontal, and as soon as the poured plate has solidified, it is removed and another poured, so that the mould remains warm. The plates removed from the mould are cleaned with wire brushes. Then they are rolled and sometimes hammered. Sometimes they are rolled hot only, and sometimes the hot rolling is finished by cold rolling. This depends upon the nature of the brass. The composition may be capable of extension by rolling only if hot. Between each rolling the sheets are annealed to give back the ductility which the previous rolling has taken from them, and before passing between the rolls they are coated with oil. If the final sheet be required soft, the last process is one of heating and quenching in water, while if a hard sheet be required, this heating is omitted.

The sheet at this stage does not resemble brass. It is black, and must be pickled—that is, dipped into a bath made of water with 10 per cent. of sulphuric acid. This may complete the preparation for the market, or another bath of nitric acid in water or a mixture of nitric and sulphuric acids in water may be given. Nitric acid dissolves zinc more quickly than it dissolves copper, so that a sheet that has come from a nitric acid bath has a surface richer in copper than the body of the sheet; hence a redder shade of brass.

Casting Bronze Statues. France is the headquarters of statue-founding in bronze. In that country the appliances and methods are the best, and the results unexcelled, and seldom equalled. The old process of statue-founding was by what is known as the *cire perdu* process [see pages 1674 and 5526], and this is still practised. By this process a rough model of the object is first made in sand or porous cement, and this is coated with wax to the same thickness as the metal which is to form the statue. Then the artist works upon this wax surface, giving the final form by delicate touches. Then several pieces of wire are pushed through the wax into the core. Now the wax is carefully coated with liquid sand, and is placed in an iron frame, which is filled up with sand. The frame is taken to a warm place, where the moisture escapes from the sand, which becomes firm. Holes are now pierced through to the wax coating, and the frame is then placed in a hot oven, where the wax melts and runs out, leaving the core supported in position by the wires which were inserted for the purpose. Bronze is now poured in by the holes through which the wax escaped, and the statue is cast. If this process produce a perfect statue, all is well, but this result is by no means certain. The operation is delicate, flaws are frequent, and if the statue be imperfect, the work of the artist has gone for nothing, because his wax model has been destroyed in the process. For this reason the *cire perdu* process has been superseded in the best French practice by a less risky process, which leaves the work of the artist uninjured if the casting be bad, so that subsequent attempts may be made without the necessity of beginning the work again *de novo*.

Piece Moulding. By this newer method the sculptor makes his design in plaster, and the rest of the work is mechanical, albeit demanding a high degree of skill on the part of the founder. The plaster statue is placed in a bed of sand, so that it may rest solid and still be comparatively safe from injury. Then the moulder begins the operation of *piece moulding*, so-called. Selecting a small section of the statue, he presses sand into every crevice in it, and obtains thereby a mould giving an exact impression of that section to which he has been devoting attention. He does the same with another section of the statue, and so on until he has the whole surface of the plaster statue impressed upon the several moulds that he has made. The plaster statue itself may now be put aside, and may not again be required. The small impressions that have been taken in sand are carefully fitted together in their proper places in the mould-box—a task requiring high skill. A rough facsimile is now made, a little smaller than the original statue, and this does duty as a core, the space between the two faces representing the thickness of metal of which the statue is to be. The mould and core are then dried in an oven to remove moisture, and to harden the sand. Vents and runners are made, and when all is ready the casting is poured. Should it be faulty for any reason the operation must be repeated; but this is not the serious matter it is by the *cire perdu* process, because the plaster statue remains upon which to work.

In statue-founding great care is taken in selecting the metal. Colour and homogeneity depend upon the bronze alloy, and no metal of which the exact composition is not known is allowed to enter. No old brass and copper are used, and the ingot copper employed is usually purified by liquation before the actual process of founding. Good work is possible only by having a highly-finished mould capable of producing a sharp casting which will require only very little chasing. The sand employed is also important. It must be carefully selected: it is usually blended to suit the nature of the work in hand, and is then passed between cast-iron rollers to give it uniformity. The moulding boxes must be accurately fitted, and their edges are usually planed.

Dressing Castings. Castings which come from the mould must be *dressed* or *fettled* before being ready for the more delicate operations of finishing. The nature of the dressing depends upon the metal under consideration, the perfection or rather imperfection of the casting, and upon the subsequent finishing processes, if any, to which it is going to be made subject. The processes of dressing castings are similar whatever metal may be employed, and we shall describe briefly the appliances used, having special regard to the fact that we are considering castings of brass and bronze.

The usual extraneous metal upon a casting as it emerges from the sand takes the form of ragged edges, fins and spurs. Cores are removed from castings usually in the foundry, and if they be large this is usually done before the casting is quite cold. A casting is *trimmed*, the first process entailing the removal of prominent spurs, by being *chipped*, by the hammer only, or, if necessary, with the assistance of a cold chisel. Sometimes pneumatic hammers [see page 5455] are used. Then fins, which are not sufficiently prominent to be properly removed by this means, are rubbed, generally with old files, which have served their first usefulness in the fitting or machine shop. Sometimes cast-iron files are used. For brass there are not the same reasons of economy for the use of old files, and good files may be employed, the brass being softer. Then the castings are usually ground. Grindstones used to be employed, but the better practice is to use emery wheels [see page 5210]. They are better than grindstones. They should not be "forced"—that is, the work should not be pressed against them with too great force, as this is bad for both the work and the tool. For large castings, which cannot be moved about over the periphery of the wheel, an emery wheel fitted to the end of a flexible driving shaft may be used. It can be applied to any accessible part of a stationary casting, but brass castings are seldom of so large size as to demand treatment by this method. But a wire brush mounted upon a flexible shaft in this manner is often used, and is valuable as an instrument for removing adhering sand.

Another process often employed for small casting is that of "rumbling"—that is, placing them in a cylindrical chamber which is made to revolve upon a horizontal axis. As this process wears the edges chiefly, it is not suitable for small castings of an ornamental nature. We have seen a similar process in pin manufacture [page 5171], and in tinning [page 6164]. Sharp sand, small star-shaped castings, known as "stars," and sometimes sawdust are placed inside the rumbling cylinders, and made to revolve with the castings under treatment. But perhaps the best method of cleaning cast surfaces is by a sand blast machine. This ingenious invention—similar to that used for decorating glass [see page 4932]—is a vessel in which a supply of sand is contained in a chamber with an aperture at the bottom, this aperture being capable of regulation as to size and as a thin stream of sand falls through the aperture it encounters an air blast—usually of from 5 lb. to 15 lb. per square inch—which carries it through a flexible tube to a nozzle, whence it is blown upon the surface of the casting. The workman guides the nozzle, and its value over the tumbling process already described is that the work can be directed to the points where it is most required, and not to prominent points only.

Brass Spinning. The die press and the draw press have modified the practice of working sheet metals considerably, not only by doing away with the need for much of the hand or "piece" work formerly undertaken, but also by making possible many forms of work formerly unattainable. The process of spinning sheet-metal is usually subsequent to the work of the press, which is an economical means of securing a blank suitable for spinning. Spinning is the operation whereby an object such as a reeded curtain-pole end, a brass bed-knob, or a berry pan, is given its shape. The operation is simple, but clever. It can be carried out upon work in the flat state which has been cut out by hand or by press, but it is economical in most cases to put the work through the draw press before spinning. For spinning, a "former" is required. This former must be of the shape which it is desired the final form of the article shall have. The widest part of the former, however, must never be larger than the narrowest neck of the spun article, else the former could not be withdrawn after the article had been spun.

The spinning lathe, in which the work is performed, is a machine with a bed and fixed headstock having a chucking arrangement suitable for holding the articles, usually of cylindrical or cup shape, or something approaching thereto. The article is held in position on the formers by a movable tail stock, and special burnishing or friction rollers carried upon a compound slide-rest are made to press against the work, and cause the metal to "flow" into the required shape, the form being given by applying the pressure at the proper points. It is possible to give by spinning not only plain ridges and grooves, but ornamental patterns, such as milled, beaded, and spiral edges, such forms being attainable by the use of pressing rollers and formers carrying the particular pattern it is desired to impress upon the work. For spinning work, the result depends upon the high speed at which the work is made to revolve. The operation we have described utilises burnishing or friction rollers attached to the slide-rest. This is the modern practice, and is the best for cheap work where thousands of one article are being made, but for some work, other than brass, such as spun Sheffield ware, it is common to use burnishers, held by hand and pressed against the work without mechanical aid other than the strength of the workman.

GARDENS IN TOWN & COUNTRY

Garden Tools. The " Back Garden" in Town. Window Decoration. Trees and Shrubs for Town and Country. Walks and Lawns. Rock and Water Gardens

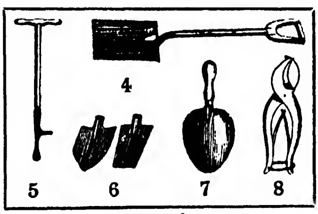
Continued from page 6206

By HARRY H. HAVART

The Gardener's Tools. The most important garden tool is, of course, the spade [4], which is an implement perfectly distinct from the shovel, although the names are often interchanged, and one tool used for the purpose of the other. The spade is used for digging, and the bottom of the blade should be of steel, and the upper part of iron, thoroughly welded together. Young gardeners often suffer pain, when digging, from the pressure of the foot on the tread, or shoulder, of the spade. This can be obviated by using a little contrivance called a " digging shoe," a sort of anklet of leather which buckles over the middle of the foot, so that there is a good layer of leather acting as a protector where the foot presses on the spade. Spades are made in four sizes—1, 2, 3, and 4, of which No. 3 is probably the most useful implement.

The Shovel, Fork and Rake. The shovel [6] is used for shifting loose soil, clearing trenches, handling manure, and similar purposes. Its blade is broader than that of the spade, and it is usually pointed, so that it can be pushed into piles of loose earth more readily than the spade. A shovel with a long handle is the best, as this obviates the necessity for stooping.

The garden fork is a most useful, though somewhat neglected implement. Much of the work of breaking up ground, which is at present done with the spade, could be done far less laboriously with the fork. A four-pronged fork is the most useful, though some are made with three, and some with five prongs. The fork is particularly useful in stirring the surface soil between plants, to aerate it. Short-handled forks are handy implements for taking up small roots, transplanting, or weeding, being, for this purpose, generally handier than the trowel.



GARDENERS' TOOLS
4. Treaded spade 5. Bulb planter 6. Shovels 7. Trowel 8. French secateur

The rake is not so much used as formerly, except the wooden variety, which is used for removing dead leaves from lawns, and other similar purposes. There is a variety of rake, however, called the " daisy rake." This has short teeth very close together. It is used to drag over lawns, to pull off the heads of daisies, dandelions, and other lawn weeds.

Lawn Mowers and Other Tools. Lawn mowers vary a good deal in detail, but most of the best makes are so equal in merit that there is little to choose between them. It is well to consider the area of the grass to be mown in selecting a lawn mower as far as size is concerned. A large lawn mower on a small lawn means expenditure of unnecessary labour, and the same remark applies to the opposite condition—a small mower on a large lawn. The chief thing to be observed is to keep the cutters properly sharpened, as an attempt to mow a lawn with blunt cutters is simply waste of time. The edges of grass which the mower cannot well reach must be cut by means of shears, which are made with both straight and curved handles.

The pruning knife has been almost superseded by the secateur [8]. This instrument is really a sort of miniature shears, and, in the hands of an inexperienced gardener, is certainly a much better implement than a pruning knife as it makes a cleaner cut, and there is less danger of cutting away too much with it.

The trowel [7] is an indispensable little implement for transplanting cuttings and small plants. First of all the hole to receive the plant should be made, and then the trowel should be used to scoop around the root of the plant, and lift it out bodily, when it can be carried on the trowel and placed in the hole prepared for it. A bulb-planter [5] is particularly useful for planting bulbs in lawns.

Other gardener's tools include the watering-pot, wheelbarrow, saw, and hammer, the uses for which are obvious.

The Little Back Garden. The poor little square patch which is known to the town dweller as the back garden is the most handicapped piece of soil in the world. It is situated so that surrounding walls and sides of houses either cut off air, light and sun from it altogether, or else admit the blinding glare of the sun's rays to scorch the ground up, while effectually screening any refreshing breezes. Further, the prevalence of smoke chokes up the pores in the stems and leaves of the plants, and prevents them from breathing, while the elaborate systems of drainage with which all towns and cities are replete, act indirectly upon the gardens by drawing away the moisture from the subsoil. Without this moisture in hot weather the roots of plants can never be healthy, and success in cultivation becomes more difficult.

Laying out the Small Garden. These little back gardens are usually square, and where any attempts at gardening are made they generally take the form of a narrow border running all the way round, while the remaining space is devoted to turf, with, perhaps, a circular bed in the centre.

The one point in favour of this plan is its simplicity, but it has the effect of making a garden look hard and formal. A more picturesque way of laying out a small garden is to make the border of an irregular width, curving it in and out as fancy directs, easily and gracefully, though never in such a complicated manner as to appear grotesque.

The centre of the garden can either be laid out simply as grass (the best method where there are children, as it gives them just a few yards to play in), or it may be broken up by arranging for the planting of one or two flowering shrubs, or by the introduction of a bed or beds as may be desired. A very interesting and easily-attained feature of a town garden is a small bed treated as a rock garden, particulars of which are given later.

Trees and Flowers in Town Gardens. Large trees are a mistake in a very small city garden. Although it seems a pity to advocate the cutting down of even one tree, there can be no doubt that their presence in a tiny back garden is a grave menace to the health of the inhabitants of the house, and also militates against success in growing plants, owing to the terrible drain it is upon the nourishing elements in the soil. The same remark applies, to a certain extent, to laurels and privets, which form the lazy man's garden.

The names and habits of many flowers and plants suitable for city culture will be found in future pages, but for general use it may be mentioned that the two most useful climbers for hiding walls and fences that face the east or north are the Virginian creeper and Rægner's, or a variegated ivy. Variegated ivies like poor soil; it brings out the variegations better. For sunny situations, purple and white clematises, Veitch's ampelopsis [11], or vine, Canary creeper, Japanese hop, and yellow, winter-flowering jasmine are the best. Of shrubs, the best are the mock orange, aucuba, flowering currant, variegated euonymus, rhododendrons, and Syrian hibiscus.

These may be put in when the laying out of the garden is first begun. If put in in the autumn, a handful of straw laid round the bottom of the stem will prevent the frost from getting at the roots.

Window-boxes. Every window, whatever its aspect, can have a box upon its sill in which flowers will grow [11]. Such boxes, with tiles or ornamental fronts, are to be bought, but there is an easy way of making them. Measure the window-sill, and make a box to fit it, about 9 in. deep. Get a piece of clay and daub it, putty-wise, along all the joins and corners, so as to make it watertight. To each bottom corner nail a strip or block of wood about 1 in. in depth, so as to prevent the box from standing close on the window-sill. In the middle of the bottom of the box bore three or four small holes, about a couple of inches apart from each other to allow superfluous moisture to drain away.

9. RHODODENDRON BLOOM

Then paint the outside only of the box a dark green or brown. Fill the box to about one-third its depth with bits of broken flower-pots, china, brick, stone, or any similar material, to form drainage, and then fill it up with earth which has been carefully picked over, or sifted, to get rid of all big stones, and well mix with silver sand. The window-box need not be a thing of beauty in the summer-time only. When gardening operations begin in the autumn, some dwarf conifers should be put in to keep the boxes bright during the winter, and at the same time bulbs must be planted to keep them gay from March till June, by which time the spring-sown plants will be bursting into bloom.

One of the most important points in connection with window-box gardening is that the plants should have sufficient water in the winter time. It is just the season when plants fully exposed in the open air are being soaked by wet and snow, so that if the window-box is in a sheltered position it should be watered, if not as frequently as in the summer time, at least twice a week.

Trees and Shrubs for the Town. It is impossible to expect a good garden if the trees and shrubs which it contains are either of the wrong sorts, or are wrongly planted.

Of the trees most suitable for planting in town gardens, the following is the best selection: Sycamore, common almond, plane, poplar, common elder, horse chestnut, American cherry, ailantus glandulosus, and most of the hollies, which, although of slow growth, will more than repay the care bestowed upon them within a few years after planting. The same remark applies to the euonymuses, of which the variegated sorts are preferable, their foliage being brighter and more pleasing.

Many of the privet hedges now to be found in surburban gardens might, with advantage, be replaced by box, which, although of slow growth, is neater in appearance, and readily kept in hand. An excellent, though much neglected, tree for a suburban garden, especially where there is anything in the shape of a lawn, is the black mulberry (*Morus nigra*). Not only does it thrive under the most unfavourable conditions, but yields a generous supply of delicious fruit in the autumn. It is for this reason that it must be grown in grass, as otherwise the fruit, which should not be gathered, but allowed to drop, will be injured when it falls to the ground. The presence of the turf prevents it from getting damaged.

The best evergreen shrub for town planting is undoubtedly the rhododendron [9]: until lately it was thought to be not quite hardy, but by means of hybridisation many kinds, embracing all colours, are procurable. The old-fashioned ponticum rhododendron is now usually relegated to countryside coverts.

Trees and Shrubs for General Planting. Trees and shrubs which may be used for general purposes in gardens throughout the country embrace some thousands of species. Many of these will thrive only in the sheltered gardens of the South and West of England, and it is useless to attempt to grow them in other districts. They are divided into two classes, one known as deciduous, or summer leafing, and the other as evergreen. The latter class is green all the year round, while, during the winter months, the deciduous kinds have nothing but bare stems to show. At the same time, the most brilliant displays of bloom are usually to be found on the summer-leafing shrubs and trees.

A list of the most useful evergreen trees and shrubs includes the following: Andromeda, arbutus, aucuba, berberis, cerasus, choisya ternata, cistus, cotoneaster microphylla, daphne, elæagnus, erica, escallonia, euonymus japonicus, garrya elliptica, hedera, ilex, kalmia, laurus nobilis, olaria haasti, quercus ilex, rhododendron, skimmia, ulex europæus veronica, vinca major and vinca minor, and yucca gloriosa.

The following are among the best of the summer leafing sort: Acer, aesculus, ailantus glandulosus, alnus, amelanchier, amygdalus, aralia spinosa, azalea, berberis, betula, buddlea globosa, calycanthus

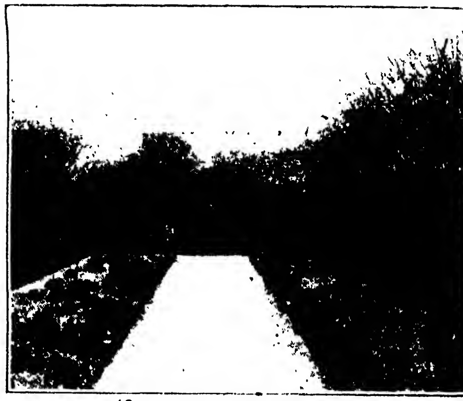
floridus, carya, catalpa bignonioides, cerasus, corylus avellana, cotoneaster, cratægus, cytisus, daphne mezereum, deutzia, elægnus augustofolia, fagus, forsythia, fraxinus, genista, hamamelis, hibiscus, hydrangea, juglans regia, kerria japonica, laburnum, liquidambar, liriodendron tulipifera, magnolia, morus, persica vulgaris, philadelphus, platanus orientalis, populus, prunus, pyrus, quercus, rhus, ribes, salisburia adiantifolia, salix, sambucus, spiræa, syringa, tamarix gallica, tilia, ulmus, viburnum, and weigela.

How to Plant Trees. Upon the proper planting of trees at the outset their future welfare depends. It is not sufficient merely to dig a hole in the ground, cram the roots of the tree or shrub into it, throw back the soil, and make the whole thing firm by stamping upon the base of the stem with an iron-shod boot-heel.

In preparing a hole for the reception of a tree or shrub, it is best to dig it wide and shallow, rather than narrow and deep. The roots should be examined carefully before planting, and any that are broken or injured cut away with the pruning knife, or secateur. The roots should be well spread out in the hole, and the soil gently but firmly pressed in. Should the weather be dry, the young plants should have a liberal dose of water as soon as they are put in the ground. Trees or shrubs that are planted on hillsides, or in other open situations, where they are likely to be exposed to the full force of the wind, should be supported by means of stakes driven firmly into the ground, to which they should be fastened, the stakes being left in for two seasons.

The Time for Planting. Trees and shrubs may be planted with safety at any time between the late autumn and early spring, say from November to March. The bulk of planting is usually done in the autumn, as at this time work is slacker in the majority of gardens than it is after the turn of the year. In town gardens, however, and others in which the soil is of a poor quality, advantage is often to be derived by deferring the planting till the spring. The reason for this is that the roots have the whole of the summer in which to get established before being called upon to undergo the rigours of a winter.

Planting should never take place in wet weather, or when the ground is sodden with moisture, as shrubs and trees planted under these conditions are more likely to rot than thrive. It is also useless to attempt planting when the ground is frozen hard, for not only is digging then almost an impossibility, but the soil cannot be properly replaced, and frost will percolate to the roots through the crevices left, and kill the plants. When, of necessity, planting must be done in frosty weather, it is well to cover the surface of the ground round the bases of the stems with a layer of straw, litter, or other mulch, to afford protection from frost.



10. CLIPPED YEW HEDGES

Transplanting Large Trees. To transplant a large tree, it is first necessary to expose its roots. This is best done by loosening the soil around the base of the tree, preferably with a fork, for a distance which corresponds to a spread of two-thirds of the distance covered by the branches above. The soil should be carefully cleared away with shovels, care being taken not to injure the roots, which should be lifted up out of harm's way as exposed. When the soil underneath the tree has been well tunnelled, a shallow trolley should be run underneath and the tree carefully levered on to it, being held in position by props consisting of young larch poles, and secured with ropes. If the roots are not wide spreading, it is well to lift the tree with as large a ball of soil attached as possible, as this not only prevents damage, but helps the tree to more quickly establish itself in its new surroundings. It is important that a transplanted tree should have the same aspect as it did originally; hence before moving it is usual to mark one side of the tree with a dab of whitewash.

Making Woods and Shrubberies. The trees most generally employed in the making of woods are the fir, pine, beech, birch, oak, larch and, to a smaller extent, the elm. This latter tree has fallen into considerable disrepute, especially for belts, or avenues, overhanging roadway or path, where it is often a considerable source of danger. This is owing to the fact that for some reason unknown up to the present, branches apparently sound, often weighing many hundredweight, are liable to break off suddenly and fall to the ground without warning.

Oak plantations are, in the fulness of time, the most profitable of any, but the reason that so little young oak is laid down at the present day is that it is of very slow growth, and few landowners are prepared to lock up the capital entailed in the establishment and maintenance of oak woods.

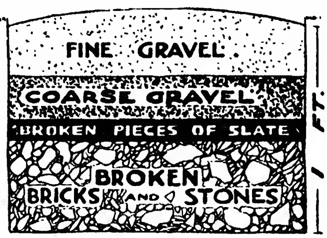
The system which has been found to answer best in making a plantation is to employ nursery grown plants from two to three years old. These are inexpensive, ranging in price from about 5s. per thousand

11. THE WINDOW-SILL BEAUTIFUL
(Pelargoniums and ampelopsis)

for the cheaper sorts of firs up to 30s. per thousand for oak and the other choicer varieties. Opinions differ as to the best distance apart at which to plant these young trees, but a good all-round rule is to allow a space of 5 ft. every way between them. It is usual to "nurse" trees of slower growth, such as oak, by planting a quick-growing timber, such as larch, between them. By the time the oak is sturdy enough to take care of itself, the larch may be thinned out and cut down, if it is not desired to retain it.

Some of the tenderer growing firs are often "nursed" in a similar manner, but there is a simpler way in dealing with this variety of tree. This is to sow the ground, when planting the young firs, with seed of the common gorse, which, being a very rampant grower, speedily affords all the protection needed. Care must be taken not to let it go too far, however, or the gorse may choke a large number of the young conifers. Many firs have a tendency to develop what are called side breaks. These are shoots which appear near the top of the tree, so that instead of tapering away gracefully to a point, as it should do, the centre stem breaks away in three or four directions, not only destroying its symmetry, but greatly lessening its commercial value. These side breaks should be cut off in the early stages of growth.

Where not to Plant Trees. Much care must be exercised as to the position in which young trees are planted. The gardener who fails to look far enough ahead is apt to place them where, although they are very pretty and effective for the time being, they will be the source of great trouble, say, fifty years hence. Trees should never be planted quite close to a house. First of all there is a danger that the roots may spread sufficiently to injure the foundations of the building; secondly, if the house be a low one, there is risk of damage from the dripping of the rain upon the structure as it falls from the leaves and branches; and, thirdly, the presence of big trees near a house interrupts the free circulation of air, and consequently makes the place damp and unhealthy.



12. MAKING A GRAVEL PATH

It is not wise, either, to plant a tree quite close to the edge of a path, for, as it grows older, it will be found necessary either to alter the course of the path or remove the tree.

Making Hedges. A living hedge is always better than a dead wall, and wherever they can be used in gardens in the place of dividing lines of wood or brick, hedges should certainly be planted. Unfortunately, practically all the trees which go to form good hedges are of slow growth, and take a good many years to form a substantial barrier. The quickest growing of all hedge plants is the privet, and this is probably why it is seen so much in every little suburban front garden. At its best it forms but a straggly barrier, and where, owing to circumstances, it cannot be dispensed with, its ugliness may be redeemed by employing one of the variegated sorts. Plants about a foot in height should be used, and they should be put in in the autumn or spring, at a distance of about 9 in. apart, or closer to form a thick hedge.

The best hedge of all is the holly hedge, but this is one of the slowest to attain respectable dimensions. Plants 2 ft. in height are the best to begin with, planted from 1 ft. to 2 ft. apart, according to their size. They should not be trimmed for at least two years after planting. An old holly hedge forms a barrier that nothing can get through, especially if it be clipped regularly.

The ordinary hawthorn hedge requires practically the same treatment as the privet, though, if it is not cut back within a year or two after planting, it is apt to get very "leggy," the lower part being nothing but a collection of stems.

A yew hedge is probably, next to the holly, the densest and most compact, provided it is clipped regularly in the early spring, before the young growth commences [10]. It should, however, only be used inside a garden, and not to form a boundary by a road or field, or any other place where horses or cattle will be likely to get at it, on account of its poisonous nature.

A Hedge of Sweetbriar. One of the most charming garden hedges may be formed by the employment of sweetbriar. Though this is very little used generally, it makes the most fragrant of all hedges, and deserves to be much more widely known than it is for this purpose. It can be planted at any time when the roses are being planted, and can always be clipped into a neat, compact hedge. This is quite hardy and simple for town use, and is full of perfume during the summer months, in direct contrast to the privet, which, at this time of the year, bears evil-smelling flowers of a dirty white colour.

Near the seaside the euonymus makes a splendid hedge. Particularly is this the case on the South Coast, most of the favourite Sussex watering-places having excellent examples of what can be done with this plant for hedge-making. The tamarisk and the sea buckthorn are also useful in these situations.

During the early years of a hedge's life, it is necessary to watch the young plants very closely, and remove all dying or weakly specimens, otherwise, when the hedge attains maturity, gaps where weakly plants have been will be disclosed.

In clipping hedges, no matter of what composed, they should be cut wedge-shaped, to a certain extent, the narrowest part being at the top. In this way the lower portions are not overshadowed, and thick growth at the base is encouraged.

Walks and Lawns. The making of walks and lawns, and the preparation of formal beds for the latter, are branches of gardening which have to be carried on in such near relation to each other that they should be studied simultaneously.

Most gardens have too many walks. In public parks, certainly, a large number of paths is necessary, because it is only by providing this sort of accommodation for them that a crowd of sightseers can be kept within bounds. No such precaution is necessary, however, in a private garden, where the majority of the walks should be grass ones, prepared and looked after in the manner recommended for lawns. It is impossible to lay down a hard and fast rule as to where a gravel path should be put, as conditions differ in practically every garden of decent size. The carriage drive, of course, must be gravel, so must the main walk to the kitchen garden, the one to the glasshouses, and others which are being tramped over every

minute of the day. An economy, both of time and labour, is effected by making most of the others grass walks.

Unless the exigencies of space compel, it is better never to make a gravel walk a perfectly straight one. Such a path, running hard and uncompromisingly out in the perspective, is rarely a pleasing sight, even if fringed by the choicest flowers. At the same time it is absurd to make a path wriggle all over a garden for the mere sake of doing so.

Nowhere in the world are such lovely lawns to be found as in our own gardens, and few things are more refreshing to the eye, or more beautiful, than an expanse of smooth, unbroken turf. This fact should be borne in mind when laying out a garden, and care should be taken to keep all beds near the edge of a lawn, and not to go dotting them at regular intervals all over the turf just for the sake of symmetry. Such a garden is sure to be hard and unnatural.

How to Make Walks. The first step in the making of a walk or path is to map out exactly where it is to go. In the case of a large garden, a plan must be prepared on paper first, otherwise confusion will invariably result: but with a small garden this is not necessary. Then the course of the path must be traced out on the ground by means of cords, to which, at intervals, small pegs are attached. These strings and cords are one of the gardener's most important tools in the early work on the ground, as they serve to outline every bed and border, and determine the width and direction of every path.

When these points are satisfactorily settled, the soil, to the depth of about 1 ft., should be dug out all along the course of the proposed path, and carted away. Needless to say, it will be much appreciated elsewhere. At the bottom of the trench thus made a layer of broken bricks and large stones should be distributed in as level a fashion as possible, to the depth of 6 in. or 7 in., for the purpose of drainage. These should be well crammed down, and covered with 2 in. or 3 in. of coarse gravel, which must be well rolled in. Upon the top of this the final layer of fine gravel rests, to the depth of 2 in. or 3 in. In building up the path the surface should be made a little higher at the middle than at the sides [12].

If available, a layer of pieces of broken slate, about 2 in. in thickness, should be placed between the broken brick layer and that of coarse gravel, as worms cannot penetrate this material, and unsightly worm-casts are prevented. Much rolling is necessary when a path is first made, as otherwise the top layer will never become hard and firm.

When once a walk or path is made, there is always the task of keeping it free from weeds to be considered. By far the most efficacious way is, of course, to pull up the weeds by the roots as fast as they make their appearance. There are many chemical weed-killers on the market, but they require very careful handling, as not only do they kill weeds, but everything else with which they come in contact. A dressing of salt is a pretty effective weed-killer, and an application of boiling water serves a similar purpose.

13. WATERSIDE PLANTS, KEW GARDENS

A stone path is a good path if properly constructed, and is always practically dry. In constructing such a walk, proceed as indicated for gravel walks, until the layer of coarse gravel is laid and rolled. Upon this should be laid just an inch or so of soil, and in this, embedded roughly, shaped pieces of flat sandstone, in the form of an irregular mosaic. Old paving-stones, such as may be procured from any contractor's yard, and broken up with a sledge hammer into pieces of any size from 6 in. to 2 ft. across, are excellent material for the purpose. As these are embedded, a little soil should be pressed into the chinks between each piece, and in these chinks stonecrops and mosses may be planted. These will quickly establish themselves, and form a very pleasant walk in the course of a season or so. Such stone walks are, as yet, comparatively rarely met with, but their many advantages over the gravel walk, and their picturesque appearance, are gradually bringing them into favour.

The Making of a Lawn. There are two ways of making a lawn—by turfing and by seed. In places where, in forming the garden, good turf has been cut off and stored from parts of the ground when levelling is going on, it may well be replaced; but where an entirely new lawn has to be made it is better to employ grass seed than to purchase turf and lay it.

Before sowing, an operation which is best carried out in the springtime, the ground should be well dug over with a spade, all lumps being broken up with a garden fork, and afterwards gone over with a rake, to ensure that the surface soil is nice and fine, and, moreover, free from stones. Then go over it with the roller, being careful, especially in the case of a tennis lawn, to see that it is quite level.

As soon as the surface is nice and smooth, it is ready to receive the seed. The regulation quantity of seed, as recommended by all the leading authorities, is 1 lb. of seed to every 16 sq. yd. In other words, a bushel of grass seed will sow

14. A MIXED BED (Mostly *Lilium speciosum rubrum*)

an area of 400 sq. yd. Two apparently trivial but really important points must be observed when sowing a lawn. There must be no wind, and the sower must not wear high-heeled boots. Grass seed is very light, and even a moderate breeze would blow it into uneven patches as it leaves the sower's hand, while high heels would dig into the ground, in its unsettled state, and disturb the level. A pair of cheap canvas shoes with indiarubber soles and no heels are the best footwear for this work.

When the seed is sown it should be covered by just the slightest covering of loam or sand, and rolled lightly. If the soil be a heavy clay, the covering of sand will be the best, while if the soil is in itself a light one, it will benefit more by the sprinkling of loam. This must in turn be rolled, but lightly, otherwise the delicate little blades of grass might find difficulty in forcing their way to the surface. Where there is any danger of the seed being attacked by birds, black threads should be stretched at intervals across the ground, 2 in. or 3 in. above the surface.

The new lawn should not be rolled or swept until the grass is 2 in. or more in height, when it may be rolled lightly and swept gently. A lawn mower should never be used to a new lawn, as it is apt to tear the tender young grass up by the roots. The scythe is the proper implement to employ for this purpose. This operation should be carried out early in the morning, when the dew is on the grass, as the scythe works best at these times. The mowing machine, which may be used when the summer comes and the grass has got well established, works best when the ground is dry, and may therefore be employed at midday. To ensure a good velvety turf, a lawn should be well mowed and rolled at least once a week. Daisies, dandelions, and other weeds should be rooted up without mercy by the instrument known as a daisy fork.

15. A PINK-FLOWERING WATER-LILY
(*Nymphæa rosea*)

Carpet-beds on Lawns. A carpet-bed is a bed formal in outline, and also in the nature of its contents, which are composed of dwarf plants of a similar height, arranged in a set pattern, sometimes to form a word or motto, or else according to a geometrical plan, so that they resemble a part of a pattern or a carpet. Carpet-beds are not by any means the only sort of beds that can be made on lawns [**14**]; but as lawns are the only place for them, and their preparation is really part of the garden design, it is best to deal with them here.

Many gardeners maintain that to arrange plants in such a formal way is an outrage upon Nature, and ought to be tabooed; while, on the other hand, there are many gardens in the kingdom where carpet-bedding is carried to excess, and the only effect is a hard and ugly one.

The best way is to strike an intermediate line, and have a little carpet-bedding, if it be desired, near the house, whence the bedding can gradually get less and less formal, until it merges into the wild garden.

Before making a carpet-bed, the design should be drawn out on paper, and marked with the names of the plants it is proposed to use in each section to give the varying colours. If the bed is to be circular, it is usual to peg out a square on the site, and then cross it with two diagonal strings. Where these strings meet is the centre of the bed. Place a peg there, with a string attached, and, just at the point where the string touches the side of the square tie an old knife, steel point, edging tool, or anything that will cut the turf. Then, by dragging this round the ground, a perfectly circular cut will be made.

Plants for Carpet-bedding. The soil for a carpet-bed should be broken up fine, or sifted, for preference, and a little sand mixed with it, unless the soil is already sandy itself. Before, however, the work can be proceeded with any further it is necessary to prepare the plants which are to fill the carpet beds. These are a class by themselves, and their culture is of the simplest. The pyrethrums, which give gold, pale green, grey, and yellow tints, are grown from seed, which must be sown in a greenhouse, with heat, in early spring, in boxes of sandy soil, and will be ready for putting out in the bed in May, which is quite soon enough, in order to escape the possibility of a touch of late frost. Red and blue lobelia are treated in a similar manner.

Alternantheras are another important family for carpet beds, and their colours range from yellow to red, but cuttings of these must be purchased in the first instance as seed is not readily procurable. These cuttings must be put into sandy soil, and rooted on a hotbed. A hotbed is made in a frame, or frames, in the garden, and consists of a layer of about 18 in. of manure, covered with a good layer of soil. The decomposition of the manure induces heat, and this heat causes the cuttings to take root and thrive. As the spring progresses, the glass top of the frame should be raised during the day to allow the young plants to gradually harden off.

Other prominent carpet-bedding plants are iresines, antennarias, stonecrops, and Herniaria glabra, while the familiar rosette shaped plant often seen round the edges of carpet beds is known as Echeveria secunda.

When the plants are ready for putting out, the pattern of the bed must be carefully mapped out on its surface in silver sand, and the young plants put in, about 2 in. apart, with great accuracy, commencing at the centre and radiating outwards.

A carpet bed, carefully prepared, will last on into the autumn until the early frosts spoil it. It should then be cleared, and, in order to avoid ugly brown beds during winter, they should be planted with dwarf evergreens and bulbs of snowdrop, crocus, and early-flowering daffodils, the culture of which will be dealt with elsewhere.

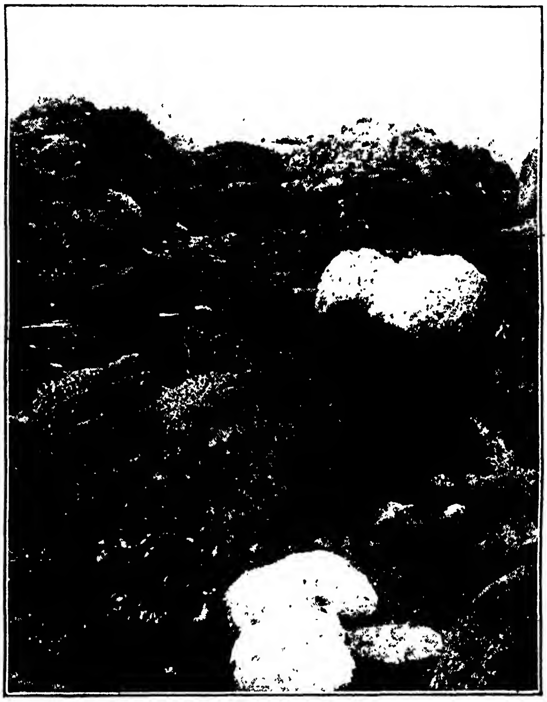
The Rock Garden. Rock gardens, as at present constructed, are, generally speaking, capable of a great deal of improvement, and in preparing one its true purpose should not be lost sight of. This purpose is, in the main, to enable the choicest Alpine and other mountainous plants to be grown in this country under as natural conditions as possible. Therefore the piling up of masses of rock and stone with no thought for the needs of the plants that are to adorn them is not at all likely to produce satisfactory results. Worst of all, perhaps, are the masses of burnt brick which are found in many gardens, tossed about in heaps,

and crowned with a few hardy ferns, which would probably thrive ever so much better if planted in the garden in the ordinary way.

The spring is the best time of the year in which to commence making a rock garden, and a sunny position in the garden is the best spot at which to construct it. It may be of any size, but should be irregular in shape, though there is no need to go out of the way to make it curious in this respect. If the soil is not good and deep at the spot where it is proposed to construct the rock garden, the ground must be dug out to the depth of 18 in. or more, and a good mixture of peat, loam, and sand put in its place. This bed of soil should be raised well above the level of the surrounding ground, or a picturesque effect will not be obtained. The so-called rocks may be pieces of any kind of stone which is common to the district. In fact, in towns, many effective little rock-beds can be built up by employing pieces of ordinary sandstone pavement, broken up into irregular shapes. Sufficient for the purpose can generally be procured at a nominal price at any builder's yard.

The whole secret of successful rock gardening is this: Plants suitable for growing under these conditions require full exposure to the sun, though at the same time they must have plenty of moisture at the roots. Hence the real use of the rocks is to act as a shield and prevent the evaporation of the moisture so essential for the well-being of the plants.

There are some shade - loving rock plants, but they are comparatively few in number compared with the others. It is impossible to lay down any hard and fast rule as to how pieces of rock should be arranged in every garden—so much depends upon position and surroundings in each instance. Individual taste must be brought to bear upon the matter, taking care to avoid all trace of formality and "building" [16]. Rock gardens should never be made near trees, as their shade destroys the very object with which it was constructed.



16. A WELL-MADE ROCK GARDEN

When first constructing a rock garden it is best to put a few pieces of rock in the most prominent positions, and then insert the plants, gradually embedding the minor pieces of rock in the soil as the planting goes on. In this way not only is a more natural aspect assured, but the plants are more securely rooted than they would be if the rocks were arranged methodically at first, and the plants tucked in between the crevices afterwards. One or more members of the following families go far to make up a representative collection for the sunny part of the rock garden: Alpine harebell, orchis, Alpine anemone, stonecrop, allium, androsace, antennaria, arnebia, armeria, chionodoxa, colchicum, daphne, Alpine pink, sea-holly, dog's-tooth violet, geum, iris, leucojum, lithospermum, muscari, pentstemon, Jacob's-ladder, potentilla, primula, saxifraga, sempervivum, sternbergia, trillium, trollius, foamflower, and viola. Those which thrive best in shady situations are the lady's slipper (hardy cyrpripedium), gentian, ranunculus, epimedium, hepatica, and iberis.

Water Gardens. It is quite possible to construct water gardens in places of modest dimensions; in fact, there are many instances in which water lilies have been successfully grown through no more ambitious medium than a half-barrel sunk in the ground. The orthodox method of making a pool in a country garden is to dam a stream at some convenient spot and form a pond of the overflow.

Where there is no stream at hand, the water must be brought to the spot by pipes, unless the owner is satisfied with a stagnant pool. First of all the piece of ground which it is proposed to transform into a water garden should be dug out to the depth of 3 ft. or 4 ft., and the soil carted away. The edge of the hollow thus made should be purposely left irregular in shape, as, if it is cut square or circular in form, the effect is formal and unpleasant. A layer of clay about 1 ft. in thickness should then be spread over the bottom of the basin, and thoroughly beaten into the ground. This operation of beating is most important, as it is to render the basin watertight, and if carelessly done the water will leak away. On top of the clay a layer of good loam from 6 in. to 9 in. in thickness should be spread, and the water may be let in.

Water Lilies in the Small Garden. Even where the only water available is the half-barrel just alluded to, it should be sunk well below the level of the ground, and the formal edge broken up with a few groups of moisture-loving plants. The best form of barrel to employ is a petroleum or beer cask. It should be sawn in two, and charred on the inside so as to remove all traces of oil or alcohol. It should then be pitched on the outside, after which it is ready to be plunged into the ground. At the bottom of the barrel place a layer of good stiff clay, and on top of this a few inches of a compost of two-thirds good fibrous loam and one-third old, well-decayed leaf soil. This should leave ample room for about 1 ft. of water, which

can be poured gently in after the water lilies have been planted.

Planting water lilies in the water garden is merely a question of getting an openwork basket, filling it with soil, and inserting the tuber. A stone should be tied to the basket to prevent it being washed away, if the water has a current. Water lilies thrive best when fully exposed to the sun, and the best time for planting is during the months of April, May, or June. The following nymphæ are the best six to plant: Alba, Rosea [15], Froebellii, Laydekeri, Odorata, and Robinsoni. Other flowers which should be planted in the water itself are nuphar (often mistaken for a water lily), the Cape pond-flower, buckbean, arrowhead, reed mace, arum lily, bullrush, and the water forget-me-not.

As the banks of a water garden are sure to be damp and marshy, they should be liberally planted with moisture-loving things in the springtime [13]. Among the best of such plants are the Japanese iris, marsh marigolds, globe flowers, several varieties of the hardy bamboos, day lilies, American swamp lily, royal fern, and several of the arundo, or reed family.

The Wall Garden. The wall garden is almost a thing of the past, except in old-established places, notably those in the West of England. This is probably due to the fact that brick walls and wooden fences have practically superseded stone as boundary lines.

A good wall garden is, however, always a charming sight, and may, for the sake of illustration, be called a vertical rock garden. The whole system of wall gardening consists in planting suitable subjects between the chinks and on the top of stone walls, taking care that such chinks have sufficient soil to enable the plants to live. The best of all these plants is, naturally, the wallflower itself (*Cheiranthus cheiri*), which is sometimes found self-sown on the sides of disused quarries, chalk pits, and in other similar situations. It seems to thrive on practically nothing, growing almost on the bare rock itself. The majority of wall plants are rock-garden plants as well, though their number is necessarily limited, as most rock plants are deep-rooting subjects. Varieties of the following are among the most suitable: Alyssum, arabis, erodium, gypsophila, linum, polypodium, saxifraga, sedum, and sempervivum.

Climbing Plants. One of the principal features which make or mar a garden are climbers. This is particularly noticeable in gardens of modern formation, which are usually those attached to ugly houses. So few modern-built houses are handsome in appearance that it is a good thing to clothe them, as far as possible, with climbing flowers and plants. It is not only against the walls of houses that the climbing plants are both beautiful and desirable, but out in the garden itself, where summer-houses, arbours, covered walks (which are known as pergolas), walls, fences, old tree stumps, and many unsightly objects may be improved by their use. In many cases, indeed, climbing plants may be allowed to grow over living hedges and up tree trunks, though in this last capacity they should be employed in moderation: if used to excess, the result often gives the impression of careless gardening. The climbing plants most sought after are, naturally, those varieties of the rose which have this habit. They will thrive in almost any aspect, though, naturally, such good results cannot be expected on a wall facing north as in more sheltered situations. In a loamy soil, which is about 2 ft. deep, however, they would do well, even in many town gardens. It is a mistake to prune climbing roses too freely; nor should they be nailed against the wall at every few inches, as if they were undergoing a species of crucifixion, but only given such support as is absolutely necessary, so that they can make their way upwards as naturally and gracefully as possible. This remark applies to practically all climbing plants. The best of the climbing roses are: Reds—Crimson Rambler, Chesunt Hybrid, and Waltham Climber. Yellows—Maréchal Niel, Gloire de Dijon, Bouquet d'Or. White—Aimée Vibert and Niphetos. Pink—Climbing La France and Pink Rover. Apricot—William Allen Richardson, Rêve d'Or, Madame Berard.

Clematis and Creepers. Next in importance to the rose as a climbing plant is the clematis. Most of the varieties are grafted on wild clematis. The most useful hybrid for general purposes is Clematis Jackmani, the large purple flowers of which are so often to be seen in town gardens. It has a variety—Alba—whose flowers are equal in size and number, and white in colour. The clematis flourishes well in a light soil, and flowers freely from May to July.

Other spring and summer flowering climbers include the wistaria, white jasmine, and the honeysuckles, while seed of the common climbing nasturtium and canary creeper, sown at the bottom of an arch or arbour during the month of April, will cover it in a month or two. Being annuals, such sowings must, of course, be renewed every year.

For exposed situations there is, of course, nothing to equal the common ivy, or one of the variegated sorts. This has the advantage of being evergreen, and is consequently in evidence all the year round. The Virginian creeper is noteworthy for its beauty in autumn; but after the leaves fall it presents a very untidy appearance. A much neater climber of this class is Ampelopsis Veitchi.

Winter Flowering Climbers. There are three climbers which are of inestimable value, as they flower in the winter time. Two of these are admirably adapted for town gardens. The best is the yellow-flowered jasmine, which, though its stems are bare at the time, is covered during the most unfavourable months of the year with a shower of bright, yellow blossoms of diminutive size, which make a brilliant contrast with the dark-brown stems of the plants and the brick walls.

The second perfectly hardy winter climber is the pyracantha, which it is hardly accurate to describe as "flowering," as it is its bright orange-red berries and rich dark evergreen foliage which render it valuable during the dark days. It thrives with equal vigour in any sort of soil.

In favoured situations the winter-sweet (*Chimonanthus fragrans*) may be grown on a south wall. Like the jasmine, its flowers are borne on bare stems. It is particularly sweetly scented, and if the flowering shoots are cut and floated in a shallow vessel of water, they will diffuse their fragrance through a dwelling-room for many days. No harm is done by treating the shoots in this way, as in the ordinary course of events they would be pruned after flowering.

POLE AND WIRE WORK

Erecting Telegraph and Telephone Poles and Running the Wires. Insulators. Wire Tables. Ohm-mile Constant

Continued from page 6181

By D. H. KENNEDY

Aerial Lines. Great skill and judgment have to be brought to bear on the construction of aerial telegraph and telephone lines. When a conductor suitable from the point of view of resistance and mechanical strength has been chosen, there remains the mechanical problem of supporting and insulating the conductors at a suitable height to secure freedom from interference and with sufficient strength to meet the static stresses due to the weight of the materials and the kinetic stress due to wind pressure.

The static stress is greatest at the pole where the line begins or ends, usually called the *terminal pole.* There it is the sum of the stresses of the wires; at intermediate poles, where the line is straight, the static stresses due to the wires on each side may balance each other, and in this case the pole, together with half of the span of wires on each side of it, may be considered as analogous to the mast and sail of a ship; the wind presses on the side of the wires as on the side of the sail, and if the pole is not sufficiently strong it will snap off at the bottom as does many a good mast. For this simplest case, then, we need to know something about wind pressure.

Wind Pressure. Wind pressure varies as the square of the velocity. A brisk wind of 20 miles an hour exerts a pressure of 1·08 lb. per square foot. A very high wind of 40 miles per hour gives 4·32 lb. per square foot; 70 miles an hour gives over 17 lb. per square foot; while a hurricane may attain a velocity of 100 miles per hour and a pressure of over 32 lb. per square foot. Standard practice has decided that lines should be built to resist a maximum pressure of 17 lb. per square foot. Next, we must ascertain the dimensions of the resisting surface. As the wires are circular, the effective area is taken as two-thirds of the diameter into the length. A simple calculation will, therefore, give the horizontal stress due to wind pressure. But this is at the height of the wires. To find the moment of pressure at the ground line, we must multiply by the distance between the centre of the wires and the ground line. The result is usually expressed in foot-cwts. This tells us, then, the stress which will act upon our pole at the ground line. The engineer is provided with a table in which the breaking stress in cwts. for various thicknesses of poles is recorded, and he might now obtain from this list the dimensions of a pole which would give the required strength. Where wooden poles are concerned, however, the possibility of a particular sample being much below the average has to be borne in mind, and in this case, as in all similar engineering designs, it is necessary to introduce a factor which shall make for safety; and is, indeed, always referred to as the *factor of safety.* For poles and supports this factor is taken as 8; so that before selecting from his list, the engineer would multiply the "foot-cwts." result by 8. For poles at angle points allowance must be made for the increased static stress.

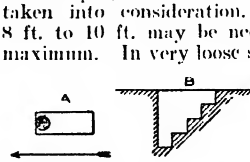
Selection of Route. The erection of a line is preceded by careful surveys in which the relative advantages of different routes are considered and that one is chosen which combines most of the following advantages:

Shortness, so as to reduce the cost;
Straight rather than tortuous roads;
Ease of access for building and subsequent maintenance;
And freedom from difficulties as to wayleaves.

During the progress of the detailed survey all information for the guidance of the foreman who will erect the line is carefully tabulated, positions being chosen for the poles so as to avoid causing obstruction to the public and danger from passing vehicles. They must also be chosen so that the wires shall not hang longitudinally over the carriageway, and poles should be placed so that if the wires fall, they will fall clear of traffic. Road crossings should, as far as possible, be avoided, and on hilly roads the heights of the poles are adjusted as far as possible, so as to avoid abrupt differences in the level of the wires.

Poles. Wooden poles are most largely used in this country, but the use of iron poles is gradually increasing, in spite of their heavy cost. Wooden poles are preserved from rot by creosoting; 10 lb. to 12 lb. of creosote per cubic foot is injected into the pole. Poles so treated have very long lives. They cannot, however, be painted, and where this is required, the process of burnettising, which consists in injecting a solution of chloride of zinc into the pole, is used. Creosoted poles having lengths up to 85 ft. and diameters up to 20 in. can be obtained. For light lines the poles are placed at 70-yard intervals where provision is made for up to eight wires, but for cases where only one or two wires will be needed the poles may be spaced 80 yards apart. For heavy lines 66 yards is the usual interval.

Hole Digging. The hole for the poles should be dug in the direction of the wires. As little ground as possible should be disturbed. It should be arranged so that the pole will stand at one end and this end should be cut down perpendicularly [29]. For ordinary lengths 4 ft. to 6 ft. is the usual depth, but the character of the soil must be taken into consideration. For very long poles 8 ft. to 10 ft. may be necessary, but this is the maximum. In very loose soil or running sand it is sometimes necessary to use concrete. The poles should be set so as to bear against the stress of the wires. In returning the earth to the hole great care must be taken that the soil is thoroughly punned in, and on completion, the soil of the roadway should be returned, as far as possible, to its original condition.



29. HOLE FOR POLE

The height of the pole should be such that on country roads the lowest wire is not less than 12 ft. from the ground: in crossing roads this must be increased to 20 ft., while in towns a height of 30 ft. is necessary.

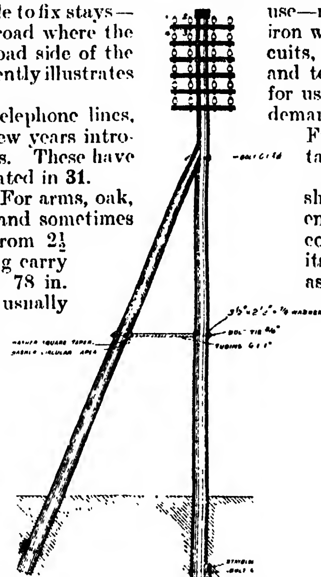
Iron poles are made of 11 ft. parallel lengths with 16 ft. tapering lengths, and the bottom fits into a cast-iron base, which gives a good hold in soft ground. A concrete foundation is usually provided, so that the pole may be secured by bolts let into the concrete. The parts of the pole are put together on the ground.

Stays. The strength of a line is enormously increased by a proper discrimination in providing stays at suitable points. Stays are usually made of iron wire, and they are arranged so that the upper end is attached as nearly as possible at the resultant point where all the forces acting upon the pole can be balanced by an opposing force. They are, therefore, specially suitable at angle points. The lower end of the stay is connected to an iron rod fitted with a stay tightener, and the further end of this rod is passed through a wooden block, usually a 2-ft. length of old pole. The hole for the stay block is usually arranged so that the block is placed in an undercut space and fits against the solid earth. Where it is impracticable to fix stays—as, for instance, at an angle in the road where the stay would have to be put on the road side of the pole—struts are used, and **30** sufficiently illustrates their application.

For the heaviest class of trunk telephone lines, the Post Office has within the last few years introduced a system of trussed " H " poles. These have given splendid results and are illustrated in **31**.

Pole Arms and Fittings. For arms, oak, well-seasoned, is usually employed, and sometimes Karri wood. The sections vary from $2\frac{1}{2}$ in. to 3 in. square. Arms 48 in. long carry four insulators, and lengths up to 78 in. are in common use. Arms are usually spaced 12 in. apart from centre to centre, and this distance also obtains between the respective insulators.

Poles are always provided with an iron wire, which is arranged to act as a lightning conductor, and is stapled down the side of the pole and terminated in one or two coils stapled round the bottom of the butt. The main purpose of this provision is, however, to prevent what is called "weather contact." In wet weather a film of moisture bridges the distance between the adjacent wires, and current would leak from one circuit to another. The " earth wire " provides, however, an alternative path. The arms are also earth wired. It will be seen that the loss of current per circuit is thus slightly increased, but interference is averted.



30. POLE WITH STRUT

Pole Roof. The top of the pole is usually cut obliquely, coated with a mixture of coal-tar, creosoted, and provided with a galvanised iron roof. In towns ornamental pole finals are used. When the fitting of the pole with roof, earth wire, arms, and, in some cases, galvanised iron steps, has been completed, it is erected by pushing the butt into the hole, so that the butt end comes easily into the place it will finally occupy. The stepped end of the hole acts as a fulcrum in such a way that the weight of the butt assists in lifting the top, and the pole is gradually raised to the vertical position at first by hand, and subsequently by ladders, half a dozen men being usually employed. Even for the heaviest poles, ten men are quite sufficient where the foreman exhibits proper generalship. The presence of too many men is apt to be a source of danger, and a proper understanding between those concerned in the work is of the utmost importance.

Insulators. The standard pattern insulator used in England is made of white porcelain, screwed so as to fit on a screwed steel spindle, and provided with two petticoats [**32**]. For short lines, where a very high standard of insulation is not necessary, brown earthenware made in the same pattern is frequently used. In fixing the insulator an india-rubber washer is inserted between it and the shoulder of the spindle to allow for differential expansion. The insulators are put into position after the pole has been erected, the steel spindles being securely bolted to the arms. It is interesting to note that in America glass insulators are used instead of porcelain, and wooden (locust) pins instead of steel spindles. At terminal poles, where the pull is all on one side, J-shaped spindles are used, fixed to the under-side of the pole, and arranged so that the pull of the wire comes opposite the centre of the arm.

Wire. Three classes of conductor are in general use—namely, iron, copper, and bronze—iron wire for unimportant telegraph circuits, copper for important telegraph and telephone circuits, and bronze wire for use in towns where irregular spans demand increased mechanical strength. Full particulars are given in the table below.

Ohm-mile Constant. This should be carefully memorised. It enables the resistance per mile of any conductor, which may be named by its weight per mile, to be at once ascertained. Thus, if 70 lb. bronze is referred to, $\frac{1,820}{70} = 26$, which is the resistance in ohms per mile.

Erection of Wire. The effects of temperature have a most important bearing upon the erection of aerial wires. It is clear that if wires are erected in hot summer weather, when winter approaches, owing to the decrease in temperature, they will gradually shorten, and if sufficient allowance is not made for this, it is possible that the limit of elasticity may be passed and the wires ultimately broken Arrangements are therefore

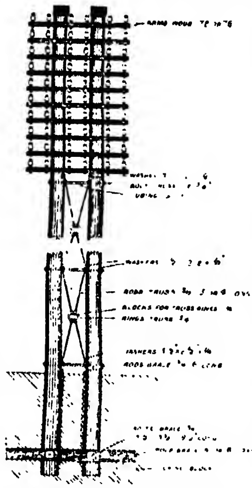
made, so that the stress to which the wires are pulled up on erection is arranged with reference to the temperature in such a way that should a winter temperature of 22° F. occur, the stress will then be at the maximum allowed—namely, one-fourth of the breaking stress. This is another way of saying that wires are erected with a factor of safety of 4 for low winter temperature, and that at all other times the factor of safety is higher than 4. To secure this state of affairs, tables showing the stresses for various lengths of span corresponding to different temperatures are prepared for all classes of conductors, and supplied to the wiremen, who are also supplied with thermometers. Owing to their differing temperature coefficients, dissimilar conductors are never, if it can be avoided, erected on the same pole route. For bronze, a factor of safety of 3 instead of 4 is employed.

Twisted Wires. For the purpose of eliminating inductive disturbance in metallic telephone circuits, it is necessary to arrange the two wires which form a loop in such a way that their average distance from all disturbance is the same. This condition is attained in England by causing the wires to revolve round each other. Four wires forming two telephone circuits are taken together, and arranged so that they form a square on, say, the left side of the pole on the top two arms [30]. These are numbered as follows:

No. 1.—Top outside.
No. 2.—Top inside.
No. 3.—Bottom inside.
No. 4.—Bottom outside.

At the next pole the wires from No. 1 position will shift to No. 2 position, the No. 2 wire to No. 3, and so on, and this process is continued, so that on the fifth pole the wires come back to the same position that they occupy on the first, having completed one revolution. If, now, a single-wire telegraph circuit is sending out disturbing electro-magnetic waves, the inductive effect on one wire of the telephone circuit will be balanced by the equal and opposite effect of the other, and the disturbance will be completely eliminated. Here, again, a curious difference exists between English and American practice. In America it is preferred to run the wires straight on the arms, introducing, however, crosses at frequent intervals on what are known as "transposition poles."



31. POLE FOR HEAVY TRUNK LINES

Joints. The connections between successive lengths of wire are made by means of the Britannia joint. The ends of the two lengths of wire are cut off and laid side by side for about 2 in., binding wire is then wrapped round the conductors over the whole of the over-lap portions, and with a few turns on the single conductor at each end: 50 lb. tinned copper wire is used for copper conductors, and 60 lb. galvanised iron for iron conductors. A flux is then applied, and the joint rapidly soldered, overheating being carefully avoided and the joint being allowed to cool naturally. In order to prevent electrolytic action, the joint is subsequently black varnished.

Wire Running and Binding-in. In order to pay out the wire uniformly, and for the purpose of avoiding kinks, a rotating drum is employed. A long length of wire is run out sufficient for eight or ten spans, the wiremen passing it out loosely over the arms at each pole. The wires are first drawn up as tightly as possible by hand, and then by draw tongs. A tension rachet is connected to the draw tongs for the purpose of observing the stress. When the wires have been drawn up to the proper tension they are attached to the insulator. This is done, in the case of iron wire, by using 60 lb. binding wire. This is first lapped round the line wire on one side of the insulator, then taken round the neck of the insulator and lapped round on the other side; two thicknesses of wire are usually employed. For copper wire, a different method is in vogue: the line wire is first served with a sheath of copper tape to protect it from abrasion against the insulator neck; a copper binder, about 20 in. long and having its centre of round copper and its ends flattened out, is then applied; the round part passes round the insulator neck, and the flattened ends are wrapped round the taped conductor, the wrapping being arranged over on one side and under on the other. It need hardly be stated that the stress is greatest at the point of the attachment to the insulator, and that this is where breakages most usually occur.

Maintenance of Aerial Wires. Skill and judgment are as necessary for the maintenance as for the erection of lines such as have been described, and in stormy districts the lives of the engineers and linemen are seldom troubled by monotony. As the number of wires increases, constant vigilance has to be exercised, to eliminate weak spots. The poles have to be examined periodically to see that the normal factor of safety has not been unduly encroached upon. In districts where snow prevails accumulations sometimes take place which transform the wires into white ropes of 3 in. to 4 in. diameter, a result which is usually followed by the practical demolition of the lines, especially where frost and wind follow the accumulations. Trees are often blown by the wind across the lines, and when one span has been broken through, the trouble may run back for a considerable distance, owing to the sudden removal of the balancing stresses. Spans over rivers and ravines have to be negotiated, and in all cases the work of repair has to be done against time, as communication must be restored after the briefest possible interval.

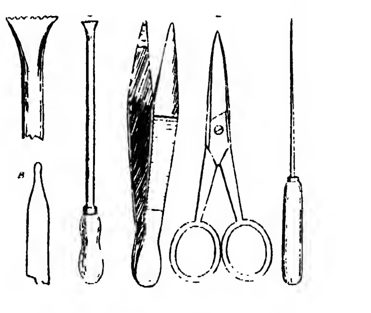
PRACTICAL TAXIDERMY

How to Stuff Birds, Animals, and Fishes. Mounting Horned Heads. Finishing Mounts, Cases, Rockwork and Scenery. Skin Cleaning and Preserving

IN attempting the practice of taxidermy the best subject for a beginner to experiment on is a bird—not too small or delicate—such as the common starling, the feathers of which are not difficult to handle, and the skin fairly tough.

The tools [1] necessary are a sharp-pointed knife—a penknife will do; a pair of strong, pointed scissors; a sharp-pointed awl or pricker; a pair of side-cutting pliers for cutting wire; a pair of tweezers for arranging the feathers; a file, and a needle. We shall also require some cotton-wool and wire; some pins and glass eyes; tow, wood-wool shavings, similar to those used for packing; some strong thread and soft cotton; powdered alum, arsenical soap, fine sawdust, and a little plaster of Paris.

Preparing the Bird. The first operation is to put a thread through the nostrils of the bird, making a knot, and leaving a loop as long as the neck and body of the bird. The loop will be of great assistance in returning the head when the bird is skinned. Plug the nostrils, throat, and any shot holes with wool. If the body is very moist use a little sawdust and plaster of Paris to absorb the blood. Break the wing bones (the humerus) close to the body. Make an incision in the middle of the breast [2], first blowing the feathers apart, and continue the cut to the vent. Care must be taken not to cut too deeply in the abdomen, or the intestines will protrude, and give great trouble by making the feathers dirty: sawdust and plaster should be applied to prevent this. The skin should be pressed back with the side of the knife. No further cutting will be necessary until the tail and the legs are undertaken, when the scissors should be used to snip the tail-bone. The legs should be pushed up, and the first joint exposed must be cut with the knife.



1. TAXIDERMIST'S TOOLS
a. End of stuffing iron *b.* Section of stuffing iron *c.* Complete stuffing iron *d.* Tweezers *e.* Scissors *f.* Pricker *g.* Skinning knife

Remove the flesh from the leg down to where the feathers end, return the leg-bones to the skin, and proceed to press the skin away from the back. Cut through the wings where broken, and turn the skin inside out down to the head, holding the body between finger and thumb. Great care must be taken not to split the skin in getting it over the head. The ears will first be met and cut through; then the eyes, which require still more care. Skin down to the bill [3]. Cut through the base of skull and remove the neck. The brain, tongue and eyes should now be removed and the sawdust and plaster brushed off. Apply alum if the skin is very moist or not quite fresh; anoint all bones and the inside of the skin carefully with the arsenical soap, and place a ball of wool in the orbit of each eye.

Stuffing. Now lay the skin on the table, and return the skull to its proper position; the loop of thread in the nostrils will assist this operation. Coax the skin with finger and thumb over the skull, and the whole skin will, with a little shaking, return to its natural position. Smooth the feathers of the head the right way, and work the body-feathers downwards into position. Now make an egg-shaped body the size of the one taken out, using the wood-wool for this, pressing it together tightly, as the leg wires must depend on it for fixing firmly. Cut a wire twice the length of the neck and body, and point it at both ends. Drive the wire through the body, make a loop, return it, and then clinch it.

Wind a little tow round the wire to form the neck, being careful not to make it longer than the one taken out; and drive the wire through the centre of the skull and work the skin down over the body. Cut two wires three times as long as the legs, point at one end, and insert one underneath each foot, working it up the back of the leg; a little tow must be wound round the wire and bone to make up the flesh removed from the thigh-bone. The wire is now driven through the body, out under the opposite wing, turned, and pulled back into the body. A slit must be cut in the skin to allow the loop to pass and so leave the skin free. Insert a little pad of tow in the base of the tail, and sew up the skin, taking care not to sew down any feathers. The legs should be bent into their natural position.

Mounting. The bird has now to be fixed on a twig or a perch. Two holes are bored through the perch to take the leg wires, and the wires are twisted firmly to the perch. The tail must now be adjusted, one, and sometimes two pointed wires being used to fix it in position. The wings require two wires each, one through the shoulder, the other near the roots of the primaries or quill feathers. Fix both wings the same height or the bird will appear lopsided when completed.

The throat may be filled out from the mouth with tow, finely chopped with scissors, and the cheeks filled from the eye. The eyes are then inserted, and the tail expanded to the required width between two slips of cardboard.

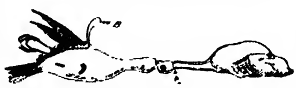
The final binding with cotton is next, a long pin being inserted in the back, and one or two in the breast, keeping to the centre line of the body. The pins, with the four long wires, and the wire protruding from the head, are utilised in winding the cotton round the bird to compress the feathers gently into place while the bird is drying [4]. The novice must not expect his first bird to be a great success, or perhaps his sixth or twelfth, for, simple as the operation may seem, it requires practice to get the natural shape and pose.

Animal Stuffing. Small animals up to the size of a rabbit will require the same tools and

materials as those required for mounting small birds. Before skinning, an outline of the animal should be made by laying it on a sheet of brown paper in as near the position as possible in which it is intended to mount it, and its shape marked with a long pencil or crayon, the size of the body being marked on this sketched outline.

Always skin an animal down to the toes. The tails in small animals can be drawn without cutting them open. The lips must be split, and moist clay inserted to give them fulness. The ears must be skinned and clay used to replace any flesh taken away; sheet zinc, cut to the proper shape, is used to stiffen and keep them in position. Always keep the leg bones on the skin, as they are invaluable in shaping and posing the animal.

2. BIRDSTUFFING: THE FIRST INCISION
Thread loop tying up beak

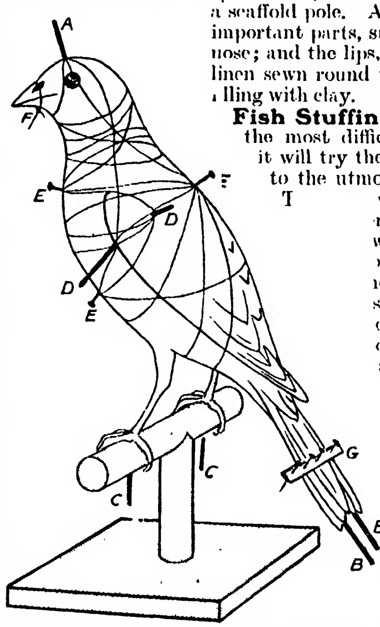


3. BIRDSTUFFING: SKIN TURNED INSIDE OUT
a. Point to cut head from neck *b.* Thread loop to assist in returning the skin

The hard, egg-shaped body used in bird-stuffing is not used for stuffing animals. The head and body wire is twisted tightly in with the fore legs first, then the hind legs. The length of wire used must allow for fixing the animal upon the stand.

The neck and body are gradually filled with chopped tow, wood-wool, and sometimes with hay, keeping the shape and ultimate position in view. Never use tow without chopping it up small, or it will form an immovable ball inside the skin, and show an ugly lump; cotton-wool, also, should be avoided for the same reason. Soft pipeclay is very valuable in the head, feet, and those parts where such details as muscles must be shown. Always use annealed iron wire, thick enough to give stability, and bear in mind that it is easier to add a little stuffing than it is to get it out.

The hair must be cleaned and brushed and combed in its natural direction while the specimen is wet; blood and grease must be washed out before stuffing. Fat left on the inside of the skin prevents any preservative acting properly, and will cause the skin to rot. It is better to allow the skin to remain a few hours for the alum to act on it before applying the arsenical soap. The action of alum is astringent, shrinking the skin and so fixing the hair firmly by the roots; it will also extract the surplus moisture from the skin, but any crystals remaining undissolved are better brushed off before applying the arsenical soap. The eyes, ears, lips, and toes require special attention, to see that the alum is worked in well. If the skin cannot be stuffed immediately, do not let it remain folded on itself; place a little hay or tow inside it to prevent the inner surfaces touching. If this is not done, the skin will sweat, decompose, and the hair will fall off at the slightest touch. The leg bones must also be wound round with tow.



4. STUFFED BIRD READY FOR DRYING
a. Head, neck and body wire *b.* Tail wires *c.* Leg wires *d.* Wing wires *e.* Pins to keep cotton in position *f.* Thread to fasten beak *g.* Cardboard slips to hold tail feathers

Larger Animals. The larger animals require a different treatment: the legs in animals the size of deer and larger must be opened right down the inner side, so that the seam is least noticed when mounted. The irons for the legs will require to be tapped, and two nuts fitted to each leg, to give the support to carry the weight when fixed up. The irons must be bent to the proper curves and angles, which the paper outline will give. A board, about 2 in. thick, must be cut to the shape and size of the body. The leg irons are very firmly fixed to the board by iron staples, as also is the iron for the head and tail. The head iron is brought through the skull by passing it through the nostrils, and is cut to its proper length when the head is finished [5].

The bulk of the body is made up by fixing dry straw to the body board. It must be tied securely round the board with string, shaped as nearly as possible to the pattern and measurements, and made a little under the proper size [6]. The skin may now be tried on, and if the edges meet comfortably, and the legs are the right length, the skin may be sewn up. Begin sewing at the neck and work downwards.

The dried skins of the larger animals are very stubborn, and require to be pared down with a spokeshave, the skin being laid on a short length of a scaffold pole. A knife must be used for the more important parts, such as the ears, the eyes, and the nose; and the lips, if they cannot be split, must have linen sewn round the edges to form the pocket for filling with clay.

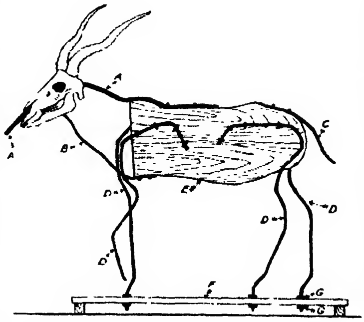
Fish Stuffing. The stuffing of fishes is one of the most difficult branches of taxidermy, and it will try the patience and skill of the novice to the utmost.

T water perch is a good species to nt with. Choose the best side for w side, and mark its outline on a f paper as a guide. Make a cut e other side with a strong pair of sors, down the middle of the dy from the centre of the gill over to the root of the tail. Use a knife to free the skin from the flesh, and cut from tail to head.

The skin of a scaly fish must not be turned, as in birds and animals, or the scales will be disturbed. The root of the tail and fins must be cut with the scissors inside the skin. See that the points of the scissors do not cut the skin, or a few scales will drop out. The gills and all the bones of the head must be cut away with the scissors. When the skin is ready, it must be soaked in water to remove any blood and slime that may adhere to it. All loose scales should be saved, as they will, perhaps, be wanted for repairing the skin.

There are several methods of stuffing fish, and one of the simplest of them can be used for fish up to the weight of 5 lb. Take fine yellow sea-sand, damp it so that it is just tenacious enough to retain a

shape when grasped by the handful. After using arsenical soap on the skin (alum should not be used for fish), sew up the skin a few inches at the head, and also at the tail. Place a loose ball of tow in the mouth to keep the sand from coming out, and fill the skin with the wet sand, pressing it tight and modelling the shape as the filling proceeds. Finish the filling in the middle of the body and sew it up. The fish must now be turned over on a board a little longer and wider than itself on which it is to lie and dry. Pat the head into shape, and work the body downwards to its proper curve. Fish skins always tend to become longer, and this must be prevented, or the result will be a failure. The fins and tail must be extended and fixed between two pieces of cardboard, pins being used for fixing them. The fins and tail must not be allowed to dry during stuffing, as in this state they are very brittle, and cannot be extended properly.

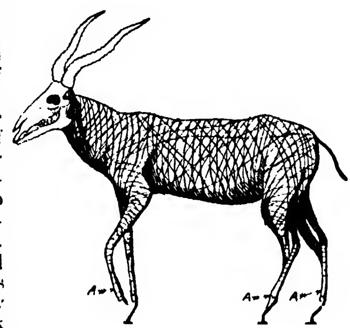


5. ERECTION FRAME FOR AN ANTELOPE
a. Head iron b. Neck iron c. Tail iron d. Leg irons e. Body wood f. Temporary stand g. Leg iron nuts

When the fish is properly fixed, a thin coat of gelatine, melted in warm water, will keep the scales in position. The fish must now be placed on a warm shelf to dry slowly, and examined occasionally to see that it is drying smoothly.

When the fish is dry, remove the sand by opening the seam and gently tapping the body. It is then filled with tow, wood-wool, etc., and the seam glued together and covered by a strip of linen. A small wooden block to which are fixed two wires is also glued on the seam for fixing up the fish in a case. The finishing and colouring of fish require much practice, and it is easy to overdo the colour. Use whenever possible transparent oil colours and a clear "crystal" varnish. The belly colour is the most important point to get right. It is usually white, and is shaded very gradually to the colour of the sides.

The eyes must be of the same size as in nature: the orbit of the dried fish is always larger than in nature, through shrinkage, so it must be filled up to its proper size with a composition to be described hereafter.



6. MANNIKIN READY FOR SKIN
a. Artificial leg bones of wood

Mounting Animal Heads. If the animal has horns, it must be skinned by having a cut made up the back of the neck until it is level with the base of the horns, when a T-shaped cut must be made up to each horn, and continued round the bases to free the skin, so that the skull comes away entirely from the skin [8]. Remove the flesh from the skull, which must be boiled until thoroughly clean, and when it is dried it will be ready to mount inside the skin. The skin is rubbed, first with alum, and then with arsenical soap, and the ears fitted with zinc and clay.

Heads are fitted up differently from those of animals stuffed entire. Thick wood takes the place of iron for the support, and a piece of quartering, longer than the neck, is fixed in the skull, and several long screws driven at right angles through the bone into the wood. Cut a board not less than 1 in. thick, nearly the shape of an elongated egg, and trim off all sharp edges smoothly. This is called the back-board, and must correspond with the size of a cross-section of the neck at its extremity [8]. The quartering, having been fixed in the skull, must be cut to the length of the neck. The neck should be as long as the skin will permit; short necks look very bad, and an animal stuffed with a long neck can be made to look much more lifelike.

The skull, as at present fixed, should be hung on a wall, to find if the quartering is cut to the proper angle, so that the neck may be given a graceful curve. If there are horns in the specimen, the points can be brought to within 2 in. of the wall with safety. Horns do not always grow evenly, but it is possible to rectify this slightly while fixing up the skull. When everything is satisfactory, wood-wool is bound round the quartering to the shape of the neck [9], the skin is fitted on, and sewn up. Begin the sewing at the horns, and work down to the back-board; any stuffing which the neck requires must be inserted before the skin is fixed to the back-board. Three-quarter inch French nails are the best to use for fixing the skin, as in drying the skin strains very much, and would pull shorter nails out. The cheeks are stuffed from the mouth and eyes, and the head finished as in entire specimens, plenty of clay being used in modelling the eyes, nose, and mouth. The glass eyes should be put in after the skin has dried, on account of the shrinkage during drying.

The shrinking of the skin is the bane of the taxidermist. The chief causes of shrinking are insufficient paring down of the skin, using clay too wet, stuffing the specimen too loosely, and not fixing and sewing up the skin tightly.

Before colouring the eyes, nose, and mouth, the specimen must be cleaned and beaten thoroughly. White French polish and methylated spirit in equal parts, and dry powder colours, are the best materials for colouring. Use stiff hog-hair brushes to work the colour in, and do not forget that the colour will, when dry, be half as light again when the spirit evaporates, which it does quickly. A little varnish will be required on portions which in nature are wet, such as eyelids, nostrils, open mouths, and lips. The horns are cleaned with soda-water, and rubbed with linseed oil and turpentine, to darken them.

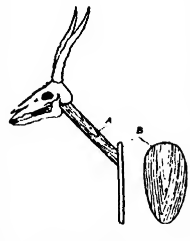
Finishing and Casing. Cases should not be cramped, plenty of room being allowed for rock-work, glasses, and fittings, in order that they may be displayed in a natural way.

The case had best be made by a cabinetmaker: the wood used mostly is deal. Insist on having the best material and workmanship, as a faulty case will spoil everything. Panel backs to all cases are best, as splits in the wood are thus avoided. The

back is lined with calico, carefully stretched and fixed with glue and tacks. When this is dry, paste white lining paper evenly over the calico. All the woodwork which is inside, except the bottom, must be coated with size mixed with powdered red lead; if this is not used the resinous matter and knots of the wood will show through the paper and make ugly spots. The inside of the case should be coloured with water colours, and a landscape may be represented.

Rockwork. Rockwork is made with brown paper supported with wood, and in large work the basis is canvas, covered with paper wetted with warm water, and laid on evenly with glue. Considerable taste and practice are required to get the appropriate angles and curves to imitate different forms of rock.

When the glue is dry, the basis is quite stiff enough. Melt some size by adding one-fourth its bulk of water, add slowly to it crushed whiting until it has the consistency of gruel; apply this *hot* to the prepared basis. Have some dry sand, yellow or silver, according to the rock you wish to represent, heated to a temperature comfortable to handle, and throw it forcibly on the hot composition. When cold gently knock the rockwork, and all sand which has not adhered will fall off. Colours ground in oil will do for colouring the rockwork. Do not overdo the colours—follow Nature in every way.

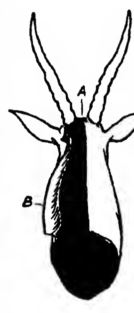


7. WOODWORK FOR GAZELLE HEAD
a. Quartering fixed in skull *b.* Back-board

Grasses, ferns, rushes, and boughs must be thoroughly dry before using, and may be coloured with oil colours to which a very little varnish is added. Avoid stiffness; everything should look as if it were growing. This portion of the work is one which requires and deserves as much time as possible to be devoted to it.

The glass should be cut to fit the case exactly and fixed by strips of wet paper of the same colour as the case. Black is by far the best colour to show up most subjects. The paper is applied with very smooth paste made from ordinary flour. As the paper shrinks in drying, it gives a stronger fixing.

Cleaning Skins. Fresh blood can be removed easily by washing the blood patch with warm water of a temperature not above blood heat, in which is dissolved a little of Hudson's Extract of Soap. If a bird is the subject, never allow the feathers to be wet longer than is absolutely necessary, and extract as much moisture as possible with a dry duster. Then saturate the feathers with benzoline, sprinkle plaster of Paris over them, beat the plaster off again at once, and repeat the process, using fresh plaster and adding more benzoline until the feathers appear dry.



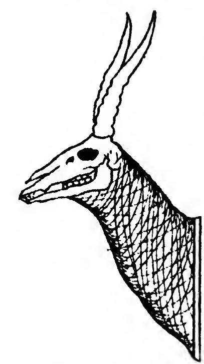
8. SKINNING A HEAD
a. Cross cut *b.* Skin partly removed *c.* Shape of cut

Benzoline is a solvent of grease; it also forces out the water contained in the feathers and prevents the plaster from setting, but quick beating is required when the first plaster is applied. The plaster absorbs the grease dissolved by the benzoline and also cleans the feathers; but the skins must be thoroughly beaten to get the plaster off. If the skin has no blood on it, the soap-powder and water will not be required and much time will be saved. This recipe will also answer for the treatment of small and large animal skins.

The composition for stopping up and repairing holes is made by mixing melted glue and well ground whiting to the consistency of stiff dough; the amount of glue must be determined by testing the composition with the fingers. It should feel tacky and stick to the finger; if it crumbles add more glue. When worked well together, add one tablespoonful of boiled oil for every pound of glue used and knead the constituents until they are thoroughly mixed. The composition can be used after it has become cold and hard by steaming.

In fixing artificial eyes, modelling nostrils, lips, tongues, and the innumerable requirements of taxidermy, this composition is used. It can be made to imitate any surface by manipulating it properly, and is easily coloured.

Arsenical Soap. This is made of 3 lb. white curd soap, 3 lb. arsenic powder, and 8 oz. camphor. Slice up the soap and melt over a fire in as much water as will just cover it, and stir well to keep it from burning. Crush the camphor very small with a little methylated spirit and add this, together with the arsenic powder. The whole should form a creamy paste. Arsenical soap has been decried by some taxidermists, but it still holds its place with the trade, and will do so until a better preservative is found.



9. GAZELLE HEAD
Ready for skin to be fitted on

Treatment of Skins for Storing. Animals' skins are sometimes found infested with a pernicious insect (Dermestes) the grub of a small beetle. It is the most destructive insect with which the taxidermist has to contend. It eats through the toughest skins and it has been known to eat through cork. When this pest is found in any specimen, instantly saturate everything in the same case or box with turpentine, and keep the case closed for a short time.

Naphthaline crystals are very good to use in boxes of specimens of all kinds. Cyanide of potassium is a dangerous poison, but a powerful insecticide if placed in boxes of skins; it should be enclosed in a block of plaster of Paris, the cyanide being placed in the plaster before it has quite set. If it is not enclosed in plaster, the chemical will absorb moisture, and run on to the skins with which it is in contact and spoil them.

HARBOUR CONSTRUCTION

General Construction of Several British and Foreign Harbours. Natural Harbours. Breakwaters

By A. T. WALMISLEY

Dublin Harbour. This is a type of the jetty harbour, with jetties converging towards the entrance. The river Liffey forms the channel of the harbour, dividing the flat, sandy beach into two strands, called the North and South Bulls. The tendency of the sandy deposit from the sea was to form a continuous strand all across the western shore of the bay, which was only partially prevented by the tidal flow in the river, and the result was a bar at its outlet. The outlet channel of the river was regulated by the construction of a rubble embankment along its southern side, called the Great South Wall, completed in 1796, which served to protect the channel in south-westerly gales, and prevented the inroad of sand from the South Bull, but no improvement resulted owing to the absence of scouring power in the river. The North Wall was constructed from 1820 to 1825 in order to deepen the channel across the bar. This wall was raised to only half-tide level along its outer portion, so as to allow the earlier half of the ebbing current to flow over it, this portion of the current possessing little scouring effect. The construction of these solid jetties—3¼ miles and 1¾ miles in length respectively—gradually lowered the bar from 6 ft. below low water in 1819, to 16 ft. in 1880, this result having been aided by dredging in the inner channel, and by the removal of ballast from the north strand within the northern jetty.

Sunderland Harbour. The outlet of the old entrance to the port of Sunderland was originally guided by parallel jetties across the sandy beach, but when docks were constructed, a new southern outlet with converging piers was provided, affording a better depth of water. As the chief littoral drift comes from the north, the entrance has been made to face south-east. The plan of the outer harbour is specially favourable for stilling the entering waves, and gives easy access to the two dock entrances; it also affords ample area for dredging. The docks and outer harbour form artificial sluicing basins, which concentrate their scouring current through the narrow entrance.

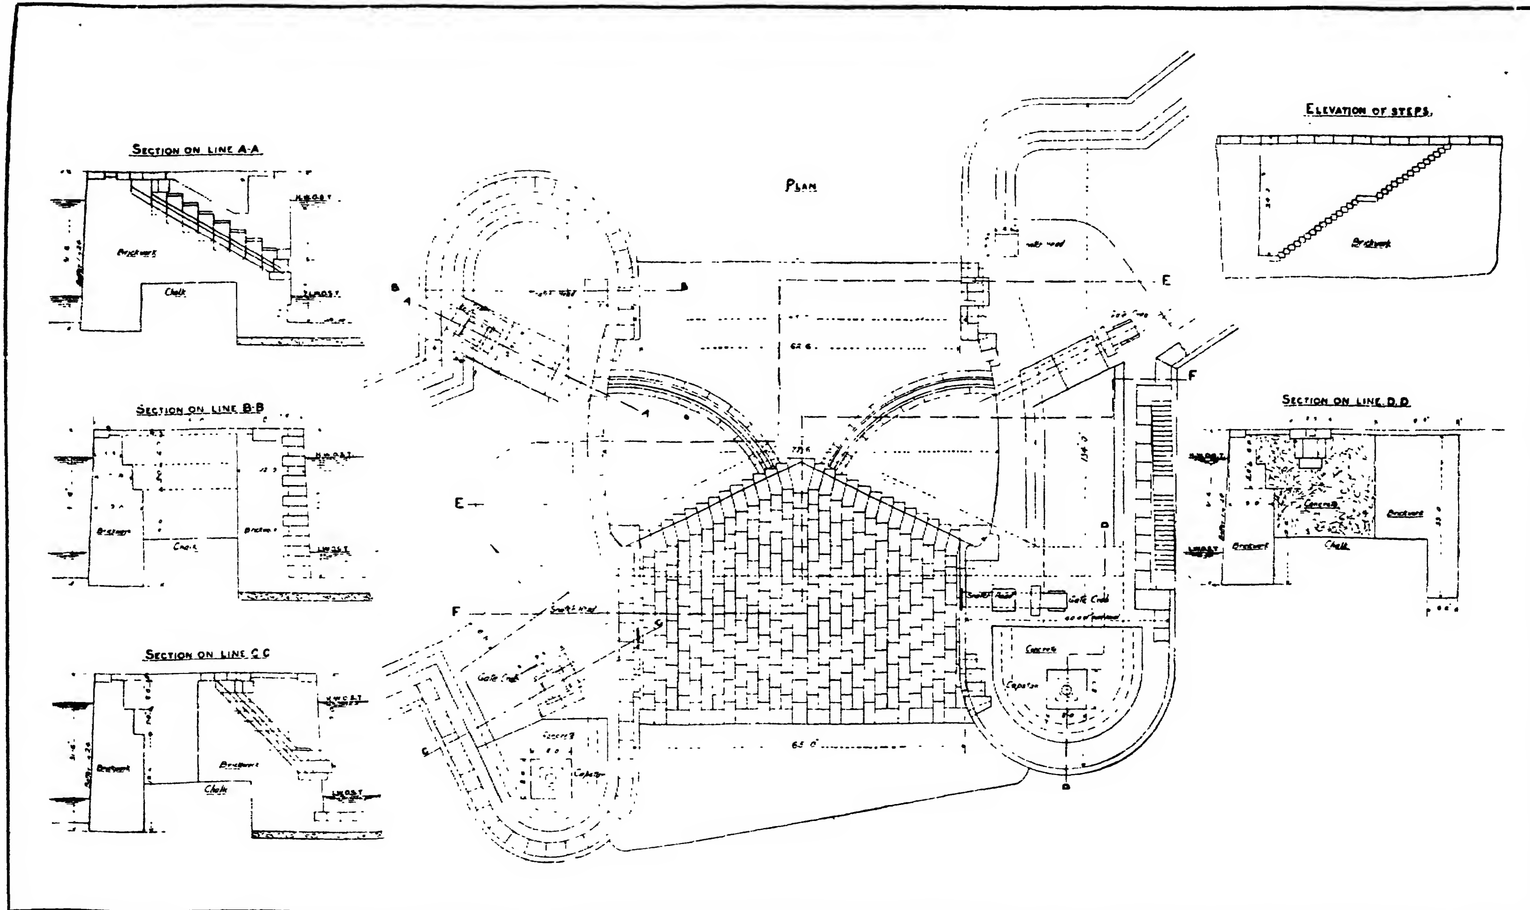
Aberdeen Harbour. This harbour consisted originally of the natural channel of the River Dee at its outlet into the North Sea. During north-easterly gales a channel over the sandy beach could be maintained only with difficulty by the tidal waters, and a bar existed at the mouth of the river. The north pier was constructed about the year 1773 to a distance of about 1,200 ft. from high-water mark, with the object of stopping the drift of sand along the shore from the north, or of carrying it out to such a distance that the main tidal current would convey it away, thus removing the bar. The scour produced by this work and by a southern pier, which was constructed parallel to the river on the opposite side, maintained a depth of about 2½ ft. over the bar at low-water spring tides. In order to provide a large harbour with better shelter, new works were carried out consisting of a southern breakwater and north pier extension. The southern breakwater was completed in 1873, and the north pier extension in 1877. The construction of both was concrete on the upright wall system, and both are somewhat similar in section. The works have so far accomplished the objects for which they were designed, in having provided a large harbour sheltered from south-easterly gales and in giving a wide entrance (1,100 ft.) between the pier-heads in a depth of about 15 ft. at low-water ordinary spring tides. The bar which formerly existed has been kept down by dredging during the summer months.

Parallel jetty harbours have not proved universally successful in the North Sea and in the English Channel for providing a deep entrance without constant works of maintenance. Silt generally accumulates outside the jetties from the pier-heads to deep water, and consequently dredging is required here. Parallel jetty harbours are among the most difficult class of harbours to design and maintain successfully, but the construction of sluicing basins, and the development of dredging plant tend to improve their condition considerably.

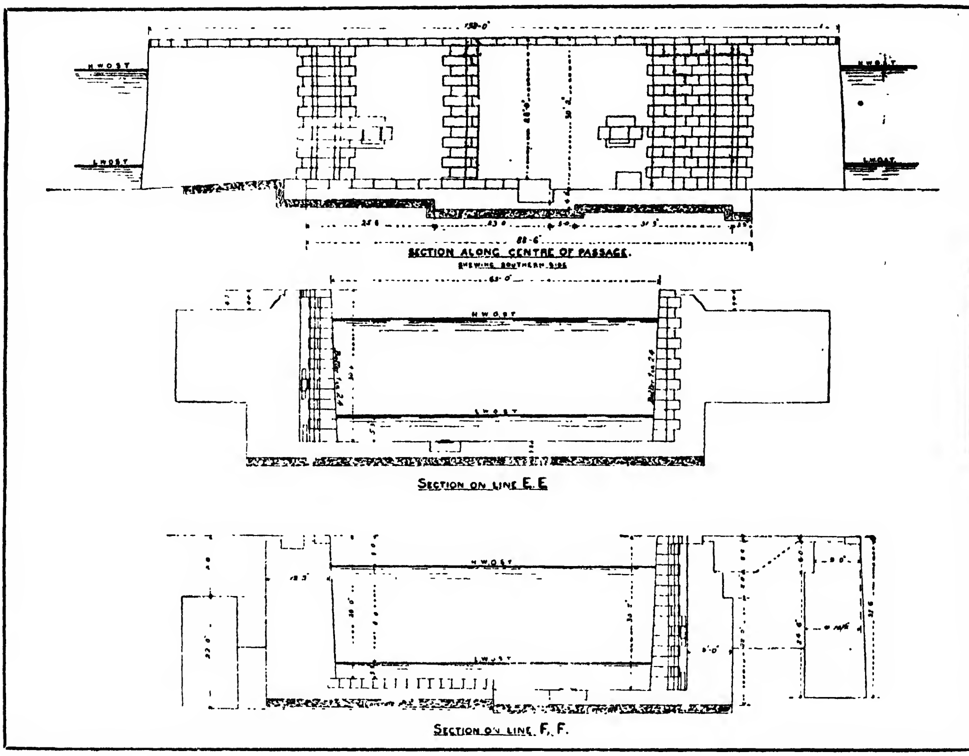
Lowestoft and Ostend Harbours. Lowestoft Harbour was originally formed by cutting a channel from a low-lying marsh, called Lake Lothing, to the sea, and parallel wooden jetties were carried out across the beach, on each side of the channel, to a depth of 12 ft. at low water spring tides, but it was found that the scour produced in the channel by the ebbing of the tide from Lake Lothing, was not powerful enough to contend effectually against the drift of sand and shingle from the north across the entrance, and consequently a bar was formed. Subsequently additions were made to the harbour by building piers on each side of the old entrance channel. The harbour authorities have had to resort to dredging from time to time in order to maintain a sufficient depth of water.

The peculiarities of the site of Ostend, where open jetties control the harbour entrance, lie in the fact that as the coast-line projects, the sea tends to encroach rather than to recede, so that the foreshore has not advanced like other jetty harbours. Groynes formed along the beach to the west of the harbour protect the shore. The jetties cannot be lengthened to reach deep water owing to the "Stroom-bank," which extends in front of the entrance at a short distance from the shore, and the navigable channel is between this bank and the end of the west pier-head. Though a regular mail service has existed for many years between Ostend and Dover, the bar has at times hindered the entrance and exit of the steamers. The sluicing basin near the entrance to the harbour has helped to maintain the necessary depth of water for the passage of the mail steamers, but the development of modern dredging plant has helped to minimise this trouble.

Dieppe and Boulogne Harbours. The entrance channel at Dieppe harbour is guided and protected by parallel jetties. It has a sluicing



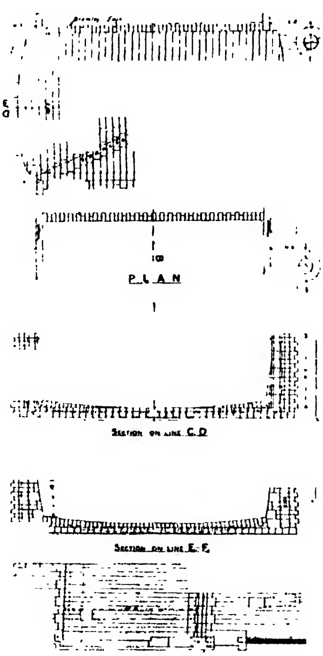
1. GRANVILLE DOCK, DOVER HARBOUR



2. SECTIONAL DETAILS OF GRANVILLE DOCK, DOVER HARBOUR

basin for maintaining the depth of the channel. The outer, or tidal harbour, gives access to the various basins, which are entered through locks, provided with gates for maintaining a high-water level. Solid masonry quays line the inner portion of the jetty channel, except for a portion where there is an open jetty of ironwork which communicates with a stilling basin for reducing the swell following the concave side of the channel. Open jetties are constructed along the outer portion of the channel near the pier-heads, with stilling basins behind for receiving the entering waves, the older western jetty being made of timber. Shingle travelling along the coast used to obstruct the channel to a certain extent, by passing round the west jetty and settling along its inner face, but was removed temporarily by the sluicing current. This travel of shingle has been partially arrested by a series of groynes constructed along the shore to the west.

The south-west jetty at Boulogne is built of masonry up to high-water spring tides, with a superstructure of open timber work, and extends out



3. WELLINGTON DOCK, DOVER HARBOUR

beyond the other to facilitate the entrance of vessels. The north-east jetty is solid along the inner portion and consists of open timber-work for the outer 1,000 ft.

A sluicing basin, having an area of 163 acres, maintained the channel between the jetties at a depth of $5\frac{1}{2}$ ft. below low-water spring tides, but the bar beyond the pier-heads was sometimes a foot above low water. Dredging by means of sand pumps had to be resorted to for improving the depth. The south-west jetty has been extended and two additional jetties constructed, so as to enclose the old jetty harbour. Two entrances are provided facing north and west respectively, 820 ft. and 490 ft. wide. Docks and quays have been constructed within the area, sheltered by the breakwaters. The breakwaters consist of a solid superstructure of masonry resting at low-water level upon a mound of rubble with concrete blocks to protect the sea slope.

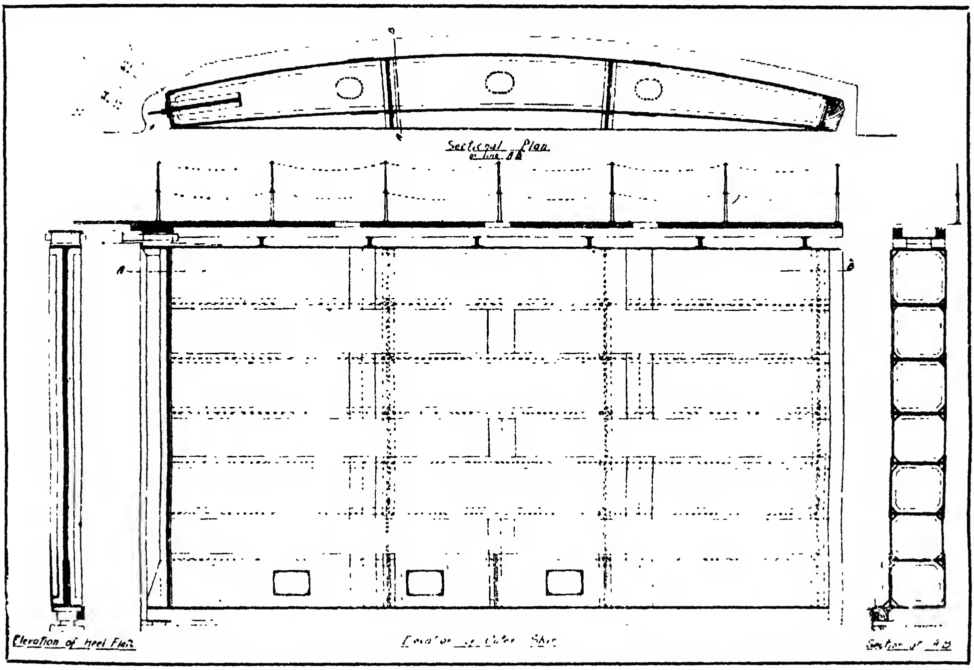
Calais Harbour. The jetties forming the entrance to Calais harbour consist of open timber-work resting upon a foundation of pitching and

fascines carried up slightly above the level of the beach, to allow of the free flow of the currents, but preventing the inroad of sand into the channel. The inner portions of the jetties are constructed with masonry up to high-water level. The width of the entrance is 430 ft. For sluicing the entrance channel, a sluicing basin having an area of 250 acres is discharged, and dredging is also practised to obtain a minimum depth of 13 ft. of water below ordinary spring tides in the channel. The harbour entrance has been improved as described in a paper read before the Institution of Mechanical Engineers at their visit to Calais in 1889.

Harbours with Detached Breakwaters. The best protection for vessels (next to an estuary) is that afforded by Nature in the form of a bay, with projecting headlands on each side, which requires shelter only at its entrance, to form a perfect harbour. The construction of a detached breakwater across the entrance provides the necessary additional shelter. A space being left between each extremity of a detached breakwater and the coast (or between each extremity of a detached breakwater and jetties connected with the coast) two entrances are formed. If these entrances are made to face different directions, an advantage is gained, in that one entrance may be used when the other, according to the direction of the wind, may not be convenient. Another important advantage in having a double entrance lies in the fact that a current is generally produced through the harbour, which prevents the tendency towards silting.

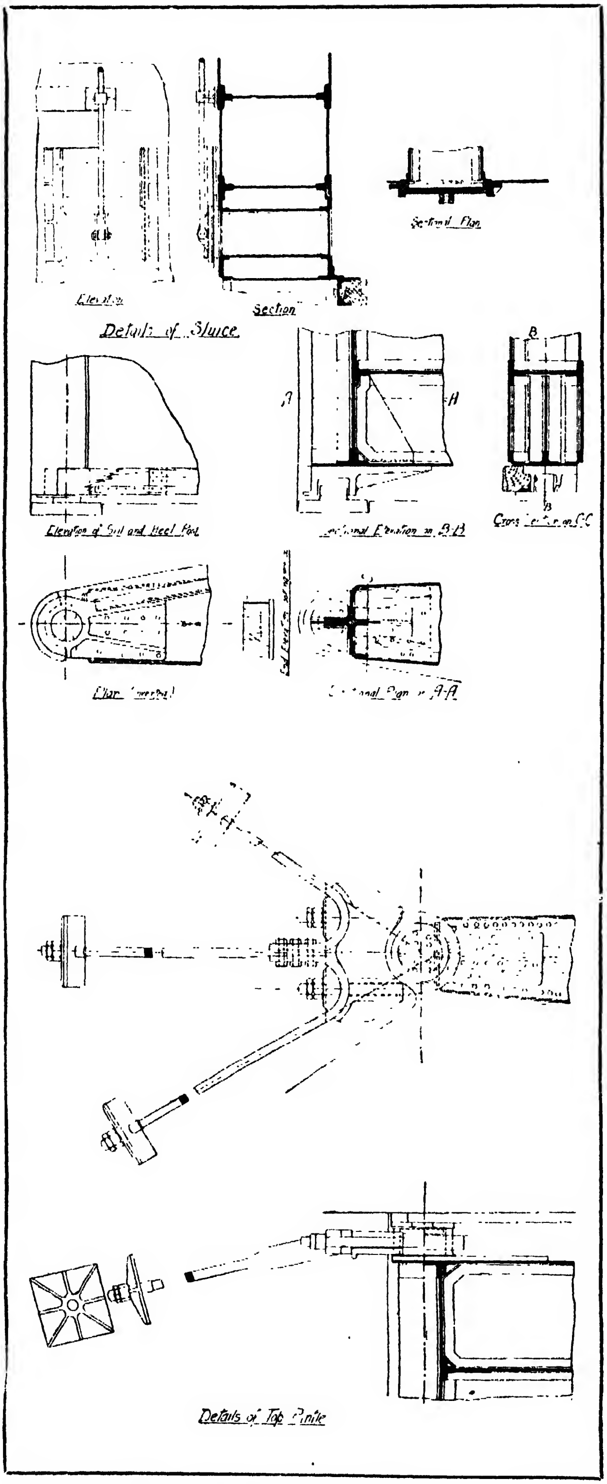
In designing harbours, however, exposed to silting, it is impossible to procure tranquillity without at the same time promoting deposit unless the silt-bearing waters are excluded, in which case the silt accumulates outside instead of inside the harbour.

Dover. The entrance to the inner harbour, 140 ft. between piers, leads to a tidal harbour having an area of about 13½ acres, including the entrance passage. The inside basins form the Granville Dock [1 and 2], which has an area of about 4¾ acres within the gates, its entrance being 65 ft. wide, with 21 ft. clearance over sill at high-water spring tides, and the Wellington Dock, having an area of 8¼ acres within the gates, its entrance being 70 ft. wide, with 15 ft. clearance over sill at high-water spring tides. The Admiralty pier was begun in 1847, and completed to a length of 2,100 ft. in 1871. In 1877 a portion of the parapet on the west side of the pier was carried away during a south-westerly gale for a length of 1,050 ft., and subsequently reconstructed to an increased transverse width. As a whole, the pier has proved to be a stable breakwater, requiring only ordinary maintenance and affording excellent shelter. This pier was constructed to form the western arm of the large harbour then contemplated for the Government Harbour, and has been lengthened to meet present requirements, having been recently extended 2,000 ft., and has a batter of 1 in 12 on the outer face, so that no resistance may be opposed to the upward movement of the water. The inner face has a similar batter, with timber fenders attached to enable vessels to be moored alongside. The average height of the pier from foundation to roadway may be taken at about 78 ft., the base width being nearly 56 ft. The Prince of Wales Pier is 2,910 ft. in length, and was built to give shelter to the east side of the harbour. This pier is 30 ft. wide, but has been widened by means of a landing-stage on the west side to provide for a station. This pier now becomes an inner boundary between the Admiralty Harbour and the commercial harbour.



4. WELLINGTON DOCK GATES, DOVER HARBOUR

Sites for Harbours. Not only is a geological knowledge useful in selecting sites for harbours, but the geographical position must be considered. Bays and indentations of coast-line offer the appropriate sites for harbours, and



5. DETAILS OF WELLINGTON DOCK GATES, DOVER HARBOUR

advantage should be taken of the shelter afforded by natural headlands to enclose the greatest area of deep water within the works. Rivers, while contributing a ready and satisfactory position for trade centres, may have their drawbacks in the shape of swift currents as well as bars and shoals.

Natural harbours form some of the finest harbours in the world, for even when not complete, they in many cases require little alteration to render them safe and commodious.

Breakwaters. The type of breakwater formed of large mounds of rubble, paved on the sea face from low water up with heavy stones so as to present a smooth slope to the waves, has frequently been much damaged by storms tearing away the paved slope and eating into the heart of the work. The type of breakwater formed of rubble mounds reaching from the bottom of the sea to a little over low-water level, along which mound a vertical wall or backbone of masonry is built, having its foundations laid at low-water level, may fail by the sea washing away the foreshore of the rubble and undermining the masonry wall, which is then readily reached by the waves. The type of breakwater formed of rectangular blocks of stone or concrete of comparatively small size, built into a vertical wall from the bottom of the sea upwards, is very costly when the blocks used are small. The type of breakwater formed of rubble mound reaching from the bottom of the sea upwards, along which is built a vertical wall formed of comparatively small blocks—the foundations of this wall being laid not at low-water level, but several feet below low water—is liable to damage from settlements in the mound and from the size and bond of the individual blocks proving insufficient. Large blocks have been used at recent harbour works, the largest, weighing 360 tons, being those used at Dublin by Mr. B. Bindon Stoney.

Except in rock foundations, more or less settlement can seldom be avoided, and the greatest occurs in rubble mounds. Breakwaters built with sloping courses readily accommodate themselves to settlement by an exceedingly small opening of the joints.

A general settlement is of comparatively little importance. A settlement of about 3 ft. 6 in.—approximately one-fifteenth the height of the mound—occurred in the Holyhead breakwater after the superstructure had been built, but the movement was so gradual and regular that the work was not affected by it. In the Colombo breakwater, which is composed of sloping blocks, the settlement amounted to about one-tenth the height of the mound, measured from sea bed to the base of the superstructure. The superstructure followed it down without any appreciable disturbance of the work.

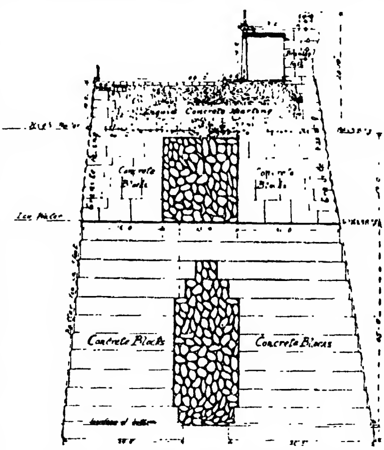
Breakwaters with side walls of concrete blocks and hearting of dry rubble is a form of construction which has many disadvantages, and is suitable only when the amount of exposure is small. The hearting of dry rubble is the chief cause of weakness. There is nothing that commends itself more to the mind of the engineer where a foundation is established upon an unyielding strata obtained at a workable depth below low-water level than continuity of a pier foundation.

Concrete Breakwaters. Breakwaters are also formed of concrete blocks throughout, laid in horizontal courses. The foundation must be carefully levelled to receive the first course of blocks, which necessarily must be laid by divers, the remaining courses of blocks being laid by a "titan," or setting machine. The blocks below low water having to be bedded without any cement mortar, are open to the defect of uneven bearing and possibility of breakage and settlement. All blocks are preferably laid as headers; loose beach stones dropped into recesses left in the sides in a similar manner to holes for dowels serve admirably below low-water level to prevent one block sliding in front of another. Divers do not care to work at a greater pressure than 45 lb. per square inch or in a depth of, say, a little over 100 ft. of water. The foundation sometimes is formed with mass concrete, or with concrete in bags, deposited by means of iron skips of from 5 tons to 20 tons capacity, having their bottoms formed of lids or flaps opening outwards, or with boxes with similar arrangements. Precaution must be taken for concrete bag work to be deposited as soon as possible after mixing. Bag work can be roughly levelled by divers pressing it directly after deposit, and before setting. The bags may be made of jute.

For concrete used in bag work, the most suitable proportions are 1 of Portland cement to 4 or 5 of sand and shingle or broken stone, and quick-setting cement is usually employed. Any voids or spaces between the bags after being deposited can be filled up with small bags or mass concrete. More rapid progress can be made with the type of breakwater composed of concrete blocks laid in sloping courses, as compared with the horizontal block type, and less overhanging is required in the "titan." The scar or free end of the breakwater is more easily protected from heavy seas during construction. The inclination of the blocks is generally about 70° to 76°, and the blocks, besides breaking joint with each other, are bound together by joggles, formed of grooves filled with concrete in bags. Sometimes the blocks have grooves to receive the tongues or projections of the other blocks. In any tendency of the toe of the work to get out of alignment with the angle or slope, compensating courses are introduced.

Rubble Stone Breakwaters. Mound breakwaters of rubble stone are suitable only when an abundant and easily accessible supply of durable stone is available. A mound of rubble deposited in the sea will, by the action of the waves, assume a profile which will be subject to variation for possibly many years without any superstructure built upon them. Plymouth, Kingstown, and Portland are examples of this type of breakwater. In some cases the slopes are faced with heavy stone pitching down to low water; but while it obviates the disturbance of rubble, it increases the scour at the toe of the pitching. Placing a vertical structure upon a rubble mound alters the pre-existing conditions, and an excavating action comes into play owing to the action of the waves against the face of the wall.

The surface of the rubble mound should be carried up well above high water, as at Holyhead; or it should be kept at a sufficient depth at low water so as not seriously to affect the character of the waves, or be exposed to their disturbing action. In the construction of such breakwaters the material is generally conveyed and discharged by means of barges, cranes, etc. The circumstances must admit of an ample width of base. This type of breakwater is sometimes constructed of concrete blocks thrown together upon a rubble bed or base. The voids in mound breakwaters materially assist in breaking up waves and checking their progress. Where a reliable base can be reached at a workable depth the pier can be built up in regular horizontal courses, and a side batter provided suitable for the requirements of the section. In laying blocks in a built-up pier as headers, and making alternate face blocks shorter than the others, the benefit of a transverse bond must be considered. If face blocks in a pier exposed to the action of rough seas are not joggled as soon as the joints become displaced air settles in the apertures, and the effect of rising water is to compress the air, causing the compressed air to force out the block. Dowelling or joggling is adopted in order to prevent the withdrawal of individual blocks, usually made of rich, fine Portland cement concrete, and well grouted into the blocks. Iron cramps and bolts are frequently used.



6. SECTION OF ADMIRALTY PIER, DOVER

Timber Pile Breakwaters. Breakwaters are also constructed of timber framing filled with stones. Where suitable materials can be obtained close at hand and cheaply, this type of breakwater can be constructed quickly, and at a much lower cost than if built of solid masonry or concrete.

When the ground permits, the timber piles can be driven from a travelling stage, and the ties and braces fixed as soon as possible after they are driven. The largest stones being selected for the faces of the breakwater being in their rough state, and no dressing being necessary, they need to be packed together so as to form as close a work as possible. Smaller stones are then used for the interior filling. The filling in with stone should closely follow the completion of the timber work.

PHRASING AND ARTICULATION

Nuances. Expression and Tone Colour. The Art of Correct Phrasing. Elocution and Declamation. How to Study a Song

By MARY WILSON

"MESSA di voce" has been defined as "the swelling and diminishing of the sound of the voice upon a holding note." To obtain this a note must be attacked *very* quietly, gradually increasing in force until the lou est tone is obtained, then must be diminished carefully and gradually until the original power of tone is reached.

These swelled sounds are shown thus <, >, and this sign usually applies to *one* note only, although it may happen that a whole phrase is to be included. But in either case it must be executed in *one* breath. At first the student must practise half the exercise—that is, begin very softly, making a gradual crescendo from the softest to the loudest tone. This should be practised twenty times, then the process should be reversed, begun very loudly, gradually diminished to a *pp.* This, too, should be practised many times. Finally the whole exercise should be practised.

Rules for Singing "Messa di Voce." The following rules must be observed:

(1) Breath must be inhaled slowly, calmly, quietly, and deeply before each exercise.

(2) The vowel sound must not alter as the note becomes louder or softer.

(3) Once the note is attacked the mouth must remain unaltered.

(4) The quality of the note must be unchanged throughout.

(5) The note must *not* be held until the last particle of breath has been exhaled: a little must remain in the lungs after the completion of the note or phrase.

The "messa di voce" may be practised on all the notes suitable for the respective voices, given in Ex. 1 [pages 6183–4], the vowels A (ah) and E (ee) being used.

The object of "messa di voce" is to give colour to the singing. It must not be attempted until the student has acquired a correct management of the breath.

The principal ornaments used in singing are the appoggiatura, acciaccatura, mordente, grupetto or turn, shake or trillo, portamento, legato, staccato, and picchettato.

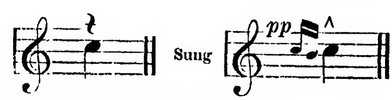
[For appoggiatura, acciaccatura, grupetto or turn, shake or trillo, see page 271.]

The mordente consists of the written note, the note above—either tone or semitone—and the written note.

Written Sung

There is also the *inverted mordente.* This consists of the written note, the note below and the written note.

Written Sung



By portamento is meant the "sliding" of the voice from one note to another of different pitch. When used with discretion it is very effective, but a common mistake made by many singers is that they use it continually without discretion. As to how it must be sung—slowly, or quickly, loudly or softly—the student must be guided entirely by the context. The following sign ⌒ or ⌒ is used.

A note must never be "slurred" to and then from consecutively.

The sign called a slur, used for the legato, is written ⌒. The notes over which the slur is placed must be sung very smoothly, but there must be no "sliding" of the voice from one note to the next, and the notes intervening between the written notes must *not* be heard as in portamento.

Great care and perseverance must be exercised before the legato can be acquired; but once the student has mastered its difficulties, he is amply repaid, for, as Signor Randegger says, "Efficiency in *legato singing* is the most prominent and valuable attribute of a good singer."

Speaking generally, it may be said there are three kinds of staccato.

(1) Write Sung

(2) Written Sung

(3) Written Sung

No. 1 is usually called staccato, and No. 2 picchettato. The notes marked picchettato are half as short again as those marked staccato.

The strictest attention must be given to the rests between the notes; neither the voice nor the breath must be heard.

Breath must not be inhaled between the notes, but that which was inhaled at the beginning must be regulated so that it is sufficient for the whole phrase. Each note must be firmly and sharply attacked.

In singing No. 3 the notes should be firmly attacked, but not so marked or detached as in Nos. 1 and 2. The student is advised to write exercises for himself on the different ornaments and embellishments, and then practise them carefully and diligently in the keys best suited to his voice.

Word Picturing. Upon "word picturing," facial expression, tone colour, emphasis, expression, and phrasing, all to a large extent depend. Each of the above will be treated separately; but it is essential that the student should first really understand what is meant by "word picturing."

Before a student can do justice to a song he wants to sing he must take the words apart from

the music, read them through carefully and thoughtfully, then re-read them. They may be merely descriptive, or they may be of an emotional nature combined with description. No matter of what nature they may be, the student must draw upon his imagination and make *mental pictures* of the scenes and emotions to be portrayed, as an artist has to do before he can place on canvas illustrations of a poem.

To a painter this word picturing is, perhaps, more natural than to a singer; the former is trained from the first to make a mental picture of all he reads. Here is this difference between the painter and the singer: as the latter will probably have to describe the whole of the poem, he must, perforce, *mentally see* the *whole* of it, whereas the painter is limited to a few lines, for he cannot paint a picture illustrating the whole of the poem.

The student will find it very helpful—until he is able to draw upon his imagination more, and mentally make pictures for himself—to recall past experiences in his life, and work on them. For example, if he is singing of a lovely garden, or a quiet graveyard, he must think of some garden he knows that once appealed to him, or a quiet, peaceful graveyard he has seen and noticed; if he is singing of a person, he may think of someone he knows who seems to fit the situation; if his song refers to the passions or emotions, he must think of the time when he hated, was afraid of, loved, or was angry with some person, and he must try and recall some of the feelings he may then have experienced, and work them into the song. The whole of what is represented in the song must be *mentally seen* if he wishes to make the rendering of it clear to his audience.

Facial Expression. For examples of real facial expression one should look at the face of a child. How quickly its little face brightens, and with what smiling eyes it looks at one when anything pleases it! On the other hand, how suddenly its wee face clouds if it is disappointed, and how it pouts when it is cross!

As the child grows up it gradually loses this natural unconsciousness of self, and perhaps unconsciously strives to hide these varying expressions which are the outcome of the thoughts and emotions. English people are much too reserved: they will not speak with their eyes and the expression of their faces—they rely entirely upon the mere words.

For those whose calling does not bring them before the public, this may be passable; but to anyone who wishes to be a singer, reciter, or public speaker, facial expression is as essential as a properly produced voice. The expression of the face must change with the mood.

No hard and fast rule can be laid down for facial expression, as all the expressions natural to one's face are the outcome of one's inmost thoughts.

The student must make a list of the different emotions—love, hatred, rage, and so on, and, standing before a mirror, practise the different facial expressions which represent each. He will see for himself how necessary it is to get a thorough reading of his song, and practise his "word picturing." When these have been mastered, facial expression will come quite naturally to him.

Tone Colour. When the student has thoroughly grasped the meaning of the words of his song, and made himself quite familiar with all the moods contained therein, he will unconsciously have acquired the correct "tone colour" for each musical sentence. He would not use the same "tone colour" for "O rest in the Lord: wait patiently for Him," that he would for "Awake, Saturnia, from thy lethargy!" For the former he would use a warm, comforting, persuasive tone, whilst for the latter he would use a sharp, commanding, peremptory one. Ere the student can hope to attain proper tone colour, he must thoroughly understand the words he is about to sing.

Emphasis. Some singers may argue that "emphasis" does not apply to singing; that it chiefly concerns readers, reciters, and speakers. This is not so; it is as necessary to the singer as to the speaker. Every word in a phrase must be given its due importance, but one of them must be more strongly emphasised than the others, to point to the real meaning of the sentence.

The whole sense of a passage may be altered if emphasis is not put on the right word. The following examples show the correct and incorrect emphasis: "Greater love hath *no* man than THIS, that a man lay down his *life* for his friends." Properly emphasised, the word "*this*" takes the especial prominence, whilst the words "no" and "life" are the next in importance.

Wrongly emphasised, it would read as follows: "Greater love hath no *man* [as opposed to "woman"] than this, that a man *lay down* [not "take up"] his life for his friends."

The student will see for himself how this sentence can be turned about, and wrongly emphasised and made absolute nonsense of: further, he will see how essential it is that singers, as well as speakers, should emphasise correctly.

Expression. Rosseau says: "Expression is the power whereby the musician conveys to his audience all the ideas and sentiments of the music which he interprets, at the same time making it evident that he feels them himself."

Some natures are less responsive than others, but with patience, perseverance, and a tactful handling, feeling can be brought out of the coldest natures. The terms expression and feeling, as applied to singing, are synonymous, therefore every person is capable of singing with "expression."

Expression cannot actually be taught, but it can be cultivated, and to such an extent that the performer really feels what he is singing; and, what is still more important, makes his audience feel it, too. There are, of course, some people whose singing is naturally sympathetic and full of feeling, but this need not discourage the less fortunate ones, for everybody who wishes can sing with expression. The easiest and quickest way to cultivate this great gift is to read good literature, especially poetry, thoughtfully and with understanding.

Phrasing. Phrasing may mean merely a correct punctuation of a musical phrase, as: "Woe! Woe unto them who forsake Him!" (Elijah); but when one speaks of a song and piece being correctly "phrased" one generally understands that the best possible effect has been given to each of the musical sentences contained therein. This can only be accomplished after the performer has thoroughly grasped the *meaning* intended by the composer, and fully realised his ideas; he will then portray them in such a way that the audience cannot fail to grasp them too.

Besides this, he must have mastered the art of breathing, have had his voice properly produced, have studied articulation and pronunciation, be able to keep time and sing "in tune," know where to take breath, be able to use the correct "tone colour," be able to sing legato and staccato, and be thoroughly proficient in the singing of all the different ornaments and embellishments.

Lamperti, in his famous "Art of Singing," says that "the whole beauty of the art of singing lies in phrasing."

We give on the next page "O rest in the Lord" fully marked, and the student is advised to study it well. For his guidance we also give a list of the signs used:

√ Where breath is to be inhaled.
| Voice to cease, but no re-inhalation.
/ Inflection of the voice to rise.
\ Inflection of the voice to fall.
∧ Strong accent.
– Medium accent.

Articulation. The great mistake so many singers make is that they give their undivided attention to the fulness and beauty of their voices, paying no heed to the diction; the words count for nothing, and are never thought of at all. It is as essential in singing as it is in speaking that the words should be clearly heard and the correct accent used—in other words, that the articulation and pronunciation should be irreproachable.

Articulation must not be confused with pronunciation, for there is a great difference between them. Words are made up of syllables. Each syllable contains one vowel and one or more consonants. When each vowel and consonant is clearly and correctly uttered, the *articulation* is perfect. The reason why English people articulate so indistinctly is that they hurry over their words. More *deliberate* articulation is needed. The famous Mrs. Siddons used to say to her pupils, "Take time!"

It will be found that the consonants offer greater difficulties than the vowels, so the first exercises will be on the consonantal powers.

It must be borne in mind that the consonants are not all formed alike. Roughly speaking, they are divisible into five groups:

1. LABIAL, formed by the approximation, or the complete contact, of the lower and upper lips—pen, bat, man, wench.

2. LABIO-DENTAL, formed by the contact of the lower lip with the upper teeth—fine, verse.

3. LINGUA-PALATAL, formed by the tip of the tongue coming into contact with the hard palate immediately behind the two upper front teeth—ten, did, line, night, sell.

4. LINGUA-GUTTURAL, formed by the back of the tongue coming in contact with the hard palate—kind, gag.

5. ORAL, formed by a full flow of breath through the mouth—hall, yolk.

The student must first persevere with the actual powers themselves, and not add the vowels until the consonants have been *thoroughly* mastered, thus:

B as in bad	N as in name
C „ cakes	P „ pill
D „ dane	Q „ quilt
F „ fight	R (trilled) as in rat
G „ gauge	R (smooth) as in war
H „ hat	S as in sill
J „ jet	T „ tone
K „ kick	V „ vain
L „ lark	W „ well
M „ mart	X = KS as in mix

Wh as in white

Each of the powers given in the above list, beginning with B, must be practised at first *very slowly*, thus: B'B'B'B, breathing after each B. Then in four groups of two, breathing after each group; four groups of four, breathing after each group; four groups of eight, breathing after each group; then in groups of twelve, sixteen, twenty, and so on. The greater the speed, the lighter and crisper must be the articulation. The sound actually uttered is not Bee, but B as heard in the word "bad" minus the "ad" sound.

After having practised the above exercise the student should make out lists of words for each consonant, thus: Ball, bat, bell, bed, bile, bid, boy, boil, book, booth, etc. Then sentences something like these: "Black Benny Bumpkins bought beautiful blackberries, but Bertha Brown bartered Benny's best boat for bananas."

This must be practised carefully in two breaths—that is, breathing after blackberries; then the whole exercise in one breath; afterwards tried twice, three times, and four times, if possible, in one breath, throughout paying the greatest attention to the "B" power.

Having learnt something of the consonantal powers, the student must turn his attention to the vowel sounds. Whilst only five signs are used—A, E, I, O, U—they represent a great many more vowel sounds.

Five sounds for A, as in ape, ah, all, at, air.
Three sounds for E „ eel, ell, earth.
Two sounds for I „ ice, ill.
Two sounds for O „ old, odd.
Three sounds for U .. up, (n)ude, (f)ull.

O is also represented in the diphthongs, as in boy and owl.

Although the vowel sound emanates from the larynx, the real formation is decided by the different shapes assumed by the inside of the mouth and the pharynx.

The student must make for himself lists of words on each of the vowel sounds given above, thus: A as heard in ape, ale, fate, pate, grate, and practise them many times, listening carefully to each sound produced, and continue until he has thoroughly mastered them.

When he has overcome the difficulties in the preceding exercises, he should take sentences such as this from Ruskin:

"Blue, baseless and beautiful
Did the boundless mountains bear
Their folded shadows into the golden air."

Recite them very slowly, and pronounce every vowel sound fully, correctly, and distinctly.

Pronunciation. Good pronunciation is really "propriety of delivery." It is not so easily taught as is articulation; so much depends upon the student's own intelligence and his capabilities for hearing and discriminating between words correctly and incorrectly pronounced.

To a very large extent, correct pronunciation depends upon their proper use; but besides practising the vowel sounds, it is necessary to hear, listen to, and copy the best orators and actors of the day if good pronunciation is to be obtained.

Apart from the different brogues of Scotland, Ireland, and Wales, the English counties have peculiarities of pronunciation that ought to be eradicated, such as: "t' cat" for "the cat" (North Lancashire); "th' cat" for "the cat" (South Lancashire); "Charing-Crawss" for "Charing Cross" (Cockney); "Eow" for "Oh" (Cockney); and many more that can only be corrected by listening to a cultured speaker. It is not intended that the student should regard pure dialects as vulgarisms; it is the mixture of "polite speech" and dialect that is so ugly. In a number of real dialect words many of the roots of the English language are traceable, for they are chiefly of Celtic, Teutonic, Scandinavian, and Anglo-Saxon origin.

It is generally imagined that the English language is bad for singing. The sooner this absurd idea

Aria—"O REST IN THE LORD."

is abolished the better. The real reason why a voice does not sound so full and resonant when singing English words as it does when singing Italian is that the singer neglects to give the full value to the vowel sounds, and does not articulate his consonants sufficiently, besides invariably "clipping" them. Another common mistake made by singers is that they are not careful to give each syllable its proper accent, for example:

instead of

As first marked, the words would read as follows, and make no sense:

"A *poor soul* sat *sighing* by a *syc-a-more tree*." We do not pronounce the letters s y c a m o r e as *syc-a-more*, but syc-amore, so why sing the word with three accents?

The consonants must be more marked in singing than in speaking, because the vowels are more prolonged and have often to be made broader.

Great care must be taken that the end of a word is not carried on to the beginning of the next—that is to say, it must be finished on the note intended by the composer: the consonants must be articulated distinctly, especially the d's and t's; and the r's trilled where necessary, but under no consideration must false accents be introduced in the endeavour to begin or finish the words.

Elocution and Declamation. It is essential that the student of singing should study elocution and declamation. Unless he does so he will find it almost impossible to deliver his song to its greatest advantage—to give it the poetical sense and the true expression intended by the composer. Many teachers of singing are quite opposed to their pupils' studying elocution and declamation. They imagine it injures the singing voice; but this is an absurd idea. If the student uses his speaking voice properly and in moderation, no possible harm will result. Cavaliere Alberto Randegger, one of the most famous professors of singing, writes: "Elocution and declamation should form an integrant part of the singer's education." [See ELOCUTION.]

A dictionary would probably describe a song as a short poem, a ballad, a lay or a strain, but none of these synonyms fully define the word. A song is the combination of words with the singing voice. One is indispensable to the other, and they are equally important. When it is remembered that words set to music make the conception absolute, it will be seen how important a part they play.

The First Song. The first song chosen should be very simple, slow, sustained, well within the compass of the voice, the intervals not too difficult, and the accompaniment quite easy, so that if the student is obliged to play his own accompaniment he can do so without paying much attention to it, and so give all his thoughts to his voice and the words. A short song such as "The Sweetest Flower that Blows," by Hawley, or "The Night has a Thousand Eyes," by Frank Lambert, is recommended.

The student must read through the words carefully, and when he has grasped their meaning read them aloud as though they were the outcome of his own thoughts, breathing where the sense dictates.

Before beginning to sing them he is advised to learn them by heart. He should then give his attention to the song, first noticing the key, time, and marks of expression before uttering a sound. Next he should slowly sing through the melody to "La," keeping perfect time; and finally he should take the words and music together.

Recitative may be defined as a musical declamation or a speaking in music. There are two kinds—accompanied and unaccompanied. In singing the former the student must keep strict time. Example: "Awake, Saturnia" (No. 28, Handel's "Semele").

When a recitative is unaccompanied the singer makes the time according to the words of the story and his own reading of the piece. Example: "O, worse than death" (No. 17, Handel's "Theodora").

For both accompanied and unaccompanied recitative singing the meaning of the words must be very carefully studied, so that the sentences may be correctly phrased and the proper emphasis given. At all times must the words be clearly pronounced.

When studying the unaccompanied style, the student is advised to select several recitatives, and take the words quite apart from the music and read them aloud as he would a verse of poetry or a piece of prose. Having satisfied himself that he has obtained the correct meaning and effect, he may then sing them, but the phrases must be the same as when declaimed.

Three Styles of Singing. Generally speaking, there are three styles of singing—plain, florid, and declamatory. For the first the essential and distinct attributes are perfect intonation, correct breath management, and faultless diction. This is the noblest of all styles, and to it belong church music and oratorios. Example: "If with all your hearts" (Mendelssohn's "Elijah").

The florid style is not so frequently heard nowadays as it was some years ago. It is full of ornaments—grace-notes, shakes, turns, arpeggios, scale passages, etc., and the "tempo" is usually quick. For the singing of this the voice must be light and full, and the breath well under control. Example: Bishop's "Lo! here the Gentle Lark."

It is to the delivery of the words that the attention is chiefly given in the singing of the declamatory style; vocalisation is practically unnecessary. Example: Schubert's "Aufenthalt."

The Young Singer's Début. It is quite possible that the average student will feel very nervous and awkward when he makes his début as either a professional or amateur singer. This is natural enough, and only time and experience will enable him to obtain perfect self-possession; but he should bear in mind that however nervous or anxious he may feel he must do his utmost to hide it, for nothing is more trying to an audience than a nervous performer. He should come well forward on to the stage, and his face should assume a pleasing expression. The student may at all times be *anxious* when he sings publicly, but it is certain he will not be nervous if he understands and has thoroughly mastered the piece he is about to sing.

SINGING *concluded; followed by* PIANO TUNING

IN BUSINESS AS A BUILDER

Continued from page 6214

Training. Office Work. Estimating from Bills and Drawings. Measuring-up. Extras. Day Work. Building Abroad. Books for Builders

By Professor R. ELSEY SMITH and R. L. ROBERTS, M.A.

At the time of writing the building trade throughout the country is passing through a period of almost unexampled depression, and cannot be said to be a very attractive or lucrative business for a young man to enter. This is not the place to discuss the more immediate causes of this depression, but it will be as well before the subject proper is dealt with to call the reader's attention to the great changes which have taken place within the last twenty years in the trade, and have most vitally affected it.

Changes in the Building Trade. There is no doubt that for the moment, though it is to be hoped not permanently, the old-fashioned type of builder is on the decrease; the builder who had first-hand practical knowledge of some or all of the trades employed in the erection of buildings, who had gone through a most practical training in the workshops, and who, in proportion to the thoroughness of his training, took pride and interest in his business—this type of builder is being pushed to the wall in the stress of modern competition. His success depended not merely on his ability to undercut his competitors in a tender list of twenty but on a reputation gained for sound, though not always, it must be confessed, cheap building; and it is open to grave doubt whether the building public in the end stands to gain by the gradual disappearance of this type. Into his place is stepping the mere financier, who chooses the building trade as the field of his operations, and whose training has made him a master of office detail, but has left him without any practical knowledge of the various trades connected with his business. Besides the change in the type of builder, there is another tendency to be noted, which is, perhaps, its necessary concomitant—that is, the tendency on the part of large furnishing and drapery firms to establish an architectural and building branch of their business, and with the help of the large capital they have at their command, to enter into competition with the genuine contractor: for in these days of rush and hurry it is apparently a tempting consideration to be able to choose your house at the same place as you buy your furniture. It should be noted, however, that the competition of these firms has at present more effect on the decorative side of a builder's business than on the actual contracting, though not without its influence here, too.

Signs of the Times. These changes are undoubtedly signs of the times, and must be taken into consideration by any one proposing to enter business as a builder; but, significant as they are, there are reasons for hoping that they indicate a mere temporary phase, and not a permanent alteration of the conditions under which the building trade has been carried on in this country. Architects, too, it is to be hoped, will be found on the builders' side in this struggle; their work is far more likely to be intelligently and efficiently carried out by firms whose interests lie only in the building trade, and whose principals have practical knowledge of building detail, for they will thus secure the great advantage of dealing direct with such builders instead of with the subordinates of great financial houses, as they would have to do if the "trust" methods of business were to prevail in the building trade.

Technical Training. Technical training may be said to be the foundation stone of success for the builder and of most vital importance if he wishes to have a real knowledge of his trade and a living interest in his business, and in these days, such training is open to all. The old order, it is true, has changed. The days of apprenticeship, whether for good or ill, are gone for ever, but the intending builder has no lack of efficient substitutes. Thanks to the various technical institutes in London and throughout the country, practical training in all the various building trades lies within his reach at a very slight cost. Some of these polytechnics have a course of day classes for intending architects and builders, where they can learn both the theory and the practice of their business; and after having been through such a course, the student, though not master of every trade, should be sufficiently acquainted with them to know good construction from bad, and to realise whether the workman in his employ are efficient or the reverse. Perhaps the ideal training for a builder is a course of these technical classes, and at the same time attendance on a building in the course of erection. From the latter he would be able to learn not only how a building is put up from the foundation to the finish, but also to gain some knowledge of the handling of workmen and the general management of a job.

Office Work. With these remarks as to the preliminary training advisable for a builder, our subject naturally falls under two heads—the builder's work in the office and his work outside in supervising and managing his jobs. It is not at all uncommon in building firms where there are two partners for them to divide the duties, one taking entire charge of the estimating work in the office, and the other visiting the contracts in hand, seeing to the ordering of materials as they may be required from day to day, and settling any question that may arise on the work itself. The convenience of this division of labour is quite obvious, but it is not a desirable method to employ. A builder should know all sides of his business, that if need arises—as it is sure to do—he may be capable of dealing with any branch of it. The office work is by far the more important of these two, though the term may be slightly misleading. By it is meant not the mere daily routine of the office, which, with little variation, would be the same in a builder's as in any other, but more specifically preparing estimates and all that has to be done in the attempts to secure contracts. This side of the business presents far greater difficulties to-day than it did twenty years ago. The fight for work and the competition in the building trade becomes fiercer every year; prices are cut to their lowest point, not only by those who may be called the "plungers" of the building trade, and in this severe struggle for work, scientific pricing of estimates is

sometimes thrown to the winds, the writer knowing of more than one case where a builder, after making up his estimate, has taken off a good round sum "for luck," as he says. With this increase of competition there must be a corresponding increase in intelligence on the part of the builder if he is to keep his place in the ranks of the successful.

The modern builder must be prepared to face the new conditions, for though some of the severe competition is due to temporary depression, it is in the main due to causes that will probably prove permanent. The public have demanded the cheapness that unlimited competition gives, and architects have been compelled to bow to the popular demand. The builders, too, have themselves to blame in part for this state of things; when tender lists were more select, the work was often too costly, and the inevitable reaction on the part of the building public was bound to come. Under these conditions, the estimating side of a builder's work has become more than ever important and increasingly difficult, and it is no exaggeration to say that it is only after the most assiduous application that skill and certainty in estimating can be obtained.

Invitations to Tender. There are certain kinds of public work that are advertised, and are open to public tender, and there are some builders that almost confine themselves to this kind of work. Speculative work, also, is, of course, open to all builders with capital, or with the ability to borrow capital. But apart from these two classes of contracts, it is difficult, even in these days of competition, for a builder to obtain the opportunity of submitting a tender. Architects, quite naturally, send their work to the men they know, and of whose skill and trustworthiness they have had experience, and unless specially advised, would not include in their lists of "invited to tender" a builder unknown to them; but if recommended to them, architects are not hostile to the young and untried man, and are quite willing to give him the necessary opportunity. For instance, a London architect, with a job outside the London area, would always ask, in addition to his usual list of builders, the local builder to tender, if satisfied of his capacity, because, if for no other reason, he should be able to carry out the work at less cost than his London competitors. The difficulties of obtaining the entrée into the "invited to tender" lists are great, but not impassable, and should not debar any man of capacity from entering business as a builder.

Estimating. A builder may have to estimate for contracts in one of two ways — either from quantities or from drawings, and in the latter case, he will have to take off his own dimensions. In modern days quantities are almost always supplied, and it is only in the case of small alteration jobs that a builder would have to take out his own—not many of the principal builders would take out their own in competition for a large contract. It is far easier to estimate from quantities than otherwise; but even then one of the most difficult tasks a builder has to do is to prepare a correct and careful estimate. It is a comparatively simple matter, by low pricing, to secure a contract; but it is much harder to prepare an estimate that will not only secure that, but also show a profit at the end of the job. To all who know anything of the building trade it is common knowledge that there is often a variation of from 20 per cent. to 30 per cent. in the prices of different builders tendering for the same job, and all quantity surveyors can testify how greatly the different prices of different builders vary in detail—some pricing their brickwork low and their joinery high, or vice versâ. This variation can be easily understood if the detailed and many-sided knowledge that is required for accurate pricing is taken into consideration. In the ordinary building there are a dozen or so different trades employed, and the estimating builder must know not only the prices of the various materials needed for these trades delivered to a certain site, but must also have some idea of what the labour on these materials will cost; and it is precisely the latter, or the human element, of which it is so difficult to ascertain the cost.

In passing, it may be remarked that the price book is not to be relied on as a certain guide, although it is very useful for occasional reference. A builder should be able to price the bills of quantities that come to his office from his own first-hand experience; this is not to say that he is never to employ an estimating clerk—most builders do—but it is unwise to depend on him entirely.

Estimating from Quantities. Before beginning to price his bill of quantities, the builder must satisfy himself as to one or two points which might seriously affect the estimate he will be giving. Common-sense will, of course, tell him that building is more expensive in some parts than others—for instance, that in a hilly suburb of London, like Hampstead, it is more costly for him to do work than in the centre of London; all materials would cost more, owing to the heavy cartage, but such knowledge as this he will have from his own general experience. His first business should be to visit the site of the proposed building; he should discover what facilities there will be for the storing of materials—limited space for this purpose will mean increased cost—whether the site is easy of access for carts to draw into, and whether there are any special difficulties connected with it. He should satisfy himself as to the nature of the soil—whether, for instance, it is easy to work or not, and whether sand or ballast can be had from it. Another important point to see to is whether there is likely to be much water met with during the excavations. There is in most bills of quantities a clause to pump or bale out all water met with in the course of the work, and this, in some cases, would amount to a serious item. The estimator having ascertained such points as these on the spot, can return to his estimating with the knowledge that will materially affect him in his pricing, and before settling down to his work he should call and inspect the drawings, that he may know whether the proposed building is a simple one, or likely to be expensive, because of minute and elaborate detail, the designs of different architects varying considerably in this respect, and appreciably affecting the cost of their work. When beginning the actual pricing of the bills, the builder should have before him the cost of various materials, such as bricks, cement, etc., delivered to the site, and the cost of carting soil and rubbish from the works, this last item varying from 10 per cent. to 15 per cent. in different parts of London. He can sometimes deduct something from the prices thus obtained before tendering, as the merchants are likely to quote him lower prices if he succeeds in obtaining the work.

Fluctuation in Prices. It is the more necessary to obtain such prices, because the cost of some materials varies appreciably—sometimes from month to month. Metals such as lead and iron are very liable to be affected in this way, and if there is a considerable amount of such material in a bill of quantities it is advisable to obtain from the

merchant a price that will be guaranteed for a time sufficient to allow of ordering at that price if the tender should be accepted; otherwise the builder may find himself in serious difficulties. A concrete instance will at once illustrate this. A builder gives in an estimate for a contract in which there are many hundredweights of lead; he comes out lowest in the list of tenders, is accepted for the work, and begins operations about a month after the sending in of his estimate: he will not require his lead either for external or internal work for many months. He has priced this in his estimate at £15 per ton; between the time of sending in his tender and his wanting the lead it has gone up £3 or £4 per ton, and if he has made no contract with his lead merchant at the time of starting his work for lead to be delivered to his works as and when required within twelve months, he stands to lose very heavily in this part of his work. The same would, of course, be true of any other materials, but metals are particularly liable to fluctuation, and the market in them should be very carefully watched by the builder. It should not be forgotten, too, that in the case of lead, the merchants have formed a ring, and that there is not the free and open market in this material that there is, say, in bricks or cement.

Preliminary and Other Items. The preliminary items should be given careful attention in pricing, especially the time given for completing the contract—almost always inserted by surveyors in the bill of quantities—and the time required for maintenance after the building is completed; this varies from three months and upwards and is sometimes as long as twelve months, and can be a very serious item. A case came within the writer's own knowledge where the time for maintenance was eighteen months; the contract was for redraining a large estate, the drains of which had settled owing to the shifting of the ground. The builder was made liable in the contract for damage to the houses on the estate during the time his work was going on, and for eighteen months afterwards for any damage due to the work being carried out; it is obvious that with a treacherous soil this might be a very serious matter for the contractor. Two other items that should be carefully noted are the fees for the district surveyor and local authorities, and for the water required for the works. In the case of alteration to large buildings, should the quantity surveyor not have included a sum for the fees as a provisional amount, the builder would be well advised to write to the district surveyor and ask him what his fees would be. As to the water, the charges of the different water companies vary, but their fees can be obtained from any textbook, such as Laxton's. The weight of the pipe required by the companies for services is the same throughout the London area, but in some cases outside that area the service pipe is required to be heavier even than the London Board's Regulations, and the unwary builder may get caught in this way. In such a case the builder should write for the water company's regulations and requirements.

Specialities and Provisional Amounts. Where bills of quantities contain specialities such as a large amount of granite work or terra-cotta, the estimator should always obtain prices, however experienced he may be; they are quite outside the run of his ordinary knowledge, and it is imprudent to risk making any mistakes—mistakes in estimating are expensive luxuries. Provisional sums play a very large part in modern building contracts and sometimes form a considerable portion of the whole, and such specialities as those mentioned above are very often included under the heading. The continued increase in such amounts has been brought about by the great changes in modern building construction and the consequent elaboration in such matters as steel construction, sanitation, and the heating of buildings. The gradual elimination of timber and the substitution of fireproof construction in both floors and roofs has deprived the builder of much of his work, and in some cases reduced him merely to the position of general banker for the contract without any of the usual advantages of that position. For though in the bills of quantities the estimator is always instructed that he must add his profit to such provisional amounts, if he really wants the work he never puts anything on, and all he can be certain of getting out of them is a small cash discount such as 2½ per cent., and this even is not always allowed by the special firms employed on a building.

Closing Remarks on Quantities. The estimator should always carefully read through the headings that precede the bill of every trade: they usually consist of the description and quality of the materials to be used, but there are sometimes items that require pricing and others that call for special attention. There was a bill of quantities within the writer's experience where, included in the headings of the joiner's bill, was a clause that the first instalment on the contract would not be paid until all the doors had been got out and framed together, an item that quite escaped the estimator's notice. If there is any pulling down or any other spot work to be priced this should be done on the site itself; it cannot be properly done in the office. If it is stated that the builder will be allowed to use such of the old materials as are sound and suitable, only a visit to the site and inspection of the existing building and fittings will enable him to tell what credit he should allow under this head. Before finally making up his tender the builder should see the specification and contract. It is true that usually all the items that require pricing are inserted by the surveyor in the bill of quantities, but it is best to make sure. Nowadays, in estimating it is usual to add the profit on each separate item. A better though little used method is to price each item at the prime cost and add a percentage at the end for office expenses, use of machinery, the general superintendence of the job, and for profit. This way is old-fashioned and the modern surveyor is not used to it, but it is to be preferred, for two reasons—it makes pricing more scientific and accurate, and in the case of additions and alterations it certainly tells in the builder's favour to have a definite percentage added on to the whole, especially where there are items for which there is no price in the schedule.

Estimating from Drawings. If estimating where quantities are supplied is difficult, the task is doubly so where there are no quantities and the builder has merely the drawings and the specification to rely on, or in some cases where no drawings are needed, the specification only. Such cases are almost unknown with buildings of any size, and only in contracts not exceeding £1,500.

There are two kinds of work for which it is very usual for a builder to have to estimate without quantities—small alterations and additions to existing buildings, and repairs and decorations. In the case of the first, drawings would be supplied, and from these the builder can get a surveyor to

take off the quantities for him if time should be allowed, though often he has the loan of the drawings only for a day or two; but, in any case, builders of experience would prefer to take off their own quantities, and this is not a difficult matter if the builder has an ordinary working knowledge of drawings and dimensions. He will not do it, of course, with the accuracy and fulness of a surveyor, and his method will be rather rough, but, backed by experience, it will suffice. Without experience, however, the builder had far better go to the small expense of employing a surveyor than blunder along as best he can. Or if this is not feasible, owing to want of time, he had better decline to tender. In the case of repairs and decorations—much the most common—the estimator must take the specification with him to the job in question, and do all pricing there, measuring the work in the different rooms, starting at the top and working downwards.

Measuring Up. If estimating preliminary to the obtaining of contracts is the most difficult task a builder has before him, a scarcely less difficult one is the measuring up the extras and omissions on the completion of a contract, and settling up the accounts. That no contract is ever completed without extras and omissions is almost a truism. Building operations do not lend themselves to terminological exactitude, and not the most skilful architect or surveyor can foresee all the contingencies that may arise during the course of the work, much less control the changes of mind to which building clients are so liable. The questions arising from these variations in a contract of necessity lead to much discussion between builder and surveyor, and the builder needs tact, judgment, and good temper if he is to deal successfully with them. In addition, there may be also matters arising out of the bills of quantities. The builder may find them deficient in certain particulars, or may think certain items insufficiently described, or the labour to an item not properly taken. In all such matters there is plenty of room for difference of opinion. The builder is naturally anxious to get all that he considers himself legitimately entitled to, and the surveyor is equally concerned to see that the builder does not get more than his rights, though his position is not one of a partisan, but of an umpire—a position from which builders can rely on most quantity surveyors not deviating. Now, in measuring up as in estimating there are two courses open to the builder. He can himself meet the surveyor and go into all the various questions with him, or he can employ another surveyor to act on his behalf. In the case of large contracts there is much to be said for the latter course, or in cases where the builder foresees that acute disputes are inevitable, and that, in consequence, first-class expert advice will be of the utmost help to him; for it may well be that in such circumstances the builder will have neither the time nor the ability adequately to present his own case, and the extra expense of employing a surveyor will be more than justified.

Extras. There are two subjects which are very liable to cause controversy between builders and surveyors—extras, which there is no schedule price to govern, and day work. In the case of the former, when there is any considerable variation—such as, say, the substitution of wainscot for deal in a building, or any large addition to the contract—it is quite usual for the architect to get an estimate from the builder before ordering the work, a preferable method to leaving it to be settled at the end of the contract, and fairer both to the client and the builder. Where the variation is slight, and no estimate is given—and most contracts will show some few items for which there is no schedule price—compromise as to price ought not to be difficult. The usual method is for the surveyor to price out the extra and omission bills, and forward them to the builder for his approval. He may put the prices too low, anticipating that the builder will ask too much; but in most cases the builder will find himself able to accept as fair the prices offered, and will always find the surveyor open to conviction if he can prove that any particular item has been priced below its real value. For it is not the unfairness or partiality of a surveyor that the builder has to be on his guard against, but the ignorance that arises from knowledge gained by theory instead of practice. The writer has in mind one particular instance of this. The taking down of a door, casing, adjusting, and rehanging in the same position was priced by a surveyor at 1s. 3d. The builder would want 3s. for it; the surveyor might say that, theoretically, a carpenter should do the work at this price, but the builder would know from practice that not a carpenter could be found in London to do the work for 1s. 3d.

Day Work. But a more fertile cause of difference of opinion than extras outside the schedule price is the question of day work. There is not much difficulty about the actual prices—for, to most contracts there is a schedule for day work attached—but as to what kind of work a builder is entitled to charge under this head. Where the builder claims day work, the usual custom is for him to send into the architect weekly vouchers of the time and materials. Sometimes the architect will accept these outright, but more usually with the proviso that the surveyor must go into them at the conclusion and decide whether the work in question can be measured or not. Where there is a clerk of the works, he has to sign the weekly sheets; and where this is done, and the architect has accepted them, the builder should not forgo his claim to have this treated as day work; the surveyor has then no right to an opinion on the matter. But when, at the end of the contract, the day-sheets are handed over to the surveyor for adjudication, the builder must satisfy him as to the reasonableness of his claims. Some surveyors, unwilling to admit any limitation in their own profession, are too apt to think that any and every kind of work can be measured. Should the builder have the misfortune to meet such an one, he must make up his mind as to what he has a right to charge day work, and to insist on his rights. A builder's claim to day work may be based either on the nature of the work itself or the conditions under which it is carried out. Under the first head would come such work as the cutting away for hot-water fittings, unless the builder has to take the risk himself.

There is, for example, a provisional amount inserted for hot-water work, and sometimes the general contractor has to do the necessary cutting away for the fitters and to price the item as he thinks best; but more frequently there is a provisional amount also for the cutting away, and the builder returns what he does under this as day work. It is obviously impossible to measure a hole cut in one place and a hole made good in another. Under this head, too, would come alteration to work already done, such as alteration to drainage already laid. Where the day work claim is due to the conditions under which the builder has to work, it is advisable for him, before doing the work, to point out to the architect that he cannot do it at

the ordinary contract rate, always, of course, presuming that there is no clause in the contract to cover work under such conditions. Work of this kind would be, for example, that done to the interior of a school while in occupation of the children, where the builder has to do the work as best he can, and to suit the convenience of the teachers; and where the builder is not required by his contract to work under these conditions, he is quite entitled to charge it day work.

Excess and Deficiency. Before leaving the question of settling accounts, one other matter must be touched upon—the excess or deficiency of quantities. Bills of quantities can either form part of the contract or not. In the latter case the builder's claim, if he thinks there is a deficiency in some particular, would lie against the surveyor who had taken out the bills. Where the quantities form part of the contract, which is the usual course, the surveyor, when measuring up, will not raise the question of excess or deficiency, presuming that the quantities are correct, but will leave it to the contractor to make a claim if he wishes. But the builder will be advised to be very careful before he makes such a claim. Nowadays, quantity surveyors are scientifically accurate, and the contractor, unless he should discover any considerable omission, will not find it worth his while to raise questions on small points which, while involving much labour, will bear little practical fruit. In this matter the builder will do well to restrain the zeal of his foreman. Many foremen, when a job is being measured up, are eager to point out that the quantities are short in this or that particular, without, of course, having gone into the general question whether it is worth while to raise the question of quantities, and a foreman should always be advised to refer such points for the contractor's consideration and decision. One other point the builder must be prepared to meet—the accuracy of his own prices in the bills. This will arise only in the case of extras and omissions. For example, suppose there is an amount of galvanised iron tongue in the bills taken out per foot run, priced by the builder either in ignorance or mistake at 1s. 6d. per foot instead of 1½d. On the completion of the job there is found to be a large quantity extra, and the surveyor will wish to price this quantity at the usual price. The builder must here stand firm—the bills of quantities form a schedule that must not be departed from, whether the error is in his favour or not. If it had been against him, the surveyor would have shown no mercy. Of course, in some cases, errors of this kind are detected, when the builder deposits his priced-out copy of the bills with the surveyor, and in that case he is asked to correct the error without, of course, altering the total of the contract sum.

Outside Work. It remains very briefly to consider the work that a builder has to do in supervising and managing the contracts he has in hand. This side of his work, though second in importance, can be by no means lightly regarded. The great quality he will require, whether dealing with the client or the architect or his own workmen, is the quality of tact. Personality tells here more than on the other side of his business, and the possession of tact may make all the difference to the keeping or losing of a connection. The jobs on hand should be visited frequently, so that the builder may see for himself that satisfactory progress is being made, and that if any difficulties arise he may have immediate knowledge of them. One of his most necessary equipments will be a thorough practical knowledge. Questions may arise any day as to the best and safest way of carrying out his work when the knowledge of his foreman will need to be supplemented or corrected by his own. The foreman may be inclined to sacrifice safety to speed, and needs at times a restraining hand in this direction. The architect may require advice at times as to the best construction to be used, and though, should anything happen to the building through faulty construction, the first responsibility is the architect's, the builder would not be guiltless of contributory negligence if through ignorance or carelessness he had failed to see what was amiss. Then the builder should have some acquaintance with the Building Acts and the various bylaws of the central and local authorities. The responsibility of meeting their requirements is always thrown upon his shoulders, and his task is not rendered any more easy by the anomalies and inconsistencies of which they are full. His more immediate duty on his visits will be to see that the jobs are being kept well supplied with materials. In this matter he should be very careful to look ahead. Foremen are too apt to imagine that if they give an order it can be executed the next day: but the builder who waits for his foreman to order the material will find his jobs standing still for lack of them, and it often means that, while waiting, men have to be taken off from one piece of work and put on to another—a very ready way of mounting up the cost of a job.

Defective Materials. Then he will be sure at times to have to deal with the question of bad material. He will come round to his job one day to learn that the clerk of the works has condemned the bricks or timber as not being up to specification, and he will have to determine promptly by personal inspection whether the clerk of the works is justified or whether he thinks the material good enough to defend. In the case of bricks it is usual to deposit with the architect at the beginning of a job a fair average sample of the bricks to be used, and by this sample the builder should bind his brick merchant, ordering his bricks from it. This course allows a fairly wide latitude, for bricks must be judged in the bulk, and what the builder has to determine is whether the bricks condemned have been so because of a few bad ones among them, or because they are a thoroughly bad lot. In the latter case he is without defence, and he will be well advised if he has one load of bricks condemned to warn his foreman not to take in any more of them on the job unless they are up to sample. His position with the brick merchant, if the bricks are really bad, will be much stronger if he refuses to have them unloaded.

The question of timber will be a far more difficult one. It is usually specified to come from certain ports—in some cases, even, from ports whence timber has ceased to be imported for several years. The builder's best course is to inspect the timber in the docks before he buys it, and satisfy himself that it is up to his requirements. But really good timber is getting scarcer and dearer every year, and he will often have to be satisfied with the second best. If his timber is condemned and he is convinced that he cannot defend it, his best course is to take it off the job at once. That is not to say that he is always to give in. He may have the misfortune to meet with a clerk of the works who has a passion for condemning everything both in material and workmanship, and who thinks that it is his function to hinder rather than to help a job.

Speed of Work. But above all, the builder should carefully watch the progress of his jobs, and see that he is not getting behind his contract

time. It is true that penalties for time are rarely enforced, because there are so many contributory causes of delay—besides, possibly, the builder's lack of energy—that enforcement is found impossible in practice; but, in any case, slow work in these days is bad for the builder's reputation, and his pocket. It is a matter for discussion whether buildings were not better built when they were erected calmly and without hurry than they are in these days of rush. But the builder to-day has no time to stop and discuss this; he must move with the times, or he will soon cease to do building at all. But while taking care that his jobs are being pushed on as rapidly as possible, he must see to it that they are not crowded with men, or his cost book will be anything but pleasant reading. Besides his ordinary visits the builder should make a point of sometimes visiting his jobs at the time of starting in the morning; foremen want keeping up to the mark in the matter of time, and a late foreman means no work done before breakfast.

Foremen. The choice of the right men to carry out his work is a matter of great importance to the builder, and very much depends on the foremen he employs. The chief requisite in a foreman is the capable management of men; he must not only have a first-rate knowledge of the best means of carrying out work, but he must also be able to drive his workmen and get the most out of them he can, consistent with safe construction; and for this reason a foreman should be allowed a free hand in the choice of his men, with a few obvious limitations. Should a man be taken on at a job whom the employer, from previous experience, knows to be a bad workman, the builder must, of course, tell his foreman that he cannot have the man on his works; but apart from such exceptions the builder should not interfere with the men the foreman chooses, and if he has cause to feel dissatisfied with the men employed on the job, and should the results convert that feeling into conviction, the only way is to get rid of the foreman. It is almost unnecessary to say that a foreman must be sober and honest, straight not only to his employer, but to his employer's clients. A man who is dishonest towards the clients will, in the end, be dishonest towards his own employer. A builder should see that he makes his own interests and the foreman's identical; this can be assured by giving the foreman continuous employment, and keeping him on even if for the moment another job cannot be found for him. Another method by which a foreman can be induced to take a serious interest in his work is by offering him a bonus at the end of the job should it come out on the right side; but this wants careful consideration, and special care should be given to the foreman's character if this bonus is offered. In these days of cutting prices, where work is too often taken below cost price, it is a temptation to a foreman to make the job pay by scamping the work. How far should a foreman be trusted is a question that builders are always having to put to themselves. Should a foreman be allowed to pay wages himself, or ought it to be the invariable rule that somebody from the office should pay? In the case of small contracts, where the wages are not heavy, the foreman may be trusted to pay, but only, of course, provided that the builder has had him in his employ for some time, and is convinced of his trustworthiness and honesty. But with contracts of any size, it is the rule for the builder himself or a clerk from his office to pay at the job. One other piece of advice may be useful—don't sack your foreman for trivial reasons. The old-fashioned method was to send a man away at once if you had the slightest disagreement with him; that method is happily passing away, experience having proved that a man who is always in fear of dismissal does not make a good servant.

Employer and Workmen. The decay of such methods of dealing with men, accompanied as it has long been by the growth of trades unionism and combination of both masters and men, has had as its result the development of better feeling between employers and their workmen. The master has come to recognise that men are entitled to a fair wage, and the men that the builder is entitled to a fair day's work in return. It is not too much to say—speaking for London—that the best builders are to be found in the membership of the Master Builder's Association, and the best workmen in the various trades unions. The strength of these two combinations has led to a mutual respect on both sides, and reduced almost to a minimum the danger of strikes.

The Attractions of the Building Trade. It may, perhaps, be asked, can building, under modern conditions and modern competition, be made to pay? Reasons have already been given for thinking that the present depression is but temporary, and in that belief the wise builder will bide his time. It ought to be an axiom, but is not, that no builder should take work below cost price, and if for the time he finds it impossible to compete with modern prices, he had better hold his hand. It is better to play in the streets than work at a loss, and continual lowering of prices will tell its own tale in the Bankruptcy Court. Let him keep his head, get what little work he can at a fair profit, and not plunge by taking large contracts at impossible prices.

With all its drawbacks one charge cannot be brought against the building trade—lack of interest. At the end of most careers a man can only point to the amount of money he has made as evidence of his work; the builder leaves a far more enduring mark behind him, and though not, of course, sharing the artistic honours that fall to the architect, he is essential to his work, for without him the architect's ideas would find no permanent or concrete expression. For this reason, to say nothing of others, no builder who honours his business should consent to have anything to do with scamping methods or to take work at so low a price that no profit can be made without seriously deviating from fair workmanship. And here architects may well be asked to lend a helping hand by refusing to hold out to their clients delusive hopes as to how cheap work can be done.

BUILDING ABROAD

In the details of building operations and methods there is room for much diversity, and practice is regulated by climate, custom and materials.

This course has of necessity in considering the detailed methods of building construction dealt with their execution as carried out in England. To a great extent, in many of the trades the practice is much the same in the whole of Greater Britain and America, and either an architect or a builder who had received an efficient training in his own country, though he would find—especially in the details of practice—divergencies from what he was accustomed to, would, in a very short time, readily adapt himself to them.

Effect of Climate. In many of the great English colonies the climate is essentially different from that of the mother country, and the result of this difference is frequently that buildings of a

different type altogether from those erected here are required, and the disposition of various parts of a building have to be modified to suit the changed conditions. This is particularly the case with the humbler class of buildings, in which the desired result must be arrived at without any great outlay, and in which, on this ground, purely local materials must be employed and used to the best advantage. The more undeveloped any country or district is, the more primitive will be its buildings, and where entirely new ground is broken the settler must often in the first instance be his own builder and construct his log cabin in a rough and ready fashion.

But as soon as communities collect together, building passes into the hands of a special set of people who have had special training or show special aptitude; but so long as the community is somewhat isolated and difficult of access, the nature of the material to be obtained locally will greatly influence construction, and the best builder will be he who can apply them best.

Means of Transport. Transport, both by rail and from the nearest station by road to its destination, is in many newly-settled countries costly; as a consequence, when materials are brought from a distance, those that are comparatively light are sought for, and are employed, even though they are by no means the most suitable ones that can be used for the purpose. An instance of this is the very general use of corrugated iron as a roofing material in South Africa; it is unquestionably as light a material as can well be employed for this purpose, but, apart from the difficulty of giving it any artistic treatment, it is on many grounds unsuited for use in such a climate; yet its cheapness and the facility with which it may be transported has brought it into very general use, not only in South Africa, but in other colonies where good roofing materials are not produced. The element of cheapness is one that in all countries or districts that are not highly developed is usually an all-controlling factor.

A dwelling must be provided, but it must be inexpensive, and therefore without many of the comforts and even what are considered necessities in more advanced districts, and in such cases it is naturally the work in the finishing trades that is omitted. The walls and roof are essential and cannot be omitted, but such matters as internal plastering and plumbing work very often must be sacrificed in such circumstances.

Materials and Design. In a very considerable proportion of newly-settled countries wood is the most readily available building material, and, except in extremely isolated cases, sawmills are usually established early and convert the timber as felled into the various forms required by both carpenter and joiner. Wooden buildings are very largely used in many such districts and often continue to be employed long after other classes of building materials are available. Such structures are often carried out on a large scale, and in Australia, for example, and in America also, houses of considerable size are to a great extent constructed of wood in suburban and country districts.

Australia is well supplied with good timber, and hard woods are largely used in house construction, though imported woods are also used for some classes of work. The usual construction is that of a timber frame with head posts and sills, well braced, and covered externally with stout weather boarding and plastered or lined with boarding internally. Such buildings are most easily constructed as one-storied buildings, and as land is of comparatively small value in such districts the large area covered by such a building is not a serious drawback; in such cases any heavy framing can usually be avoided. And buildings of this type also lend themselves to the provision of wide verandahs, a feature welcomed in countries where the sun has great power.

The Influence of Custom. Such a verandah is a feature in the life of many of the colonies, and is commonly met with in Australia and Africa for instance: the type of building arising in such cases from the exigencies of the situation, in the first instance, is apt to be confirmed and continued when the necessity for the original methods of construction, which produced them, has passed away. In Australia, beyond the towns and in country situations houses of considerable size and value are constructed as one-storey buildings sometimes in wood, but sometimes of more permanent materials.

The influence of custom and tradition is always strong, and a type of building that has been produced to meet the needs of a locality is apt to be improved and developed, but not altogether lost sight of when somewhat more complex structures are required. On the other hand, in the case of buildings of a class which cannot be erected until a community has become highly developed, such as large public buildings, banks and churches, the traditions of the mother country often, to a very great extent, regulate their design and development, influenced in detail by local requirements as to construction, but similar in general treatment to the same class of buildings as used in the older European countries. Within the limits of the same country, especially if it is of great extent, varieties of climate and other conditions will arise which will lead to modification of any general type, much as in Europe such differences have led to the use of buildings for the same purpose but wholly different in character in the extreme north and south, for example, though in Europe these variations are further influenced by difference of race.

But in a country of even moderate size, especially in the case of countries which have to depend largely on imported materials, those towns which lie on the coast or are directly served by a railway will have a great advantage over those less well served, and this is particularly the case with all those coast towns that become ports. The necessity for handling building materials when they are transported by different kinds of conveyances—from a ship to a waggon, thence to a train, and again to a waggon—make the cost of dealing with them very heavy where several such changes have to be made; in a seaport the cost is often greatly reduced by the possibility of conveying goods direct from the ship to the site.

When a country is so far developed as to be able to depend to a great extent on its own resources for all kinds of fittings as well as for the materials of the carcase work, this special advantage is less marked; but even in countries that have been settled and developed for a long time, a considerable number of fittings and special appliances are almost always required to be imported.

The Rapid Growth of Towns. One of the surprising features of many of the important cities in the Colonies and America is the extraordinary rapidity with which they arise in what has hitherto been little more than a wilderness. A discovery of gold, or some other cause, attracts people to a centre, where buildings of a simple

character are at first hurriedly constructed; but in a surprisingly short time the original settlement is replaced by a well laid out and well constructed city, which almost immediately springs into life and full activity.

In some respects such a city possesses great advantages over many of those in older countries, as from the very first its disposition and general development can be regulated without interference with private and vested rights, such as prevented the adoption of the magnificent scheme for rebuilding London prepared by Sir Christopher Wren after the Great Fire. It is true that most towns of this class lack, and will ever lack, the picturesqueness and charm of an old world town, with its streets of irregular width and varying line; but from the purely business point of view the orderly laying out of a town on a definite plan, designed to facilitate communication between all its parts by spacious streets, is of great commercial value. Such a disposition is not necessarily incompatible with the arrangement of fine street architecture, as is evidenced by Wren's plan already referred to.

Tall Buildings. One of the striking developments of the new American cities is the enormous height to which buildings are carried up, in a manner which in this country, with its old laws as to easements and the rights of neighbouring owners will fortunately never be possible. The possibility of erecting such structures, to which, in New York, for instance, there seems to be hardly any final limit, has undoubtedly led to the development of a system of construction different in character to any developed under more reasonable requirements. Such buildings are only possible when executed, so far as their main structure is concerned, practically exclusively of steel. It would be impossible to carry up a building of 20 or 30 storeys, or even more, in height with walls of either brick or stone without making the lower walls of such immense thickness, and the whole building of such an intolerable weight, as to defeat its own object.

Special Methods of Construction. With a steel frame, however, the conditions are altered, and though the total load on the foundations will still be enormous, it is possible, by skilful disposition, to distribute this over a very large area of surface, and to erect structures extending to upwards of 300 ft. high and of many storeys, enclosed with walls which are mere screens against the weather. The walls of each storey are carried on girders independently of the storeys either above or below, so that it is possible in such a building, after the frame is once erected, to start the walls at any level without the necessity of building them up in the ordinary method from a solid foundation. In our own country steel-framed buildings are becoming common, but in London, at least, the regulations do not permit of American methods being carried out to the extent of treating each storey as an independent wall, and regulating it as regards thickness on this basis; this is, however, an essential feature in the success of such a system of construction, if full advantage is to be taken of its possibilities.

The foundations for such lofty erections must be prepared with great care; this is a matter of even greater importance than usual, when such enormous loads are to be carried, and in America piles are used almost invariably, not merely placed in rows under lines of wall, but very usually disposed in a series of lines over the whole area of the site; they are finished with a timber grillage and concrete, as already described. When once, however, the preparation of the foundations is completed the work of the superstructure can proceed with great rapidity; the erection of the steel frame, which may be prepared while the foundations are being put in, being by no means a lengthy operation. When once this is completed the filling in of the walls may be carried out at several different stages at one and the same time.

The erection of such lofty buildings does not merely affect the manner in which the carcase is erected, but all kinds of internal details—such matters, for example, as those of water supply and the means of access to the upper floors, which is usually arranged for by means of express lifts. The problems of heating and ventilation also require special consideration and treatment in such lofty structures.

Labour-saving Plant. In the great towns of the North American continent the builder and contractor is often better equipped than in this country with all kinds of labour-saving plant, and, as in the case of many other industries, many of the machines and appliances now in use in other countries have been originally invented in America to facilitate rapidity of construction.

It is largely the desire for extreme rapidity of construction that has led to such modifications as have been referred to in building methods, combined with the desire to reduce to a minimum the area of the supporting and enclosing walls, so as to render every possible inch of a site available for use for the purpose of bringing in rents. This is largely due to the immensely increased value of land in the larger and more important towns, and with such inflated ground rents it is naturally important to secure that as large a proportion as possible of the area shall earn rent; it is also important to ensure that the site shall lie idle for as short a time as possible.

All such work requires the most skilful organisation and forethought; it does not suffice for the contractor to look forward for a few days and weeks, but he must from the very first look forward and arrange for all the work that will be required to complete his building.

Drawbacks of Rapid Construction. This hasty building, the outcome of commercial pressure, is not without its very serious drawbacks. It gives no time for the thoughtful consideration of the architect's work, which, like the builder's, must be turned out as it were from a drawing machine. Buildings designed and erected under such conditions must, almost of necessity, bear a commercial rather than an artistic impress. Really good architectural work must have time and consideration given to it for its careful development, and hasty planning, and the impossibility of modifying in any way a design while the work is in progress, militates against the best work.

The system has this great disadvantage, too, that it creates a general impression that all work can be carried out at a much quicker pace than is desirable, except for such special structures as have been described. It is, however, fatal to really good building to hurry it unduly, for work requires to be given time to settle into its place; if walls, therefore, are rushed up hurriedly, too great a load may be placed upon the lower portions before the mortar is properly set, and the building is not given time to dry before the finishings are put in, resulting in shrinkage and other evils.

Effect of Climate on Individual Trades. It is not possible to deal in detail with the effect produced on the different trades by variations in climate in various parts of the world; it may be desirable, however, to point out that this is a matter that does affect methods of work and the possibilities of applying certain classes of materials, and creates a class of conditions which affect certain trades in a manner totally different from those with which we are familiar.

One or two examples may suffice to draw attention to this point. In some hot climates, for example, the plasterer has not to guard against his work being damaged by frost at certain seasons, but he may have to fear the effect of hot drying winds that will most injuriously affect the plaster; it may be just as important to suspend work at such times as with us in frosty weather.

Great heat and rapid changes of temperature, such as occur in some places, render the use of lead on roofs, and even for pipes, very undesirable, owing to the amount of expansion that is caused, and the increased tendency to "creep." In such climates, substitutes have to be provided, and in many similar ways the details of various trades must be modified and adopted to suit local conditions.

Again, in some places, the ravages of insects, such, for example, as the white ant, are so serious as to require special conditions to meet them.

The builder abroad may, in many districts, have a much greater difficulty in finding the men he wants, skilled in the various trades, to carry out urgent and important work, as the supply is often limited. The management and control of men under such conditions is one of greater difficulty than when the supply is greater than the demand.

The qualities and powers, however, that make a man successful as a builder in one country will be useful in another; and he who has had a thorough training, and has this capacity for controlling and directing labour and the complicated work in a variety of trades and managing the business of a builder's office, will not find the variation of any local conditions so great that these cannot, with a little time and attention, be thoroughly mastered and overcome if circumstances make it desirable that work should be taken up in other lands than that in which he has been trained.

BIBLIOGRAPHY OF BUILDING

GENERAL. "Notes on Building Construction." Vol. I., 10s. 6d.; II., 10s. 6d.; III., 18s.; IV., 13s. (Rivingtons); "Builders' Work," by H. C. Seddon (Longmans. 16s.); "Practical Building Construction," by J. P. Allen (Crosby Lockwood. 7s. 6d.): "Modern Buildings: their Planning, Construction and Equipment," edited by G. A. T. Middleton. 6 vols. (Caxton Publishing Co. 10s. 6d. each); "Building Construction and Drawing," by C. F. Mitchell (Batsford. 3s.); "Building Construction (Advanced and Honours)," by C. F. Mitchell (Batsford. 5s. 6d.); "Specifications in Detail," by F. Macey (Crosby Lockwood. 21s.); "Building Specifications," by Leaning (Batsford. 18s.): "Rudiments of the Art of Building," by E. Dobson (Crosby Lockwood. 2s.); "The Strength of Materials and Structures," by Sir J. Anderson (Longmans. 3s. 6d.); "Architectural Surveyors' Handbook," by J. T. Hunt (Spon. 5s.); "The Architect and Builders' Pocket Book," by F. E. Kidder (Chapman & Hall. 21s.): "Building Materials, their Nature, Properties and Manufacture," by Middleton (Batsford. 10s.); "The Mechanics of Architecture," by Tarn (Lockwood. 7s. 6d.); "Practical Treatise on the Strength of Materials," by F. Box (Spon. 12s. 6d.); "London Building Act, 1894, and Amendments" (Stanford. 2s. 6d.): "Timber and Timber Trees," by T. Laslett (Macmillan. 8s. 6d.); "The Timbers of Commerce and their Identification," by H. Stone (Rider. 7s. 6d.); "Dry Rot in Timber," by W. H. Bidlake (Batsford. 1s. 6d.).

CONCRETE AND FOUNDATIONS AND STRUCTURAL IRON AND STEEL. "Foundation and Concrete Work," by E. Dobson (Lockwood. 1s. 6d.); "A Practical Treatise on Foundations," by W. M. Patton (Chapman & Hall. 21s.); "Treatise in Shoring and Underpinning," by C. H. Stock (Batsford. 4s. 6d.); "Facts on Fire Prevention," by E. O. Sachs (Batsford. 25s.); "Concrete Plain and Reinforced," by F. W. Taylor and S. E. Thompson (Chapman & Hall. 21s.); "Stresses and Thrusts," by G. A. T. Middleton (Batsford. 4s. 6d.): "The Practical designing of Structural Iron Work," by H. Adams (Spon. 8s. 6d.); "Structural Iron and Steel," by W. N. Twelvetrees (Whittaker. 6s.): "Portland Cement, its Manufacture, Testing, and Use," by D. B. Butler (Spon. 16s.); "Fireproof Construction of Buildings in the United States," by N. W. Gibson (R.I.B.A. publication. 1s.).

BUSINESS CORRESPONDENCE

The Business Letter. Punctuation. Composition. Forms of Address. Value of Shorthand. Tuition

THE term "Commercial Correspondence" includes the whole system of conducting business transactions by means of writing. Its great importance consists in the fact that it brings into communication people far distant from one another, and helps to establish the closest business relations between them. Thus, the trader in London, by means of correspondence finds scope for his activities over the whole globe. By far the greatest part of the trade of the world is obtained and carried on by means of letters. With the rapid extension of postal and cable facilities the opportunities for business are also extended, and with them the province of commercial correspondence.

Confirmation of Verbal Agreements. Moreover, it is the rule in business to confirm by letter any verbal agreement entered into. In fact, according to the Sales of Goods Act, 1893, a contract concerning goods to the value of £10 or upwards *must* be made in writing, or it will not be enforceable by action at law.

It is obvious, too, that a letter, as a vehicle of communication, possesses advantages which are particularly useful in cases where extreme caution is necessary in the use of words. We may be led to utter a hasty word in an interview, or to make an admission that will be regretted later; but in a letter we can say exactly what we desire to say, neither more nor less, and we can consider the import of our words and their effect before the communication is despatched.

It is clear, therefore, that the ability to write correct commercial English should be carefully cultivated by business men in whatever capacity they may be engaged. That this ability is not so general as it ought to be is matter of common knowledge to all who have to do largely with business correspondence, and the object of this article is to assist those who seriously desire to acquire a qualification which is absolutely necessary if mistakes and misapprehensions in the conduct of business are to be avoided.

Everyone has a perfect right to make his own style of letter writing, and, as a rule, the more characteristic it is of the writer, the better; but custom has established certain forms and usages for business correspondence which it is generally convenient to follow. Accordingly, a letter is usually divided into parts.

Parts of a Letter. A business letter may be divided into six parts, as follows: (1) The heading; (2) the inside address; (3) the salutation; (4) the body of the letter; (5) the complimentary close; and (6) the signature. These parts should follow one another in the order here given.

The *heading* should consist of the postal address of the writer, with the date of writing and, in some cases, a reference letter and number for the purpose of classification. The parts of the heading, the street, town, etc., should be separated by commas.

The *inside address* should give the name and address of the person or firm to whom or to which the letter is written, and it should never be omitted, since a press copy of a letter without the name and address of the person to whom it was written would be of little value for reference, and of no value as evidence. The inside address should be punctuated in the same way as the heading.

The *salutation* is the "Dear Sir" or other complimentary term used to begin the letter, and it should be followed by a comma.

The *body of the letter* is the part which contains the message, the inquiry, or the information to be communicated, and it is, of course, the most important. The writer should take care to leave a sufficiently wide margin at the left-hand side of the page, and should see that all lines except new paragraph lines begin exactly at the same distance from the edge of the sheet. It is not practicable to arrange a regular margin at the right-hand side of the paper, but the termination of the lines should be kept as uniform as possible by judicious spacing and the careful division of long words. The writer should also leave ample space for the complimentary close and signature. There is nothing more distasteful than to see the formal ending of a letter and the signature occupying a space by themselves on a separate sheet and more or less detached from the rest of the communication. A business letter should never be written on both sides of a sheet. Where the communication is too lengthy for one sheet, use others and number them consecutively. The punctuation of the body of a letter should follow the rules which apply in the case of ordinary printed matter. A few general directions on the punctuation of business matter are given later.

The Close of a Letter. The *complimentary close* consists of the words of respect used to express the feelings of the writer towards his correspondent. The terms used should always be consistent with those employed in the salutation, and the words should not be abbreviated. For example, "Yrs. ffy" should not be written for "Yours faithfully." It should be noted, too, that a capital letter is necessary in the *first* word only of the "Yours faithfully" or other term employed.

A concluding sentence such as *Trusting you will give this matter your careful consideration* should begin a new paragraph; the term *We remain*, or whatever words may be used in this connection, should be placed on a separate line, and preceded and followed by a comma; and the complimentary close should be placed on a line by itself.

The *signature* is the name of the writer or of the firm he represents. It ought not to be necessary to say that the signature should be a perfectly legible one; but experience proves that there are many persons who adopt a style of signature that can only lead to uncertainty in the mind of their correspondents who are strangers to them. Intricate and absurd flourishes are employed by many in the mistaken notion that such signatures are difficult to imitate. As a matter of fact, the exact contrary is the truth. The plainer the signature, the more difficult it is to forge it successfully. Where the writer of a letter is a woman, and a reply is expected, the signature should be preceded by the title *Miss*, or *Mrs.*, in parentheses, in order that the reply may be properly addressed.

A word of warning may be added against the foolishness of constantly changing the form of signature. A sensible business man adopts a form and sticks to it.

The signature should be written on the line next to the complimentary close, and should be written so as to finish near the right-hand edge of the paper.

The manager or secretary of a public company usually adds his official position when signing: thus, *William Church (Manager)*, *Henry Winton (Secretary)*. Strictly speaking, only a partner in a firm is entitled to sign the name of the firm: but, in most houses of business certain employes are also empowered to sign the firm's name. This authority is often given by means of a legal instrument called a power of attorney, and it is usual to publish the names of persons so authorised, or to send copies of their signatures to the correspondents of the firm. These persons are said to sign *per procurationem*, which means power to conduct another person's business, and. therefore, to sign letters, etc., on his behalf. *Per procurationem* is contracted as follows: *per pro.*; *p. pro.*: or *p. p.* For example:

p p. Smiles & Co., or *per pro. Smiles & Co.,*
Charles Locke. *Charles Locke.*

There is no commoner mistake made by junior clerks than to sign an unimportant letter or post-card given them to despatch with their name, preceded by an abbreviation for *per procurationem*, when, as a matter of fact, they possess no such authority.

An employe having no special power to bind the firm should sign as in the following example:

for Smithson & Co., or *pro Smithson & Co.,*
Edwin Reed. *Edwin Reed.*

Characteristics of a Good Business Letter. These are (1) absolute accuracy and clearness as to the facts, figures, or terms referred to; (2) brevity, so far as this may be retained along with clearness of meaning; and (3) courtesy, which is at all times advisable and always possible, even in a letter which is otherwise disagreeable to the recipient.

The business correspondent, therefore, should make it a rule to see that all quotations, terms of delivery, etc., are carefully checked before a letter is despatched. No trace of ambiguity should be present to make it possible for even the most ingenious person to extract two meanings from a communication. It must be remembered that the recipient of a letter will naturally construe it in the sense most favourable to himself, which *may* mean pecuniary loss to the sender of the letter. The business letter writer should make every effort to acquire the ability to express himself clearly and concisely, and to adopt a courteous tone in both writing and speaking, even when he is most firm in his attitude, on a matter of business.

Excellence as a business correspondent can be acquired only by careful study and much practice, but the beginner will derive considerable benefit from the perusal of the specimens of actual business letters given in "Pitman's Commercial Correspondence and Commercial English" (Sir Isaac Pitman & Sons, Ltd., London), which also contains a long chapter of instruction in this necessary art.

The Arrangement of the Letter. A logical order and arrangement of the various points treated should always be observed in a business letter. It is a mistake to refer in the third and fourth paragraphs to a matter which is dealt with in the first paragraph. All that requires to be written about any subject should be written in the same part of the letter, and not scattered here and there throughout the communication. Loose writing indicates loose thinking, and gives the correspondent a poor impression of the writer.

Excessive Paragraphing Should be Avoided. It is sufficient to begin a fresh paragraph when there is a change in the subject. In letters between a firm and its agent it is usual to indicate the matter dealt with in each paragraph by writing at the beginning some word or words which serve as a sort of title to the paragraph. This greatly facilitates reference to any point in the letter, and the method is accordingly growing in favour.

Punctuation of a Business Letter. Punctuation, or the insertion of stops in correspondence, is necessary to mark the parts and sections into which sentences and paragraphs are divided, so that the exact meaning may be quite clear. The real use of stops is to cut off and separate single words, or groups of words, from one another.

The ability to punctuate properly can be acquired only by a fairly extensive course of reading of the best authors and a considerable amount of practice in original composition. The reading and copying of high-class poetry will be found of great assistance in the acquisition of the knowledge of the correct use of stops.

It should be remembered, however, that the more carefully the matter is arranged and written, the less need will there be for punctuation marks. It is a mistake to depend entirely upon punctuation for the correct interpretation of a passage. Moreover, an excessive use of stops gives a broken appearance to the matter, and may lead to confusion. After all, punctuation is largely a matter of individual taste and discretion, and depends to a great extent upon the style of the writer and the subject of the composition. The following brief hints with regard to the use of stops in the composition of business correspondence may be found serviceable to the beginner.

The Full Stop (.). This mark is used: (*a*) at the close of a sentence, as: *The goods were forwarded by L. & N. W. Ry.* yesterday. (*b*) After abbreviations, Roman numerals, and headings, as: *G. Goodman, Esq., B.A., The Laurels, Ealing, W.*; *Chapter XV.*; *Service Regulations.*

The Colon (:). This is inserted before a remark which is of the nature of an afterthought, as: *Invoices to be sent direct to customers: copies to me at this address. Please see that the pattern is copied exactly: mere similarity will not do.*

The Colon and the Dash (:—). These are used before a quotation or a list of things, as: *Referring to your inquiry about Mr. Thomas Thowell, we have a letter from our agent this morning in which he says:—"I have made careful inquiries re Mr. Thomas Thowell, and I find that he failed in* 1901, *with liabilities* £3,500, *and assets* £275." *Please quote us your lowest prices, F.O.R. Liverpool, for the following:—*

15 *cwt. Mysore coffee*
7 *cwt. Trinidad cocoa*
5*-ton lots best cube sugar.*

The Semicolon (;). This mark is employed when two or more sentences are combined, as: *I called there to-day; saw the buyer; and secured the order which is enclosed herewith.*

The Comma (,). This is used: (*a*) when it is necessary to indicate a short pause so that the sense of the passage may be quite clear. as: *Upon the*

receipt of your cable of the 10th inst., I called upon Messrs. Deane, who practically control the market at present, and asked them to alter their quotation; but they absolutely declined to budge a cent.

(*b*) When it is desired to separate a parenthetical clause from the remainder of the sentence, as: *If this trial order gives satisfaction, as we have no doubt it will, a profitable business may result, since our friends do a larger trade than any house in this particular market.*

(*c*) Before and after words the insertion of which slightly affects the smoothness of a sentence, as: *Kindly examine the account, and, if correct, be good enough to send us a cheque for the amount at once.*

(*d*) Between two phrases joined by the word "and," as: *We should be pleased to have your orders again, and we feel sure you would be satisfied with the quality of the goods we are now offering.*

The Dash (—). This mark is used to denote an abrupt break in the sentence, or it may take the place of brackets, as: *Referring to the consignment of hat trimmings—which, by the way, we are expecting daily—we have got into touch with several likely buyers, and we hope to effect speedy sales at fair prices.*

The Interrogation Point (?). This is used: (*a*) after a direct question, as: *May we send you a small parcel at this price?* (*b*) At the end of a sentence which is meant as a query, as: *We presume you would have no difficulty in making delivery of the goods by that date?*

The interrogation point is *not* necessary when the question is only reported to have been asked, as: *I saw the chief traffic manager, and he asked me when we could supply the necessary details.*

The Apostrophe ('). This is properly used (*a*) to mark the possessive case of nouns, as: *We have forwarded you to-day, per M. Ry. Co., a case containing 6 dozen men's caps, 4 dozen boys' vests, and 3 dozen girls' Tam-o'-Shanters. The manager's clerk called at the company's office yesterday, and was shown Mr. Boyd's receipt for the correct amount. We completed Mr. Evans's order last week.*

(*b*) To indicate that some letter or letters have been omitted, as: *I don't think it's possible to do anything with this man. I can't arrange an interview with him, as he won't even answer my letters.*

(*c*) To indicate the plural of single letters or figures used as words, as: *Your correspondent must mind his p's and q's. All the 2's and many of the 4's are faulty.*

The Quotation Marks (" "). These are used (*a*) when the exact words of another person are quoted, as: *Please note that our bill of £260 10s. 6d., due on the 2nd inst., has been returned to us marked "Refer to Drawer," and our bankers inform us that your account is overdrawn. The exact wording of the clause was as follows: "If loaded in the Danube otherwise than at Salina, lighterage on the Danube or at Salina, if necessary, to be at merchant's risk, but steamer's expense."*

(*b*) When the titles of books, etc., are quoted, as *I asked his authority for the statement, and he told me he had seen it in "Pitman's Commercial Law," as well as in "Pitman's Manual of Business Training," and he was therefore satisfied as to its accuracy.*

It should be noted, however, that a quotation within a quotation is indicated by single marks only, as: *Mr. Walker said, "I charged him with trying to deceive us, and he answered, 'I am not. I will pay you in a week, or I will return the goods.'"*

Parenthesis Marks [( )]. These marks are used to enclose words or figures not strictly connected with the sentence in which they appear, as: *The cargo is to be placed on board in fifty running hours (Sundays and holidays excepted), to count from the time the vessel is ready to receive cargo.*

The Exclamation Point (!). This mark is not often used in commercial composition, but it would be correctly employed to express sudden emotion, surprise, etc., as: *Ten per cent commission! Ridiculous! The terms are absurd!*

Emphasis. Where it is considered desirable to emphasise words in a letter, a line is drawn underneath the words, as: *We wrote you on the 5th April, and again on the 12th April, with regard to our overdue account, and must now request your* <u>*immediate attention*</u> *to this matter.*

Use of Capitals. The following words should begin with capital letters:

(*a*) The first word of every sentence, as: *Please instruct your traveller to call. We trust the parcel will reach you safely, and that the quality of the goods will please you.*

(*b*) The names of the days of the week and months of the year, as: *Our representative, Mr. T. Kerr, will be in your town on the first Monday in June, and will call upon you as desired.*

(*c*) All proper names and adjectives derived from them, as: *James Beamish, Esq.; India, Indian; Harrison, Harrisonian.*

(*d*) Titles of persons, as: *His Excellency the Duke of Bragga Docio.*

(*e*) Titles of books as: "*Pitman's Mercantile Law*," HARMSWORTH SELF-EDUCATOR.

(*f*) The first word of every direct quotation, as: "*Pitman's Business Man's Guide*" *says* "*An executor may be appointed by name, or by implication; but, in the latter case, is called an executor according to the tenor.*"

(*g*) The pronoun *I* and the interjection *O*, as: *If you will give me a call, I shall be glad to arrange the matter. Knowest thou not, O stupid man, thy time is near?*

To those who desire to go further in the study of punctuation, we recommend "Punctuation as a Means of Expression," by A. E. Lovell, M. A., and published by Sir Isaac Pitman & Sons, Ltd. Price 1s. 6d.

Spelling. Inaccurate spelling is an unpardonable fault in a business correspondent. With the multitude of cheap and reliable dictionaries now available, there is no excuse for the habitually bad speller. Undoubtedly, many a young man has failed in his endeavour to obtain an appointment because of the grievous faults of spelling noticed in his letter of application. Faulty spelling is difficult to eradicate, because, as a rule, the culprit is not aware of his failing. The habit of referring to the dictionary in doubtful cases can be recommended as an almost certain cure for the worst offender. "Pitman's Pocket Dictionary" is a useful little work for the purpose. The following remarks may be helpful in preventing some gross errors, which are very common:

Their is a pronoun, as: *Their books have a capital reputation.*

There is an adverb, as: *There they were, stowed away on the shelves.*

Where is an adverb, as: *Where can we learn the system?*

Hear is a verb, as: *We hear they are in liquidation.*

Here is an adverb: *Here we met their traveller.*

His is a pronoun (also construed as an adjective), as: *We have read his book, but it is not his best.*

Is is the third person singular of *be*, as: *He is very clearly uneasy in his mind as to the result. It is certain that his influence is diminishing.*

Has is the third person singular of *have*, as: *He has seen the sample, and has satisfied himself as to its suitability.*

As is an adverb or conjunction, as: *As I have already stated, such a book as he has written cannot be as great a success as he has been led to expect.*

The correspondent will find it useful to keep within reach some such book as "Pitman's Commercial Speller" or the same publisher's "Pocket Dictionary."

Some Faults to be Avoided. A carelessly written business letter indicates a certain amount of disrespect to the recipient, which cannot be expected to lead to satisfactory business relations between the parties. Blots, erasures, repeated interpolations and corrections, as well as positively illegible writing, should be scrupulously avoided. It is infinitely better to rewrite a letter than to despatch it with disfigurements of the kind here mentioned.

Keep to Business. It is also a mistake to introduce purely private affairs, or matters of personal friendship, into a business communication. Your correspondent may not desire other persons to see the remarks of a private nature which you have inserted in your business letter to him. Yet how is he to prevent it if the letter follows the usual course, and is filed away by a junior clerk? It is, of course, easily conceivable that intimate private friendship may exist between persons having close business connections. But the relations ought to be kept strictly separate, as far as written communications are concerned.

Intemperate Language. Every business correspondent has had experience of awkward clients, persons whose peculiarities of temperament are evidenced in their communications in the form of ill-chosen and even rude expressions. The most even-tempered man is strongly tempted sometimes to write a hasty reply to a letter of the kind referred to. But the temptation should be resisted, and the answer allowed to wait, when calmer feelings and further consideration will probably suggest a widely different and much more courteous reply. A curt reply, dictated in a fit of temper, has been the immediate cause of many a closed account. A business man cannot afford to indulge in sarcasm at the expense of his customers.

Inaccurate or Insufficient Details. In letters ordering goods, asking for quotations, or inquiring with regard to non-delivery, etc., the writer should be careful to specify exactly what is wanted, or what goods are referred to. Such expressions as "Same as we had before" are more than likely to occasion unnecessary trouble and annoyance to both parties.

Abbreviations to be Avoided. The abbreviation "gents" for "gentlemen" is excessively vulgar, and should never be employed. The ampersand (&), while correctly used in the title of a firm, as: "Messrs Brown & Jones," should never be used in the body of a letter. It is also wrong to employ "etc." in the complimentary close. "Yours, etc.," should never appear.

Unnecessarily Long Letters. It is a mistake to write unnecessarily lengthy communications. Time is an important factor in a business man's life, and it is both impolitic and unfair to trouble him with a long letter when a shorter one would answer the purpose very much better. The author of "Letters of a Self-made Merchant to his Son" says that, "Beginning before you know what you have to say, and keeping on after you have said it, lands a merchant in a lawsuit or the poor-house, and one's a short cut to the other."

Some Hints on Business Composition. The late Sir Courtenay Boyle, in one of his lectures to business men, gave the following excellent advice: "If we write a letter (especially if it is a business letter). first of all we must be sure that we understand it ourselves. Then be sure that our correspondent will understand it. We ought to try to put ourselves in the place of the person who receives the letter—try to ascertain, as far as we can, that he will understand that which we wish to convey. Very often both rules are broken."

The correspondent should not sacrifice clearness to brevity—undoubtedly desirable as the latter quality is in a business letter. It is much better to write an extra sentence than to send off a letter which is in any way ambiguous. A very interesting as well as useful exercise for the cultivation of clearness of expression without verbiage is to take a paragraph from the commercial columns of the newspaper, and condense the intelligence there given into as brief a statement as possible, without using any unnecessary words. Or, as a variation, to take the leading article in the same paper, and delete every word which is not necessary to elucidate the writer's meaning.

Another useful practice is to write out sentences showing the distinction between words which are very similar in appearance and pronunciation, as: The new patent *calender* is mentioned in the *calendar*. He contracted to *alter* the steps of the *altar*. The *holy* man was *wholly* at fault in the matter. The lord of the *manor* has a disagreeable *manner*. The wife of the *sower* is a good *sewer*. *Whether* it hail, or *whether* it blow, the *wether* must *weather* it, *whether* or no. Please *check* the amount of the *cheque*, and, if correct, sign it.

Technical Terms and Phrases. There are certain technical terms and phrases familiar to every branch of commerce, and it is essential that the correspondent should have a thorough knowledge of those common to the business in which he is engaged. At the same time, he should exercise prudence in the use of these phrases when writing, and should refrain from using any phrase which he is not quite certain that the receiver of the letter will understand. Those who wish to possess a detailed list of the terms and phrases employed in business should obtain "Pitman's Business Terms and Phrases," which gives also an explanation of each phrase.

Forms of Address. The following are the proper forms of address to be used in correspondence. As business men have at least occasionally to write to ladies and gentlemen of title, the list has been extended so as to include the forms proper in such cases, as well as the correct manner of beginning and ending the letter:

A Prince of the Blood Royal.

His Royal Highness the Prince of Wales,
Sandringham.

Begin: *Sir.* End: *I remain, Sir, your Royal Highness's most humble and obedient servant.*

An Archbishop.

To His Grace The Lord Archbishop of York.

Begin: *Your Grace.* End: *I remain, my Lord Archbishop, Your Grace's most obedient servant.*

A Bishop.

The Right Reverend the Lord Bishop of Manchester.

Begin: *My Lord Bishop.* End: *I remain, my Lord Bishop, Your Lordship's most obedient servant.*

A Duke.

His Grace the Duke of Fife.

Begin: *Your Grace.* End: *I remain, my Lord Duke, Your Grace's most obedient servant.*

A Marquis.

The Most Honourable the Marquis of Ailsa.

Begin: *My Lord Marquis.* End: As in the case of a *Duke*, but using *Lordship* instead of *Grace.*

An Earl.

The Right Honourable the Earl of Cawdor.

Begin: *My Lord.* End as when writing to a *Marquis.*

A Viscount.

The Right Honourable the Viscount Gordon.

Begin and end as to a *Marquis.*

A Baron.

The Right Honourable Lord Acton.

Begin and end as to a *Marquis.*

Baronets and Knights.

Sir William Nemo, Bart. (or *Knt.*).

Begin: *Sir.* End: *I remain, Sir, Your most obedient servant.*

A Member of Parliament.

Joseph King, Esq., M.P.

Begin: *Sir.* End: *I am, Sir, Your obedient servant.*

An Official.

The Secretary,
Board of Agriculture,
4, *Whitehall Place,*
London, S.W.

The Right Honourable the Secretary of State for India,
The India Office,
St. James's Park,
London, S.W.

The Right Honourable the President, Board of Trade,
Whitehall Gardens,
London, S.W.

Begin: *Sir.* End: *I am, Sir, Your obedient servant;* or, *I have the honour to be, my Lord, Your Lordship's most obedient servant.*

Commercial Firms.

Messrs. Lorric & Sons.
The Spiegel Electric Co., Ltd.

Begin: *Dear Sirs* or *Gentlemen.* End: *Yours faithfully* or *Yours truly.*

A Firm Composed of Ladies.

Mesdames Buckley and Pearce.

Begin: *Ladies.* End: *Yours faithfully* or *Yours truly.*

A French Gentleman.

M. Pierre Dupré,
Rue Reaumur, 37,
Paris,
France.

A French Firm.

MM. Jacques Moet et Fils, or *Messrs. Jacques Moet et Fils.*

A German Gentleman.

Herrn Friedrich Werner,
Jäger Strasse,
Berlin,
Germany.

A German Firm.

Herren Weber & Cie.

An Italian Gentleman.

Signor La Cava.

An Italian Firm.

Signori Bocconi e Zanardelli.

A Spanish Gentleman.

Sr. Don Franisca Bermudez.

A Spanish Firm.

Sres. Selck y Cia.

Shorthand and Commercial Correspondence. A knowledge of shorthand is essential to anyone who desires to take up the position of correspondent in a business house; of course, the practically universal Pitman system is the one that should be adopted. It is a common occurrence for one writer in an office to be called upon to transcribe another's shorthand notes, and it is necessary, therefore, that all the shorthand writers in the office should employ the same system.

A proper study of Pitman's shorthand will be found a very valuable help to the study and mastering of foreign languages. The system has, in fact, been adapted to twenty different languages, including French, German, Japanese, Chinese, Spanish, and Welsh. There are numerous magazines and books published in Pitman's shorthand, so that the learner has a wealth of high-class reading matter always obtainable. The textbooks are cheap, and the study proves quite fascinating to thousands who take it up.

The Training of Correspondents. "Commercial Correspondence" is now a regular item in the curricula of day and evening commercial schools all over the country, and systematic instruction in this necessary branch of a commercial training is given by men who are not only qualified teachers, but also practical business men. The subject attracts large numbers of students, the majority of whom submit themselves for examination in the subjects at the close of the winter session, either by the Society of Arts or some other well-known examining authority. The examinations are eminently practical in character, the papers being set and marked by men actually engaged in commerce and having the conduct of business correspondence on a large scale. The preparation for the examinations must, therefore, be very thorough, or the candidate will find himself unable to pass.

Commercial schools under private proprietorship have not only increased during quite recent years, but they have developed their methods to meet the demands of the times. Many of these institutions now teach languages, bookkeeping, and other subjects of business training, by correspondence as well as orally, and large establishments like Pitman's Metropolitan School, Southampton Row, London, W.C. (the largest commercial school in the world), keep a special staff of teachers, who devote their whole time to postal tuition. There is, therefore, no reason why students who find it inconvenient to attend classes should not pursue their studies by means of postal tuition, secure in the knowledge that they will be guided by experts in the subjects in which they desire instruction.

A Final Word. In concluding this article, the writer would like to impress upon the reader the necessity, not only that he should be absolutely thorough in his devotion to the interests of his employer, but also that he should be possessed of a strong determination to do everything possible to succeed in life. The junior clerk—and even the office-boy—should cultivate a laudable ambition to become one day the senior partner in the firm whose service he enters; and he should fit himself by strict attention to duty, earnest study in his spare time, and absolute fidelity for the position which it is his ambition one day to occupy, realising the fact that the incompetent or lazy youth cannot become a successful business man.

WINES AND CIDERS

Fermenting the Must Expressed from Grapes. The Mystery of Bouquet. Wines which Do Not Pay Duty. Cider

By CLAYTON BEADLE and HENRY P. STEVENS

WINE is the fermented juice of the grape, for the production of which the vine is cultivated in the middle and southern parts of Europe, and also in other parts of the world, especially in California and Australia. The season for gathering the grapes will, of course, vary with the climate, but for some classes of wines the grapes are allowed to ripen more completely than for others. Thus, in the Champagne district the grapes are gathered before they are fully ripe, in order that the colour of the wine may be as pale as possible. On the other hand, for burgundy, the grapes are allowed to become fully ripe, in order that the deepest coloured wine may be produced. Leaving the question of colour out of account, it is probable that the best wine would be obtained from grapes fully matured, and allowed to remain on the branches as long as possible.

Expressing and Fermenting the Must. When gathered, the grapes are crushed [1]. In the case of white wines, it is not usual to remove the stalks, as the liquor is strained off immediately from the residue, and there is little danger of absorption of astringent matter from the stalks. For red wines, the stalks are invariably removed, as the skins (*husks*) are used later to colour the liquor (*must*).

The mechanism employed for removing the stalks consists of a series of sieves. The grapes are crushed either by treading or by passing between rollers, and then passed to the press. The old form consisted of a box with perforations, through which the must was expelled, pressure being applied by a plunger worked by a screw; but this form of machinery has been largely replaced by centrifugal machines.

The next process consists in fermentation of the must, which is brought about by the albuminous matters it contains. For white wines, the operation is conducted in covered vats, provided with a hole in the cover to allow the escape of carbon dioxide.

Red wines are usually fermented in open vats in the presence of the husks, the whole mass being stirred from time to time. In this way much of the colouring matter is taken up, and the bouquet improved. In the course of the operation, which lasts from twelve to fourteen days, the yeast cells settle to the bottom, carrying with them most of the albuminous matter. The "young" wine is thus drawn off, and allowed to settle in other vats. When this second sedimentation is complete, it is drawn off into clean casks and allowed to mature. White wines are liable to a second fermentation if the albuminous matter is not completely removed with the yeast; but this does not happen with red wines, as the tannin and acids extracted from the husks prevent any further fermentation. In the process of maturing, the young wine loses any sugar it still contains by such after-fermentation; at the same time, albuminous substances and colouring matters separate out, together with acid potassium tartrate, as a crystalline crust, known as *argol* [see APPLIED CHEMISTRY, page 4782].

Before fermentation grape juice contains varying quantities of sugar and acids. From analyses that have been made, we may cite the case of must from the Rhine district, containing about 18 per cent. of sugar, making, with other extractive matters, 24 per cent. of total solids, which include albuminous and inorganic salts and 0·6 per cent. of free acid.

The chief products of fermentation are ordinary alcohol and carbon dioxide gas; in addition, there are formed small quantities of glycerin, acids, complex alcohols, and ethers, to which the bouquet of the wine is largely due.

Natural wines fermented from the unadulterated must contain from 6 per cent. to 12 per cent. of alcohol, and glycerin to the extent of from 7 per cent. to 10 per cent. of this quantity.

Flavour and Bouquet. The question as to the bouquet of wines is of the greatest importance from a commercial point of view, and much work has been done with a view to ascertaining the cause of the flavour and the means of producing it. In some cases it has been stated to be due to the action of frost on the grapes. It is also affected by the matters extracted from the *marc* (husks, stones, etc.), by the fermented juice. It appears, however, that it is possible to obtain the flavour in the case of inferior wines by the use of pure cultures of micro-organisms, obtained from high-class vintages.

It is stated by some observers that yeast from one district will produce a wine with the bouquet characteristic of that district in a must from a different source. Pasteurisation and special cultures are also employed to effect artificial ageing.

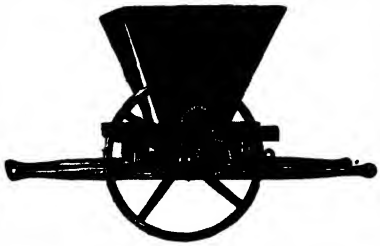
Up to now we have confined ourselves to the consideration of natural wines, but, in practice, other substances are employed in the course of manufacture. Thus, sugar is added before fermentation if less than 20 per cent. be present in the must. It is also necessary to reduce the amount of acid to 2 per cent. by dilution and addition of sugar.

Cheap and Unfermented Wines. Much cheap wine is made by covering the marc with a solution of sugar containing 18 grammes to every litre for every 1 per cent. of alcohol required, and 250 grammes of marc are taken for every litre. After fermentation, the liquor is drained from the marc, and treated as already described. Large quantities of fictitious wines are prepared from dry raisins imported into this country and into France.

Wines containing alcohol are subjected to a duty when imported into this country, but unfermented grape juice is free of duty. A case arose in May, 1906, where, by the addition of a substance to the must, fermentation was retarded for some days, permitting the importation of the must into this country, after which it was allowed to ferment, so that the wine obtained from it could be sold free of duty, the revenue being thereby defrauded. It is stated that nearly 800,000 gals. of unfermented grape juice are imported annually into Great Britain, a large proportion of which is fermented and made into wine without payment of duty. Should this practice grow, which is quite likely from its profitable nature, it will be necessary to devise some means of dealing with the question. Unfermented wines are, however, sold for temperance purposes and for sacramental use. They consist mostly of unfermented fruit juice, sweetened with saccharin, and preserved with salicylic or boric acids.

Composition and Analysis. The composition of the different classes of wines varies considerably. Many wines, such as port, are fortified by the addition of alcohol, for natural wines never contain more than from 6 per cent. to 12 per cent. Below we give results, from various sources, obtained from analyses of the commoner varieties of wines.

Analyses are made for the purpose of determining the purity and detecting adulterants. Sugar, as well as alcohol, is sometimes added to wines. The colouring matter must be examined to see if some artificial colouring matter has been added. Preservatives should be tested for and sulphuric acid estimated to see whether calcium sulphate has been added (*plastering*). For this purpose a number of determinations are made, including specific gravity, total extract, fixed and volatile acids, tartaric acid, and percentage of alcohol.

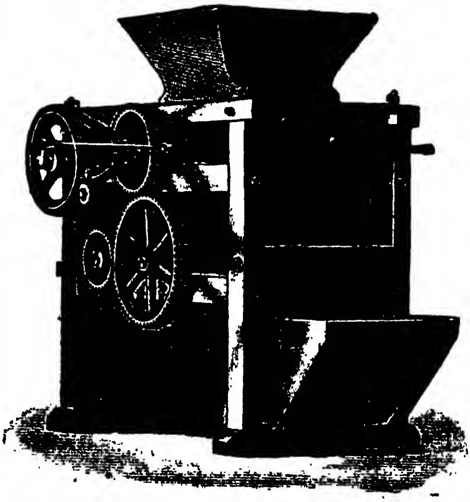


1. GRAPE MILL (Lumley & Co., Ltd.)

COMPOSITION OF WINES

Wines.	Alcohol, percentage by weight.	Extract.	Sugar.	Ash.	Phosphoric acid.	Fixed acid, as tartaric.	Volatile acid, as acetic	Tartaric acid.
Vin Ordinaire	7·0	5·0	0·1	0·45	—	0·61	0·11	—
Champagne ..	7·9	12·4	10·6	0·30	0·05	—	—	—
Hock	8·8	2·3	—	0·20	0·04	—	—	—
Sherry	17·2	4·2	2·5	0·40	0·02	0·27	0·15	0·18
Port	18·5	7·5	4·3	0·30	0·05	0·31	0·08	0·22

The determination of these figures does not present any special difficulty. The total extract is obtained by drying down a definite quantity of wine; volatile acid, by evaporating down once or twice with water and then titrating the residue; the difference between this and the total acid, also obtained by titration, gives the fixed acid. The percentage of alcohol is obtained by diluting 50 c.c. of wine with its own volume of water, and distilling. The distillate is made up to a known volume, and the alcohol it contains estimated by taking the gravity, as in the case of beer and spirits. Sugar is determined by means of Fehling's solution, while the polarimeter also yields useful information. There are generally fairly well defined relations between the proportions of these different constituents, and if the figures do not correspond, some adulteration may be suspected.



2. STEAM POWER CIDER MILL (Workman & Sons)

Fictitious wines are generally deficient in extract, although sometimes common salt is added to make up for this deficiency. The detection of added sugar is a very difficult matter, as it frequently consists of glucose, the most important natural sugar present in the wine.

Cider. British wines is a term applied to beverages made in the manner of wine from substances other than the juice of fresh grapes. The most important is cider, the best of which is made from astringent apples, special varieties being cultivated, which are suited only for this purpose. A good strong soil is required for growing the fruit, which should be regularly manured with phosphates, potassium salts, and charcoal dust [see MANURES]. When gathered, the apples are placed in heaps, preferably covered, to protect them from the rain, until they attain the right degree of maturity. The best cider is made from a judicious mixture of the different varieties; unsound fruit should be rejected.

Pulping and Pressing Apples. The older forms of mechanism for reducing apples to pulp were of a very primitive character. The apples were either mashed with a pestle in a trough or else placed in a cylinder provided with projecting spikes, in which revolved a drum, similarly fitted with spikes, and worked by a horse. In the more modern plan [2] the fruit is passed between wooden or stone rollers geared to different speeds. After mashing, the juice may be at once pressed out, as is generally the custom in this country, or the mashed pulp may be first allowed to undergo a certain amount of fermentation. When fermenting the juice itself the temperature should not rise above 40° F. The change proceeds rapidly, with much frothing; particles of fibrous material are carried to the surface by the bubbles of gas, but towards the end of the operation the solid particles settle to the bottom, leaving the liquid clear. It is immediately drawn off into fresh casks, where it undergoes a second fermentation. It is essential that the liquor, before fermentation, should be sufficiently rich in sugar, as, unless enough alcohol is formed in the first fermentation the secondary treatment does not proceed regularly, and acetic or lactic fermentation may set in, producing a flat-tasting, acid liquor. Sometimes fresh hops are added, as the tannin precipitates the albuminous matter. No doubt, a careful study of the most suitable yeast plant would result in great improvement in the development of the aroma and flavour, as in the case of wines. Good cider contains from 8 per cent. to 10 per cent. of alcohol and from 2 per cent. to 3 per cent. of sugar.

BAND-SAWS & SAW BENCHES

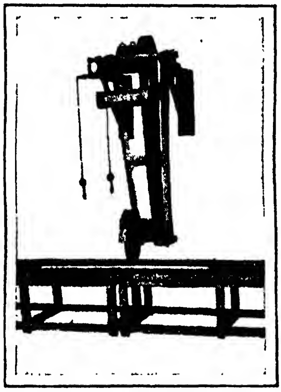
Band Re-saws. Cross-cut Saws. Portable Benches. Special Saws. Band-saws. Fret-saws

Continued from page 6146

By FRED HORNER

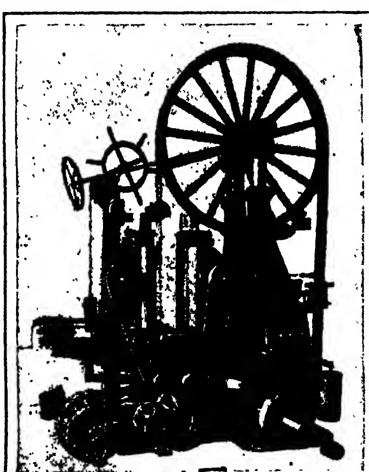
Band Re-saws. Band-saws for re-sawing are not quite so handy as the circular saws for general work, but they are popular in many cases on account of the thinness of the blade and the minimum of waste incurred in cutting. It is not a difficult matter to fit a self-acting feed to a band-saw table. In a few types a short rack-operated slide is placed on top of the table, to traverse the stuff, but the majority of machines use friction rollers, either one set, propelling the wood in contact with a fence, or a double set, both of which roll against the timber. An example of American practice is shown in 37, a Clement band re-saw (the American Wood Working Machinery Company), having 54-in. wheels, the lower one being out of sight in the photograph. The upper spindle is fitted in swivel bearings to align automatically. The pulleys are drawn apart and the saw kept in constant tension by a balance weight, which can be varied to suit the blade and the work it has to do. The feed works are driven at varying rates by belts and adjustable expansion cones, which admit of rates from 14 ft. to 120 ft. per minute. The movement is communicated to the rollers by spur gears and worm gears running in oil. Six feed rolls are used, three on each side of the saw; the right-hand ones are rigid in their bearings, but the left-hand set are elastic, to accommodate themselves to uneven stuff and so obtain a firm grip. The two sets may be used in a self-centring manner to split timber down the centre, or the right-hand set can be fixed rigidly to cut to one side. Roller guides are fitted above and below, to support the blade close to the wood, the upper guide being adjustable, to suit the differing thicknesses of stuff passed through. Two horizontal rollers support the bottom of the timber as it passes through the rolls. The greatest height of stuff which can be passed through is 30 in., and the width 20 in.

A fence and radial arm roller-feed is often put on band-saw tables, the action being then similar to that of the roller-feed circular-saw bench described on page 6145. On what are termed *combination machines* the fence and feeding arrangements are removable, to leave the table free for ordinary work, this type being useful in shops which cannot find sufficient work fully to occupy the automatic feed devices.



36. PENDULUM CROSS-CUT SAW

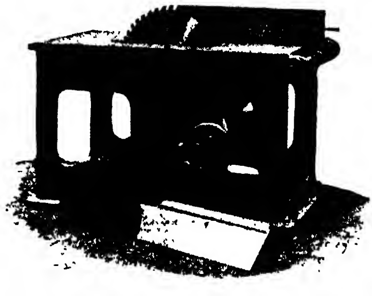
Cross-cut Saws. Before taking up the study of other classes of band and circular saws for kinds of work different from re-sawing proper, we have to note the *cross-cut* saws, which are employed for parting off deals, planks, boards, etc., to definite lengths. A good deal of this work is of a repetition character, especially for box-making and joinery, and means are provided for cutting numerous pieces to gauged lengths by the employment of fences or guides, or by putting two or more saws side by side to cut off the ends accurately. The *pendulum* saw [36] (John McDowall & Sons, Johnstone) is a pattern that is very commonly used, because of its cheapness, handiness, and the small space which it occupies. It comprises a rigid frame swinging in trunnion bearings on brackets attached to the roof or the wall, and carrying pulleys which are belted down to the saw spindle at the bottom; the saw can, therefore, be swung to and fro by pulling at a handle in the front, while a counterbalance, on levers at the upper part of the frame, draws the latter backwards automatically on letting go the handle, so keeping the saw out of the way until it is required. The spindle is started and stopped by shifting the belt on the fast and loose pulleys at the top shaft. The stuff to be parted is supported on the special bench seen in the illustration, a gap being cut through where the saw swings across. The bench may be constructed of any length required. For cutting pieces to uniform lengths there is provided an adjustable *stopper* that can be clamped in any longitudinal position, for the end of the timber to butt against, and so locate it accurately. To save lining off the lengths of timber previous to cutting various pieces, it is sometimes the practice to fit a metal rule with clamp stops, so that accurate subdivisions of the inch can be made by the sawyer. The largest saws used in these pendulum machines usually range up to 36 in., capable of working to 12 in. deep, but in a few instances saws up to 60 in. are employed for heavy work, including small logs. A guard is always fitted over the



37. A 54-IN. BAND RE-SAW

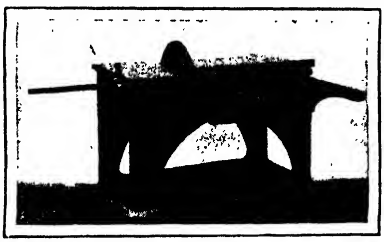
upper portion of the saw, as a protection against injury to the attendant.

Sliding Table Cross-cut Saw. The pendulum saw is especially handy for long or heavy pieces of wood, as they remain stationary. But when the length and weight of a piece permits, one of the several special cross-cut benches can be brought into use. The object is to traverse the timber across against the saw teeth, this being effected generally by a table running by rollers upon rails. Figure 39 shows one of Messrs. Robinson's benches of this pattern, which has the table of wood placed to the right of the circular saw and pulled to and fro by hand, as it runs with small V-wheels upon rails carried out to the front a sufficient distance. An adjustable gauge, fitted to a bar at the front left-hand side of the saw, provides for repetition sawing. The machine takes saws of 20 in. diameter, capable of cutting stuff up to 6 in. thick and 18 in. wide. The spindle is made to rise and fall in some of these machines. Double, or *equalising* saws, which trim off the two ends of a piece simultaneously, comprise a table travelling above a bed on which two headstocks are set in any desired position, to give variable widths. As the stuff is drawn over on the table the saws part it off at both ends simultaneously. Lengths from about 4 in. up to several feet are handled on these machines.



38. SAW BENCH, WITH RISING AND FALLING SPINDLE

Multiple Cross-cut Saws. *Multiple* saw machines are principally of two classes. In one a number of saws are set side by side to the required distance to part off a length of stuff into several pieces, such as paving blocks, the movement of the saws or of the wood carriage being continuous, so that at each stroke a piece of wood is completely cut up. Sometimes the saws are of differing diameters, gradually getting smaller, so that the work of sawing is gradual, and does not put so much strain on as though all the blades penetrated simultaneously. As many as 30,000 paving blocks can be sawn out in one day on these machines. In the other class of machine several saws are set in a long table, at differing distances apart, in order that stuff may be cut to various lengths, the pairs of saws being set in advance of each other, or, alternatively, sets may be caused to disappear below the table, leaving only those standing up which are required. The travelling tables are abolished in certain designs, and their functions performed by endless chains, having dogs which engage in the sides of the timber, and push it against the saws. These *lumber trimmers*, as they are termed in American practice, are built up with timber framings, forming a cheap and satisfactory construction. Pieces up to 20 ft. or more can be dealt with.



39. SLIDING TABLE CROSS-CUT SAW

The pendulum principle, already noted in connection with a suspended saw, is applied to benches, notably for cutting up paving blocks and similar work. The saw spindle runs in bearings at the end of a swinging arm, on the central pivot-shaft of which the driving pulley is mounted. The saw with its arm is pulled over by a hand or foot lever, or automatically by a crank-rod, to pass between the opening of an inclined fence, against which the timber is laid. The automatic crank-driven machines are, of course, the quickest in operation, and will cut the stuff as fast as a man can supply it.

One particular design of bench, which differs from those already described, is intended to deal with heavy planks and scantlings that are too heavy to be conveniently handled about and fed to a saw. The timber is laid upon a fixed table, and cut by a circular saw projecting up through a slot therein, the spindle running in bearings that can be fed longitudinally on a subsidiary bed. The foregoing machines for re-sawing and cutting off prepare the stuff for further treatment (when required) on other kinds of saws, which we shall now deal with.

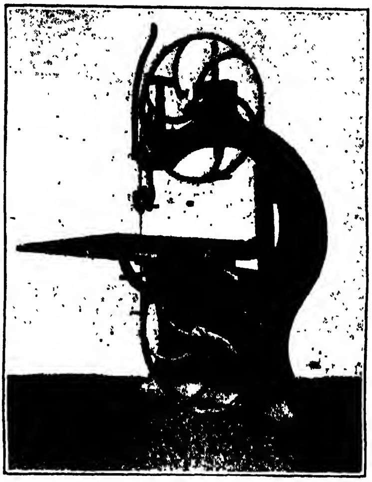
Plain Benches. The lighter types of circular and band saws, which are not fitted with mechanical feeds, appear in several forms, modified variously to suit the classes of work they have to do. The *plain* circular saw benches resemble those in **33**, **34**, and **35** [pages 6145 and 6146], but without the special attachments required for feeding, the only fitting being a fence, which is adjustable to and from the saw. The usual method of attaching the fence is by means of a circular steel bar at the end of the table, enabling lateral adjustments to be made, or, if necessary, the fence can be thrown back out of the way, leaving the table quite clear for cross-cutting. The fence proper has a *fence-plate* bolted to its front face, which can be moved to and fro as desired to suit saws of smaller or larger diameter. For bevel cutting, a canting movement has to be provided for the fence. The larger machines have rollers placed at each end of the table, similarly to **35** [page 6146], to assist in the easy handling of heavy pieces.

40. SAW BENCH, WITH RISING AND FALLING TABLE

Portable Benches. *Portable* saw benches, mounted on four trolley wheels, are used by shipbuilders and contractors, the machines being run to any locality where they are wanted, instead of transporting the timbers to the saw. An electric

motor drives the spindle direct, and the table is swivelled upon a turntable, to present the saw at any horizontal angle to the work, instead of shifting the latter. The limits of dimensions in these machines usually range up to about 4 ft. by 3 ft. 8 in. tables.

Wood Framings. A difference in the framing and the table is made in many benches, especially American, wood being employed instead of cast iron. The uprights and horizontals are mortised and bolted together, like a work bench, and the table is built of a number of narrow strips of different woods, glued together, and fastened to cross-girts, so that warping or splitting is impossible. Or the framing is made of cast iron, and the table only constructed with strips.



41. 30-IN. BAND-SAWING MACHINE

Rising and Falling Types. The range of the plain benches is rather limited, and other types are therefore used for an extended class of operations, especially in joinery work. In one type, with *rising and falling* spindle, the spindle may be moved upwards or downwards in relation to the table; in the other the movement is imparted to the table. The object in each case is to vary the depth of cut, so that the machines are adapted for grooving, tonguing, rebating, beading, and tenoning, by fitting special saws, or cutter blocks to the spindle. The saws are either *thick* for grooving, or *drunken* for grooving and tenoning. These tools will be described later, together with the cutter-heads employed. Figure **33** represents one of Messrs. Robinson's rising spindle benches. The bearings for the spindle are carried on a sliding bracket, which is vertically adjustable, by turning the hand wheel seen at the front. A boring apparatus is sometimes added to these machines, by fitting an auger in the end of the spindle, and attaching a sliding table to a bracket standing out from the side of the frame. The objection to altering the spindle height is that the belt-driving arrangements are complicated by the variations, and the rising and falling table machines are, therefore, preferred. The only disadvantage possessed by them is that the differing height of the table is sometimes apt to become awkward to the sawyer, but there is not much weight in this objection. There are two devices employed for operating the tables—racks and screws. The latter are better for the purpose, and are used in the majority of machines. The appearance of a rising table bench is shown in **40** (Robinson), the adjustment being effected by the hand wheel at the right-hand end, operating bevel gears connecting to two vertical square-threaded screws which cause the table to move by means of extensions in gibbed guide ways.

42 FRET-SAWING MACHINE

A groove is sometimes planed longitudinally in the tables to take a sliding fence, for use in cross-cutting, the fence lying at right angles to the main one; mitre cutting can be done by attaching a supplementary mitre fence. The lighter classes of rising-table machines are constructed with a narrow pillar or column, instead of the spread-out casting seen in previous illustrations.

Dimension Saws. The *dimension* or *two-spindle* saws are designed for both ripping and cross-cutting, and have two saws sharpened for cutting with and across the grain respectively. The spindles run in bearings at the opposite ends of a strong arm, pivoted about its centre in order that either of the saws may be brought up to the top ready for action, a hand wheel accomplishing this movement. The drive to the spindles is arranged so that the lower saw is thrown out of action. The special value of the dimension saws lies in repetition work, where large numbers of pieces have to be sawn to uniform sizes, as in cabinet work, pattern making, parquetry work, etc. Angular and bevel sawing is readily done by the aid of the canting and swivelling fence.

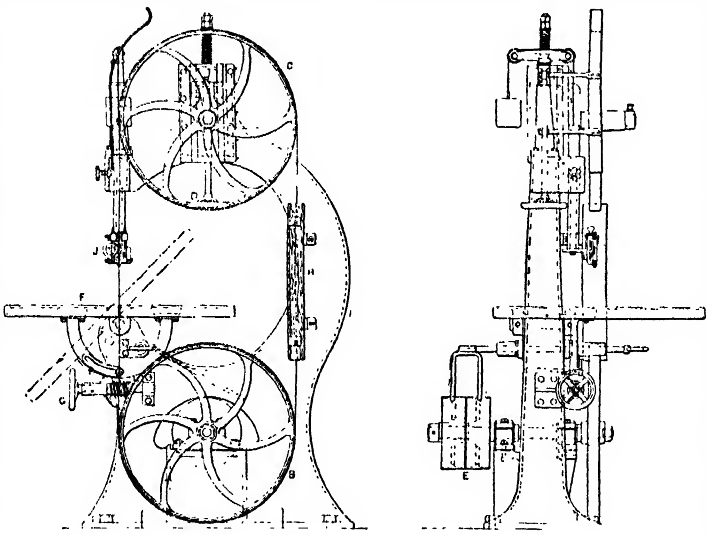
Universal Benches. *Universal* saw-benches embody the two-spindle arrangement, together with a tilting motion of the table, to present the stuff angularly in relation to the saw. Several auxiliary fittings, as gauges and angular fences, are provided, so that every class of sawing can be done, to build up intricate framings accurately.

Band-saws. The band-saw machines are particularly useful for general sawing which includes curved work, because they can tackle sweeps for which the circular saw is useless. The chief drawback is the trouble caused by breakages of saws, though this in many cases is avoidable if care is exercised.

Figure **41** gives a good idea of the general appearance of a typical machine, and **43** shows the same in side and front elevations, the example being from the practice of Messrs. Thomas White & Sons, Paisley. The saw pulleys are of 30 in. diameter and make 400 revolutions per minute. The framing A is of box section, cored out, which affords a very stiff form, able to resist the effects of vibration at the high speed necessary. The cast-iron pulleys B, C have no flanges, and are rubber tyred to avoid damage to the saw teeth, and the top wheel C is mounted on a spindle which runs in a hinged

bearing, that can be tilted to make the saw run on any part of the pulley. The hand wheel D operates a screw which slides the bearing of the wheel C up or down to suit the length of saw, and a constant tension is maintained afterwards by the coiled spring at the top. A balance weight and lever is fitted in some machines instead of a spring. The belt drives to the fast and loose pulleys at E, and is shifted across to start or stop the machine by the forks and hand lever passing through the frame. F is the table, constructed with an extension to cover over the pulley B and prevent pieces of wood from falling on it. The table is tilted or canted for angular sawing by turning the hand wheel G, which rotates a worm engaging in a worm segment on a quadrant bolted to the table, and turning the latter upon its pivot. The saw passes through a timber casing at H, and through a *guide* at J. The latter is an important feature, as it has to receive the backward thrust of the saw, and must do this without undue friction, or heating and crystallisation will occur, resulting in breakage of the saw. Rolling contact is the proper method, and there are several designs of guides in use. Jackson's, which is fitted to the machine illustrated, embodies a revolving disc, mounted on a spindle, and running by its back edge upon a ring of hardened steel balls. The back of the saw bears across a good portion of the face of the disc, and the latter runs with perfect freedom. The blade is confined sideways between two hardwood strips, adjustable for width of opening. The guide is brought down as close as possible to the stuff being sawn, and is, therefore, held in a vertical bar passing a socket in the frame A, in which it is clamped in any position by a hand screw. The bar is counterbalanced by a rope and weight to prevent it from dropping when the hand screw is loosened.

The saw passes through hardwood strips let into the table, and a rotary guide is also often fitted below the table, though in some instances nothing but wood guides are employed. The lower saw pulley is in many machines provided with a little brush, which is a considerable advantage, keeping the pulleys clear of sawdust, etc.



43. 30-IN. BAND-SAWING MACHINE

A special class of band-sawing machine, used chiefly by shipbuilders, coachbuilders, and others who have to cut out heavy ribs and bevelled pieces, is constructed with the top pulley to cant over bodily along with the upper part of the frame, so that the saw lies at an angle to the table. The latter remains horizontal, a fact which renders the handling of heavy pieces of timber much easier than as though they had to be moved about on a sloping table.

A fence is fitted to the tables of band-saws when wanted, to guide straight stuff past the saw, otherwise the operator must work to a scribed line on the timber, as in sawing curves. Combination machines, embodying both circular and band-saws, are designed chiefly for small works which either cannot afford or cannot spare space for two separate machines. The band-saw framing is built on the end of the saw bench. The smallest machines are hand-driven.

Fret or Jig or Scroll Saws. These have but a limited scope, and are used for internal cutting and scroll work which a band-saw could not manage, as the fret-saw blade can be disconnected and passed through a hole in the piece to cut out a central portion. The mechanism is simple, comprising a small crank-disc driven at a high speed, working a connecting rod which reciprocates the saw-blade, gripped in sliding holders above and below a table. The rate of working is about 1,000 strokes per minute. There are two types of machine; one has a curved cast-iron framing reaching round the table and up to the top holder, the framing, therefore, preventing very large work from being placed in position. In the other type, a suspended tension head of wood is used, consisting of a vertical beam attached to the ceiling, and strained tightly by three tie-rods, put in tension, by nuts on right and left-hand screws [see **42**]. The entire space around the table is free, and work of any area can be put on. In the machine illustrated, tension is given to the saw by means of a couple of spiral springs, which constantly maintain an even pull. A boring attachment is shown alongside the framing, to prepare work by making holes where they are necessary to insert the saw.

THE MANAGEMENT OF SHIPS

The Commercial Side of Shipping. The Shore Departments. Marine Officers and Seamen. Training, Promotion, and Salaries

continued from page 62_7

By W. CAMPBELL GALBRAITH

THE supremacy of British shipping is due principally to the efficient working of its commercial side. Nearly one out of every two merchant ships afloat is under the Red Ensign, and this because shipping in this country is a highly organised commercial business, free in its working from control of any Government department. Subjected as it is to free competition of home and foreign rivals, every improvement in steam navigation has been eagerly taken advantage of, and every economical device to save fuel or the expenses of working a ship is tried, and, if effective, adopted by the British shipowner.

Management. Each of the large shipping companies has its own method of management, which has been evolved by its directors and managers from their experience and knowledge of the particular requirements of the services their vessels perform.

In the case of a large limited liability company, such as the principal liners belong to, there are, of course, the directors elected by the shareholders, and a manager or secretary appointed by the directors. In the case of privately owned firms, there are one or more managing partners, who look after the business. The directors or partners decide the general policy and the particular trades on which their vessels run; they fix rates of freight and passage money, sometimes in conference with other shipowners, more frequently in rivalry with them, and in deciding these matters the directors have available their managers or other experts, who are usually the heads of departments.

As methods of management vary, so does organisation; but, generally speaking, in the larger companies, at any rate, it would be somewhat as follows. First would come the manager or secretary—in some cases there are both—who, subject to the directors, is in charge of the whole business, and under whom come the heads of the various departments, who report to the manager and take their orders from him. The various departments, generally speaking, would be as follow.

Accounts and Statistics Department. This department is usually under charge of an accountant well versed in shipping matters, and is one of the most important branches. All the bookkeeping is done here. Voyage accounts are compiled, profit and loss sheets made up, statistics of all sorts brought out, and generally everything pertaining to figures and working costs are furnished at call from this department.

The shipowner of to-day can quote an intending charterer with a rate for his steamer at once by referring to his accounts department, and if he proposes to send his steamer on a particular voyage outside the ordinary run, he calls for and is furnished with a pro forma voyage account, which puts before him the probable voyage expenses and earnings, and he quotes his rates accordingly. An account of this kind would be drawn out something as under.

PRO FORMA VOYAGE ACCOUNT

s.s. ——— - tons gross ——— nett

Voyage from —— to —— —— days speed — knots.

DISBURSEMENTS		EARNINGS	
Wages of crew — days @ £	= £	In this column would appear the estimated earnings worked out as so many tons at the rates to be quoted.	
Port and light dues ..	= £		
Victualling — days @	=		
Loading and discharging — tons @	=		
Coal — per day - total tons @ —			
Depreciation on £ @ per cent.	=		
Insurance on £ @ per cent.			
Deck stores	=		
Engine stores	=		
Repairs and sundries	=		
Commission account	=		
Total	£	Total	£

Estimated profit on the voyage £

Rate per ton per month — £

Of course, for steamers going through the Suez Canal the canal dues would appear as a big item on the disbursement side. The department has records showing the port dues, loading and discharging rates, and cost of coal at practically every commercial port. The depreciation and insurance are calculated on the book value of the steamer, and the average cost of many voyages gives the figures for deck and engine stores and repairs. In this department a practical knowledge of bookkeeping, of exchanges and figures generally, are necessary.

Marine and Engineering Department In small companies owning up to, say, half a dozen small steamers, or of one or two steamer companies, the masters and chief engineers of the vessels discuss with the owner the repairs, etc., required, and tenders for these are called for, and, as a rule, go to the cheapest offerer. Every big line, however, has a marine superintendent and a superintendent engineer (usually one of the most efficient and trusted commanders and chief engineers selected and taken ashore on the staff for the purpose), and they are responsible for all technical details connected with the deck and engine-room departments. In their hands, too, are left the selection and appointment of officers and engineers, as well as the promotion and transfer of the marine and engineering staffs. All questions of repairs, alterations, and so forth are dealt with in this department, and in the case of new vessels these officials give to the directors and managers the benefit of their technical advice.

These experts report on new inventions, and recommend their adoption or otherwise. When a new patent is adopted, close observation and record is made of its efficiency, and this department looks after all such records. The logs of the various steamers are entered up, their mileage and speed tabulated, their coal and oil consumption noted,

and in the case of excess over the usual average the captain and chief engineer are called on to explain the reason. In this way a check is kept on coal and oil expenditure, and careful and efficient marine and engineering superintendents mean much in the economical working of a big line. Besides the superintendents, the staff in this department is usually made up of one or more draughtsmen, an electrician, two or three junior clerks, and a few typewriters.

The young man entered in this department should apply himself to obtaining an accurate knowledge of the technical names of the different parts of a ship and her machinery.

Coal and Stores Department. On an estimate prepared for the year, this department will call for prices from contractors on their "suppliers list," and make contracts for the stores and coal required for the period fixed, usually six months to a year. In the stores department will be found samples of all the innumerable articles required by a modern ship, such as cordage, manilla and wire ropes, oils and paints, canvas, ironmongery, lamps, electroplate, cutlery, earthenware and glass, napery and linen, etc. These samples are carefully compared with the goods delivered by the various contractors, and any departure from sample is brought at once to the notice of the offending party.

When an "indent," as it is usually termed, meaning a requisition for stores sent in by the deck and engine departments, has been passed by the superintendent concerned, it is sent to the stores department. Here it is dissected, and orders sent for the stores indented to the various contractors.

A few junior clerks suffice for the work here, which is mostly routine, sending out orders and carefully checking suppliers' invoices with the ships' receipts and contracts. The responsible official in charge of this department is known generally as "the ship's husband," a happy description indeed.

Victualling Department. In close connection with the stores department is the victualling department. In some companies, in fact, they are one, and the stores do the victualling work as well. The shore purser or superintending steward is in charge here.

Into this department comes the indents from the chief stewards of the various steamers, giving their requirements for provisions, meat, wines, etc., for the next voyage. These requirements are based, of course, on the number of passengers to be carried and on the length of the voyage. Striking figures have been published of the huge piles of perishable stores, of the mountains of bread, fish, fowls, meat, hams, eggs, and so forth, consumed on a voyage of one of the Atlantic greyhounds, but such statistics scarcely come within the scope of this article.

Regular and careful accounts are kept, and on the averages a daily victualling scale is fixed to which chief stewards have to conform. The picking and selection of the chief stewards is in the hands of the shore chief, and a good and careful chief ashore is usually reflected in the work of the men afloat.

General and Correspondence Department. This department has usually at its head the general manager or secretary. In the case of firms owning a few steamers it is run directly, very often, by the partners themselves. The staff is usually the largest in a shipping office, as all the general routine work of an ordinary business office is dealt with here. Here, also, is the cash department presided over by the cashier.

Passengers are booked, passage tickets issued, and inquiries answered. Sailing and advertisement cards usually adorn the walls, and cabin plans of the company's steamers lie on the counters.

The young man entering a shipping office usually begins here, being drafted to other departments later for experience, or according to his aptitude. He starts, as a rule, by copying letters and documents and fetching and carrying for his seniors. A knowledge of shorthand should be possessed by every youth, and if he is able to use a typewriter so much the better. Typewriters, however, are usually engaged as such and kept to that work. There is a call also for a knowledge of languages, particularly French and German, and especially German, for the German is found running practically everywhere now, entailing correspondence regarding freights, passengers, and general interests.

Freight and Bills of Lading. This department looks after the engagement of freight, etc., and is usually divided into export and import sides. The export issues bills of lading for goods shipped from the home ports abroad, while the import department deals with the manifests and bills of lading for cargoes coming into the home ports.

In these days of keen competition the shipowner has to hustle to secure his freights. He does not wait for the shipper to come to him, but looks after the shipper. In London a representative of this department will be a member of the "Baltic." In Liverpool and Glasgow business is done on the "Exchange," and in Newcastle on the "Quayside," as the shipping exchange there is called locally. The "Baltic" in London is a palatial edifice in St. Mary Axe, replete with all comforts for its clients, and this may be termed the hub of the freight market in London. Here shippers and shipowners have full information as to freights and rates, and here they do their deals.

The freight department watches the trade journals, notes all big orders placed for railway materials for abroad, and then puts freights forward to the firms concerned. Here the early bird often catches the freight worm, and canvassers with a keen eye for business and an attractive manner are invaluable.

The freight being engaged, arrangements are made for shipment by a particular steamer. It is sent alongside by rail or barge, as is cheapest or most convenient, and is at the ship's risk from the time it leaves the quay wall or barge till clear of the ship's tackle when landed at the port of destination. As cargo comes on board, it is "tallied"—that is, a note is taken of the cargo, whether it is case, package, etc., and the "mark." A receipt is given, and this receipt, being presented to the freight department along with a bill of lading (which is usually in triplicate), is signed by the department "for the master," and it is then the merchant's title to the goods described. Only on production of this bill of lading, or an indemnity freeing the shipowner of all liability, will the goods be delivered to the consignee.

Particular trades, such as the Black Sea, Mediterranean, etc., have their own particular form of bill of lading, and most of the large companies have also a special form bearing their house flag or distinguishing emblem.

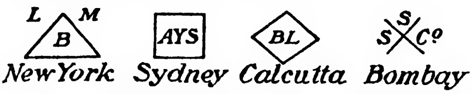
The Bill of Lading. The bill of lading gives the names of the shipper and the consignee, the name of the steamer and master, the port of shipment and the destination, the number of packages, and the date. On the margin is detailed the number of packages, their contents, and marks. Freight is payable on delivery of the

bill of lading "ship lost or not lost," and a recital is given of all the liabilities from which the shipowner frees himself, including "the act of God, the King's enemies, robbers by land and sea, restraint of princes, rulers, or people"; and such commonplace things as "strikes or stoppages of labour."

The shipowner has a lien on goods shipped for his freight. He is held responsible for loss or damage or short delivery, provided he has granted a "clean" bill of lading—this is a B/L without any remark as to the cargo being damaged or in bad condition.

All packages, as a rule, bear a mark, not an address, and all large shippers have their own particular mark, many of them well known in trade to the general public. Underneath the mark is the port of destination, and the package is usually numbered as well.

Sample marks are given below.



A mate's receipt granted on delivery to the ship and on which the bill of lading is made out would read something like this:

s.s.———

Date

Received in good order and condition on board the s s.———, ——— Master, the undernoted goods.

New York. ABC $ 1/3 3 *cases hardware.*

(sgd.) J. SMITH,
2/ mate.

A considerable number of clerks are employed in the freight department. Bills of lading for large ports have each, as a rule, a separate desk assigned to them, and the clerks employed check the bills of lading produced by the shipper with the mate's receipts, and make out the freight notes. This requires careful calculations. Goods are shipped on weight or measurement at the option of the steamer, and one freight note will involve many calculations of weight and measurement rates of freight.

The young man coming to this department needs all his wits about him. He must be careful and methodical, with a quick and accurate knowledge of figures. Here outside work is regarded as the "plum," and the ambition of the smart man is to get on the "Baltic," or shipping exchange, and do the outside freight work.

There is also usually an expert attached to this department skilled in estimating damage and settling losses. The outside public have little knowledge how many and various are the claims made by shippers for damaged or missing cargo. A smart, tactful man can save his employers thousands of pounds a year in the working of the "claims" department.

Insurance Department. In all large shipping companies there is an insurance department. It is usually in charge of an experienced man well versed in marine insurance law and customs. Many of the large shipping companies insure their steamers in a special fund of their own, and find it pays them to do so. The premiums, ranging as a rule from 4 per cent. to 6 per cent., are charged against each steamer's earnings, and credited to the "insurance fund." Against the insurance fund all claims for damage and losses are debited. The larger companies insure the cargo carried by their own steamers, and the baggage of passengers. In the case of companies where the insurance is done "outside," the risks are taken by Lloyd's and the other great maritime insurance companies.

The biggest outside policy for marine risks was the ten millions placed by the Government to cover the risks to merchant shipping during the summer manœuvres last year (1906).

Lloyd's. In marine insurance matters Lloyd's overshadows every other concern. It is also the great organisation for the collection and distribution of marine intelligence. All round our coasts and in every part of the world Lloyd's agents advise the movements of the ships of all nations, and not one vessel in ten bound to ports in the United Kingdom arrives as her terminal port without being "reported at Lloyd's."

Lloyd's, too, has a "Captains' Register," showing the service of every master in the mercantile marine, and in this connection much valuable and confidential information of great value to underwriters is available for the benefit and guidance of members and subscribers.

An inquiry office is also maintained by Lloyd's where relatives of the crew or passengers may obtain without cost information regarding the movements of the vessel in which they are interested.

It is scarcely within the province of this article, and space forbids any particular description of the business of Lloyd's, or the clauses which make up its marine policies, but to anyone engaged in shipping a knowledge of the abbreviations used is not only useful but necessary. Hereunder is a table of common abbreviations.

H.C.	Held covered.
S.A.	Subject to approval.
N.R.	No risk.
U.K. or C. ..	United Kingdom or Continent.
Cont. H. and H.	Continent between Harve and Hamburg.
Cont. B. and H.	Continent between Bordeaux and Hamburg.
F.O.	For orders.
O.P.	Open policy.
F.C. and S. ..	Free of capture and seizure.
D.C.	Deviation Clause.
T.L.O.	Total loss only.
F.A.A. ..	Free of all average.
F.G.A. ..	Foreign general average.
Y.A.R.	York Antwerp rules.
R.I.	Reinsurance.
R.D.C.	Running down Clause.
C.C.	Continuation Clause.
D.C.	Detention Clause.
L.C.	Label Clause (Bottled goods).
F.P.A.	Free of particular average.
P.A.	Particular average.
G.A.	General average.
P.L.	Partial loss.
S.L.	Salvage loss.
C.T.L.	Constructive total loss.
T.L.	Total loss.
W.P.	Without prejudice.
Wd.	Warranted.
W.A.	With average.
P.P.I.	Policy proof of interest.
A.R.	Against all risks.
W.O.B. ..	Washing overboard.

Lloyd's has a close connection indeed with the commercial side of shipping, and from the "A1 at Lloyd's," which describes the highest class granted to a merchant ship when she starts her first voyage, till her disappearance through loss or breaking up Lloyd's never loses sight of her.

In Lloyd's Register appears the name of every steamer and sailing ship afloat, showing the owner's name, the name of the builder, the classification, tonnage, and her general measurements, as well as her official number and port of registry.

The Merchant Shipping Act. This Act defines the duties and responsibilities of owners, masters, and crews, as well as the machinery of the

Board of Trade Mercantile Marine Offices (known to Merchant Jack as "the Shipping Office") and others authorised to deal with ships and seamen. The Act of 1894 in its 744 sections provides for practically every point likely to arise in connection with the owning or management of British vessels.

The first section of the Act gives the qualifications necessary for owning British ships, wherein it is laid down that a ship shall not be deemed to be a British ship unless owned wholly by persons of the following description—namely:

(*a*) Natural born British subjects.

(*b*) Persons naturalised by or in pursuance of an Act of Parliament or ordinance in a British possession.

(*c*) Persons made denizens by letter of denisation, and

(*d*) Bodies corporate established under and subject to the laws of some part of the King's dominions, and having their principal place of business in those dominions.

It is under the last qualification, of course, that the great majority of British shipping is registered.

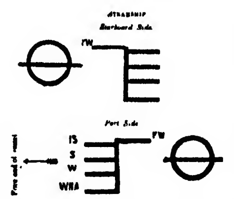
The second section of the Act provides for the registry of every British ship, and accordingly the first proceeding of an owner of a British vessel is to register her, and the procedure as to this is laid down in Sections 4 to 20 of the Act.

Registering a Ship. When a new steamer is built she is measured for tonnage by a Board of Trade surveyor, and the measurements so ascertained are embodied by the shipbuilder in a document known as "The Builder's Certificate," which is handed to the owner, who, on the figures given therein, makes out his "declaration of ownership." This document gives the name of the owners, their principal place of business, and the number of shares in the vessel. A vessel is divided into 64 shares, so that a sole owner would be described as owning 64/64th shares. This document, then duly signed before a shipping master or a commissioner of oaths, is handed in along with the builder's certificate and the certificate of the master, to the registrar of shipping at the port where the vessel is to be registered. The registrar then allots the vessel her "official number." This number having been carved on the main beam of the vessel, and her port of registry painted on the stern, and a carving note signed by a surveyor to that effect being furnished, the registrar grants the "certificate of registry." This is the vessel's most important document. It is at once her birth certificate and passport; without it she cannot obtain clearance from any port, and failure to produce it would render a vessel liable to seizure as an ownerless and suspicious craft. The certificate of registry shows the vessel's name, official number, and port of registry, gives full details of her measurement and tonnage, and the name of her owners and her master.

Selling a Ship. In the purchase or sale of a British ship there is little formality, no need for a lawyer, and the process is simplicity itself, a steamer valued at a million pounds being more easily disposed of than land or a house worth a hundred. The seller signs and seals a document known as *a bill of sale*, which gives the name of the steamer sold, and other particulars from her certificate of registry, the names of the sellers and buyers, and this document being handed over to the registrar of shipping at the steamer's port of registry, the old register is closed, and a certificate granted to the new purchaser, and the business is done. The bill of sale in its wording is a quaint survival of the days when the merchant ship was armed, as in its wording it transfers the shares "in the ship above particularly described, and in her boats, guns, ammunition, small arms, and appurtenances." The modern vessel, however, as a rule, has neither guns, ammunition, nor small arms, but the form survives. If a British vessel is lost, taken by the enemy, or sold to foreigners, notice of the fact must be given, under penalty, to the registrar, who thereupon closes the vessel's register. The owner is bound to give up the ship's certificate of registry if the steamer is sold to foreigners, or if it is saved in the event of wreck.

Legal Rights of the Crew. The Act provides and lays down conditions for the engagement of a crew, and every member of the crew must have the agreement read and explained to him by the shipping master or his deputy. Facilities are granted to seamen to complain of any grievance, and pains and penalties are enacted to protect the seamen from imposition of any kind. Even his food is provided to scale laid down in his agreement, and his quarters are certified to accommodate the number of crew.

The framers of the Act evidently looked on the sailor-man as a fool or a simpleton, and provision is made for him accordingly. "Jack," however, nowadays, at least, is quite competent to look after himself, and demand what he terms his "rights." In the agreement with the crew the freeboard of the steamer is given. This is a change from the bad old days of the "coffin ships," and the fixing of a safe freeboard was one of the points so strenuously fought for by the "seaman's friend," the late Samuel Plimsoll, M.P. The load-line cut and painted on the side of every British ship is known universally as the "Plimsoll Mark," and is shown below.



The letters shown on the load-line mark are FW, fresh water; the load draft of the vessel in fresh water, IS, Indian summer; S, summer; W, winter; and WNA, winter North Atlantic.

Part II. of the Act deals with masters and seamen, and makes provision for apprentices being carried. It also provides for the examination and grant of certificates to competent men, and states the conditions for the issue of licences to supply seamen, and for their engagement. The rating of AB—that is to say, able-bodied seaman—is granted only when the seaman has served at sea for four years.

Elaborate instructions are laid down regarding the discharge of seamen, payment of wages, seamen's money order and savings banks, and the property of deceased seamen. By law, everyone on a ship's articles is a "seaman," and when a seaman dies on board a British ship his wages and effects must be handed over by the master of the ship to the Board of Trade, who transmit these through a shipping office to the relatives of the deceased. Provision is made as to discipline, and for an official log, wherein is entered the record of any offences, births, deaths, etc. To be logged, to a seaman means much the same as a police conviction to a landsman.

The records of the service of all persons who serve in ships is kept at the office of the Registrar-General of Shipping and Seamen. The appointments of the Registrar-General and his staff are made by the Board of Trade, which, with the consent of the Treasury, regulates their salary and allowances. In this office are collected all the statistics as to

seamen, etc., also records of deaths, births, and marriages on board any British ship.

Provisions for Passengers. Part III. of the Act deals with passenger and emigrant ships, and regulates not only the equipment of such vessels, but fixes the number of passengers or emigrants such ships may carry. As to emigrants, the Act fixes that as regards steerage passengers no ship may carry more than :

(*a*) If the ship is a sailing ship, one adult to 33 tons of the ship's registered tonnage : and

(*b*) If the ship is a steamship, one adult to every 20 tons of the ship's registered tonnage.

Provision is made for the survey of passenger steamers, for the general equipment, for the maintenance of order, for the supply and inspection of provisions, water, and medical stores, and so forth.

Sundry Regulations. Part IV. of the Act deals with fishing-boats, and relates to "all fishing-boats and to the whole fishing service."

Part V. is headed "Safety," and deals with regulations for the prevention of collisions at sea, regulates the lights to be carried and exhibited, the fog signals to be used, and the steering and sailing rules to be observed. It also deals with the load-line, the loading of timber, and carriage of grain, and unseaworthy ships.

Part VI. sets up the machinery for special shipping inquiries and courts : and

Part VII. deals with delivery of goods and lien for freight.

Part VIII. defines the liabilities of shipowners, which the Act declares to be

(1) In respect of loss of life or personal injury, either alone or together, with loss of, or damage to, vessels, goods, merchandise, or other things, an aggregate amount not exceeding £15 for each ton of the ship's register ; and

(2) In respect of loss of, or damage to, vessels, goods, merchandise, or other things, whether there be in addition loss of life or personal injury or not, an aggregate amount not exceeding £8 for each ton of the ship's tonnage.

Part IX. deals with wreck and salvage, the registration of marine store dealers, the appointments of receivers of wrecks, etc. : and

Part X. fixes pilotage, and applies to all ships, British and foreign.

Part XI. deals with lighthouses and the levying of light dues, which under present arrangements are all borne by the shipowner, and which he justly claims should, in the United Kingdom, as elsewhere, be borne by the State.

Part XII. refers to the Mercantile Marine Fund, which deals with all charges in respect to fees for survey of ships, fees paid at the various shipping offices, etc.

Part XIII. deals with the methods of legal procedure ; and

Part XIV. is supplemental, and defines the general control of the Board of Trade, the appointment of surveyors, and inspectors, and the power of Colonial legislatures in regard to shipping.

The Mercantile Marine as a Profession. The mercantile marine to-day offers an excellent career to the man who has steadiness and intelligence to recommend him, and, as a rule, no other recommendation is necessary, for there is always a vacancy in the larger companies for the young man duly qualified as junior officer or engineer. The sea as a profession should certainly be considered by parents who have difficulty in deciding "what to do with the boys."

There are three departments open to the youth who decides to follow the sea : (*a*) as a deck officer ; (*b*) as an engineer ; and (*c*) the saloon department, as purser or steward.

To qualify as a *deck officer*, the youth must serve an apprenticeship, and he may do this in several ways. He may be sent by his parents to the training ships Worcester or Conway, for the two years' school course there. This will cost parents about £60 a year, but the boy gets a splendid training in seamanship and navigation, as well as an excellent general education. These two years in the Worcester or Conway are allowed to count as one year's sea service, but to be qualified to sit for examination for a second mate's certificate the youth must now serve three years at sea ; this he can put in as an apprentice in a sailing ship or as cadet or midshipman in a steamer. There is no difficulty in getting a youth apprenticed or appointed as a cadet. The large steamship companies, such as the British India Line, the New Zealand Shipping Company, Shaw Saville & Albion Co., Bucknall Bros., the Gulf Line, now carry cadets or apprentices, the premium ranging from 30 to 100 guineas, which is returned to the boys as wages. These companies endeavour to give the cadets a knowledge of seamanship, navigation, and the general duties of a navigating officer, but the steamer-trained officer is seldom up to the standard of the youth trained in a sailing ship.

A young man may also qualify by serving before the mast, as boy and O.S. (ordinary seaman), and many excellent captains and officers have begun their sea profession in the forecastle.

Nautical Examinations. After completion of the four years sea time the youth goes up for the Board of Trade examination for a second mate's certificate, and this obtained, he is fully qualified as a junior officer in the mercantile marine. The supply of officers is less than the demand, and the young man should experience no difficulty in obtaining a berth as fourth officer in one of the "liner" companies. His pay will run from £5 to £6 a month, with "all found"—that is to say, assuming a youth goes to sea between 15 and 16 years of age, by the time he is 20 he is in a position to keep himself. His first step is to third officer, when he is in charge of a watch : this step he should get in from a year to eighteen months in most large companies, and he now puts in his time for chief mate's certificate. This obtained, he is eligible for promotion to second officer, which rank he should reach after three to five years' service. Then he passes for master, and obtains afterwards, if he can, an extra master's certificate as the result of a further and special examination. Promotion to chief officer reaches him after seven to ten years, depending on the company he serves, and he reaches command after fifteen to twenty years' service. His pay as chief officer will run from £12 to £18 a month, and as commander from £20 to £60 a month, and in some exceptional lines and services he may get £800 to £1,000 a year.

Promotion. Promotion to command goes by seniority, tempered by selection, and the smart and efficient chief officer, as a rule, gets his command before men senior to him, who have not shown themselves so zealous for their employers' interests.

The large shipping companies, as a rule, engage only young officers, and train them themselves. These juniors receive promotion to the higher grades as vacancies occur, and only in exceptional cases is an officer or commander brought in over the heads of men in the service.

Application should be made in writing to the manager or marine superintendent of the line

selected, and the letter should be accompanied by copies of testimonials. This, as a rule, brings a reply, asking the applicant to call for a personal interview, and the interview being satisfactory, and his papers in order, an appointment follows.

Marine Engineers. To qualify for a marine engineer, an apprenticeship of at least five years must be served in an engineer's establishment—a marine engineer's shop for preference. Here the youth should begin at the age of 15 or 16, so that he will finish his time when he is between 20 and 21 years of age. During his apprenticeship the youth who desires to get on will attend evening technical classes in drawing, machine construction, and kindred subjects, all of which he will find most helpful when he goes up for his Board of Trade examinations, and throughout his career. The great marine shops are on the Clyde, in Scotland, and on the Tyne and the East Coast of England, and Belfast in Ireland. As a rule, no premium is charged, and in fact the majority of engineers regard the premium apprentice with suspicion, considering he is likely to have too much false dignity to learn his business properly. Wages are generally paid the apprentice, say 4s. a week the first year, rising by 1s. or 2s. a week each year of the five he serves. His apprenticeship completed, the young man should send in his application to the superintending engineer of three or four of the big companies. He should state clearly where he served his time, what special certificate he holds, his age, and send a copy of his apprenticeship certificate. When appointed, it may be as tenth engineer, or even as fifth or fourth, depending on the size and power of the steamer to which he is posted. His ambition is now to get his time in as a watch-keeping engineer, to enable him to obtain his second and chief engineer's certificate. Usually the second's examination is passed after about eighteen months to two years' sea service, and a chief's certificate is obtained after four to five years' sea service. Promotion depends on the line in which the engineer serves. He should be third after three to four years, second after seven to eight years, and chief engineer after 15 years' service. The pay of a junior engineer begins at £7 to £8 a month, with "all found"; as third he will receive £10 to £12, as second £14 to £18, and as chief £20 to £40, depending on the number of years' service. The chief engineer earns a bonus on savings in coal and oil consumption.

Pursers and Stewards. Only the large passenger boats carry pursers, and their duties vary according to the line on which employed. In some of the companies he is a clerk pure and simple, doing the captain's correspondence, writing out manifests, passenger lists, etc.; while in other lines he combines these duties with the general oversight of the saloon department. Generally speaking, however, the duties of purser and steward are separate. The purser usually secures his appointment through the nomination of a director, and puts in a few months or a year or so in the office of the company before he is sent afloat. There is nothing particularly exacting in the duties of this office, and a young man of average intelligence can easily acquire a knowledge of them. Vacancies, as a rule, seldom occur in the big lines. Pay will run from £6 to £12 a month,

Pursers are carried by river and pleasure steamers during the summer months, and here the duties are more concerned with the collection and issue of passengers' tickets. There are many applicants, and the pay is small, from 10s. to 30s. a week.
The young man who desires to go to sea as a steward must begin at the very bottom of the ladder, and, as a rule, he learns his experience in a hard school. The river and pleasure steamers, or in the steerage department of an Atlantic liner, would give an opening, and experience gained, the efficient steward works his way upward to chief by his own efforts. The pay of assistant stewards is nominal, and they depend on tips from passengers to a great extent. A chief steward will be paid from £8 to £12 a month. A knowledge of catering for passengers is essential to the efficient steward, and second only to this is tact.

Royal Naval Reserve. The officer or engineer desirous of serving his country or ambitious of social advantages, joins the Royal Naval Reserve. The qualifications necessary, aside from the fact that the applicant for a commission must be a British subject, are as under:

For midshipmen: a two years' course in one of the mercantile marine training ships, or a year at sea on board a first-class British ship. For sub-lieutenant: service as first mate of a first-class British steamship of at least 1,500 tons, or a sailing ship of 1,000 tons, and the possession of a master's certificate. Second and third mates are eligible provided that they have served for not less than six years at sea, excluding their time as apprentice, and for lieutenant, service in command of a steamer of 1,500 tons or a sailing ship of 1,000 tons is necessary for not less than one year.

A senior engineer must hold a first-class engineer's certificate, and have not less than 10 years' sea service, including three years as chief of a steamer of not less than 500 nominal horse-power.

An engineer must hold a first-class certificate and have seven years' sea service, including one year's service as chief engineer of a steamer of 200 nominal horse-power, or as second of a steamer of 500 horse-power, and an assistant-engineer must hold a first or second-class certificate and have served at least one year in a steamer as a certificated engineer.

Qualifying Drills. It is necessary for the lieutenant, sub-lieutenant and midshipman, to put in qualifying drills at stated periods, and such officers may volunteer to go through a twelvemonths' course of training in H.M. fleet. This course completed satisfactorily, officers are granted certificates, and become entitled to the following annual allowances:

Lieutenants ..	£25 a year.
Sub-lieutenants	20 a year.
Midshipmen ..	10 a year.

Officers of the reserve when called out for training receive the same pay and allowances as officers of the corresponding rank in the Royal Navy, and while on service they are treated in the same manner in every respect.

Besides the experience, and the social polish which a training in the Navy undoubtedly gives, and considering that an officer can live on his pay while serving, the annual allowance granted certainly makes it worth while for a merchant service officer to serve in the Reserve.

The tonnage of the mercantile marine under the Red Ensign grows and increases with the years, and the shrewd brains which control it are as capable now as ever, and if only the youth of the country, gentle and simple, would do their share, and come forward as they did in the years gone by, as officers and seamen, there seems no reason why the preponderance of our lead in shipping matters should not be maintained.

DYEING MACHINERY

Hand Dyeing. The Introduction of Machinery into Dyeing Practice. Typical Machines in Dyeing

Continued from page 6199

By HERBERT ROBSON

MACHINERY driven by power came into use in dyeing practically with the artificial dyes, and the subsequent enormous expansion of the trade. When the dyer had to deal with small quantities of goods—a few bundles of yarn or a small piece or two of cloth—he was content to use vats sunk to the level of the dye-house floor, as in the old and still-used process of indigo dyeing, and with tubs and kettles, working the goods with his hand, or, if the heat would not allow this, with rakes or forks or with a long crutch-like stick known as a "jigger." The resemblance of a billiard-rest to this article has given us a familiar slang-word.

Hand Dyeing. These hand-dyeing appliances do not require illustration. In cases where small quantities are to be handled, or when special care is required, they are still used. Moreover, it frequently happens that metal must not come into contact with the dye-bath, and in this case the use of a wooden vessel is compulsory. The ordinary form this takes is simply a strong, oblong box, fitted with a steam pipe below a perforated false bottom. The steam may be either blown in direct, or a closed steam coil may be used.

In dyeing hanks or skeins in this simple dye-vat the hanks are strung in festoons on sticks. These are ordinarily straight, but in some cases—in using the sulphur dyes, for instance—they are bent so as to keep the yarn constantly under the surface of the bath. The hanks are dipped into the bath, raised and lowered in the liquor a few times, and then left in the bath with the ends of the stick resting on the edges of the vat. The next stickful is then introduced in the same way, and when all have been entered, leaving a space between each to prevent entanglement, the first is lifted by two men standing one at each side of the vat. One of them thrusts a stick through the hanks and when the other has grasped his end, they lift the hanks so that they are well turned on the stick and the part of the yarn that was resting on it is now in the bath. The others are treated in the same way, and the yarn is said to have had "one turn." The men go on to give "three turns," or more, according to their judgment or instructions.

Dye-house Machinery. In the hand dyeing of cloth the goods are simply entered and worked about in any of the already-mentioned ways. A simple wince or skeleton roller may be provided over the dye-beck, and the goods, stitched in an endless band, are put over the wince and under guide rollers in the bath. The wince is then revolved and the cloth run through the bath until it is evenly dyed to shade.

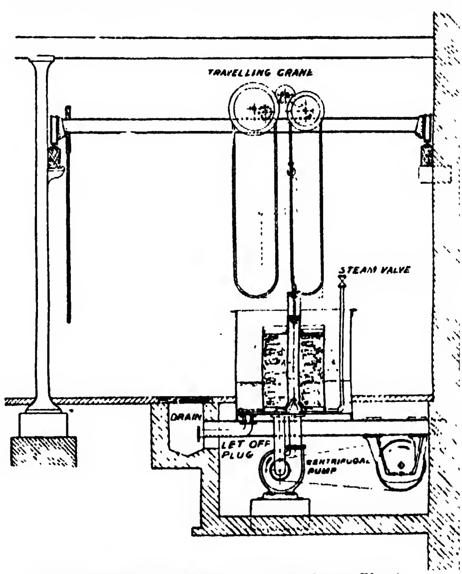
This dye-beck, with wince, represents the simplest form of dye-house machinery, and it is evident that it may be driven either by hand or power. The last thirty years or so has, however, seen the introduction of a great variety of machines for general use and for particular purposes.

Broadly speaking, the form of machine used differs little with the kind of fibre under treatment, but widely with the state of manufacture and the variety of material. In other words, a cop of yarn cannot be dyed like a piece of cloth nor will muslin stand the treatment of strong cloth or felt.

In this connection, however, silk must be looked upon as coming under the description of a "variety of material." The careful manipulation required makes it necessary to dye it by hand or with a simple form of machinery not liable to damage the fibre. The quantities ordinarily dealt with, moreover, allow most of the dyeing to be done by hand in wooden dye-vats or even in earthenware or porcelain vessels. It is dyed in the form of yarn or cloth; and in a few of the largest silk dye-houses some of the simpler form of machines used for dyeing cotton in the hank and in the piece have been adopted, in order to handle quantities rapidly.

In one form of special machine for silk yarn the hanks are placed over a reel, free at one end, so that they may be readily put on and taken off and run through a dye-vat, the reel or rollers revolving so as to pass every part of the hank continuously through the dye liquor. In another form, the hanks are hung on a pole, or between two poles, and carried through the dye-bath with a revolving action, to ensure even dyeing. As regards pieces, the wince arrangement already described is used, or a simple dye jig, which will be described later.

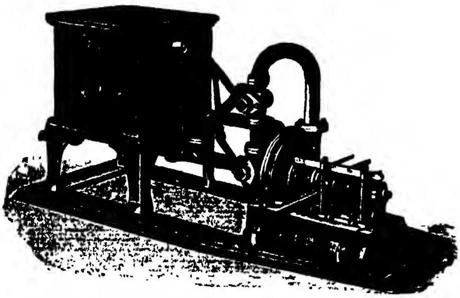
Wool and Cotton Dyeing. Wool and cotton are dyed in the raw or loose condition; in various states of preparation for the spinning frame, as rovings, sliver, or slubbing, for instance; as spun in cops; as hanks and warps; and in the form of woven fabrics. For each of these states a multiplicity of special machinery has been devised, and in this course it will be requisite to confine ourselves to typical machinery for each



7. OBERMAIER MACHINE (Mather & Platt)

form of material. It may be here stated, without fear of contradiction, that our British engineers are pre-eminent in this branch.

Loose Fibre. The advantage of using coloured weft cops, obviating the necessity of any

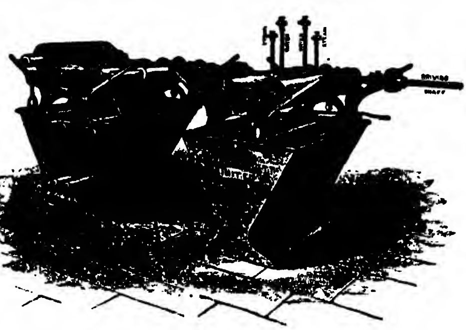


8. COP DYEING MACHINE (Walker & Rose)

subsequent reeling before introduction into the shuttles, is evident in the manufacture of fancy and parti-coloured fabrics. It is obvious that one way out of the difficulty of dyeing tightly wound cops through and through is to dye the wool or cotton before spinning. Technical difficulties, however, stand in the way, and the dyeing of loose fibre is not practised to a great extent. The dyed material injures the cards and soils the preparatory machinery generally. Wool, moreover, is liable to felt in the process, and cotton loses its "nature," as the spinners say, so that in either case the spinning is imperfect. In repeated attempts on a large scale to get over these difficulties, an acquaintance of the writer's lost a substantial fortune.

Still, in addition to the advantage of using coloured weft cops, there are other purposes for which raw cotton and wool are dyed. Different colours may be mixed and spun to produce required shades or fancy effects, or the loose fibre may be dyed to be used as coloured fillings. Moreover, another advantage, as concerns light shades, is that a faster colour is produced by mixing a dark coloured cotton with white, and then spinning, than by dyeing the cotton uniformly.

The Klauder-Weldon machine has been used for loose cotton, but it is unsuitable for wool. It is very similar to the modern washing machine in the steam laundry; a drum of copper netting containing

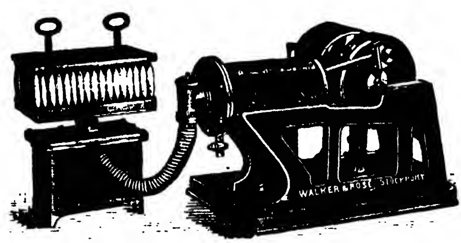


10. JIGGER DYEING MACHINE

the loose material revolves in a heated dye-bath until the dyeing is effected, and it is obvious that by changing the baths the same machine may be used for bleaching, mordanting, or washing. A much better machine for loose material is that of Obermaier, manufactured by Messrs. Mather & Platt. In this, the loose material is stationary, the liquor being forced through it, a point particularly important in the case of wool, as felting is avoided.

Sliver, or Slubbing. The advantages of the dyed cop are better obtained by dyeing what the spinner calls "preparation"—that is to say, the cotton in some state of preparation for the spindles. After it has been opened and scutched, a great amount of dirt has been removed, which interferes with the purity of shade when raw cotton is dyed, and if it has been carded, of course the injury caused to the cards by the mordant is obviated.

A fresh difficulty, however, arises. The slubbing, or sliver, must not be broken, and even cotton rovings would not stand the treatment which is allowable with raw cotton. The Obermaier machine [7], in which the material is left undisturbed, is the standard apparatus for the purpose, and this is illustrated in diagram. The movable copper cylinder can be lifted out of the dye-vat, as shown in the dotted lines, by means of the travelling crane. The vat is heated by steam, as shown. When the cylinder, which is varied in formation somewhat according to the material to be dyed, is packed with the goods, it is lowered into the vat, steam is turned on, and the centrifugal pump is set in action. This circulates the dye-liquor in the vat through the goods by means of the perforated centre tube, and back into the vat again. When the desired shade



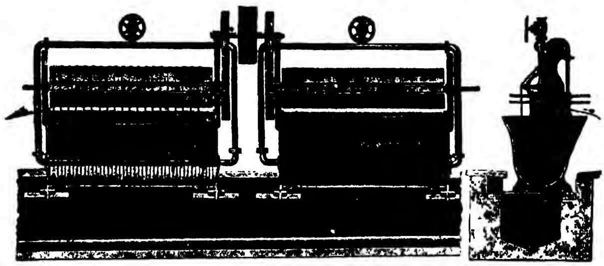
9. COP DYEING MACHINE (Walker & Rose)

is obtained, the cylinder is lifted, the goods are removed, and hydro extracted. They may be washed in the same receptacle, or dried in it by means of a current of hot air if desired.

Cop Dyeing. The cop is yarn as it is taken from the spindle. It is very compact, and consequently very difficult to dye. The advent of the direct cotton dyeing colours has, however, assisted the cop dyer, as they have great solubility, and do not require mordants, which, forming a solid lake on the fibre, interfere with the penetration of the inner layers of the cop. In dyeing, the cop is mounted on a hollow perforated spindle, and placed in a machine which forces the liquor completely through the yarn, or sucks it inwardly, or both. Weft cops for dyeing or bleaching are not mounted on the narrow paper tubes ordinarily employed in spinning weft (paper bottoms), but the first layers of yarn on the spindle are stiffened with a little paste (paste bottoms).

The cop dyeing machine of Walker & Rose, of Stockport [8 and 9], is shown herewith. The dye-vat is at one end of the machine, and the liquor is circulated by a centrifugal pump. Between the vat and the pump connecting piping is fixed, two taps being employed to allow the liquor to pass from the vat to the pump in either direction, as required. The advantage of an arrangement of this kind will be readily seen, as by reversing the liquor it can be

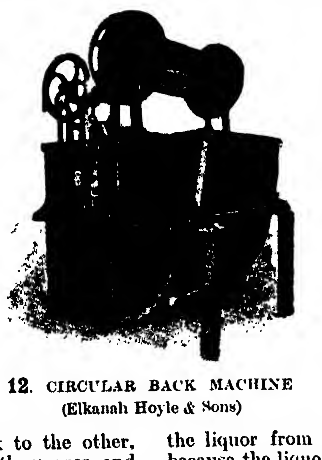
passed through the cops from the exterior to the interior, and vice versâ. The dye-vat can be made to receive any number of cops up to 1,200. The two stands to carry the cops are made portable, and are perforated to hold the hollow perforated skewers upon which the cops are mounted. At the base of the stands a chamber is formed, the bottom part being provided with a socket, so that when the perforated plates carrying the cops are in position, a water-tight joint is formed between the inlet pipe and the chamber, the liquor being thus confined and compelled to pass through the perforated plates and skewers, and consequently through the cops. The vat is heated by steam as usual. Ordinarily cop-dyeing machines are closed when in action, but this apparatus has the advantage of remaining open.



11. SPIRAL DYEING MACHINE (Mather & Platt)

Cheeses (small warps resembling a single Gloucester cheese) and spools (yarn wound, for instance, by means of a split drum) are dyed and bleached in the same form of machine, with slightly different mounting arrangements for the cheese or spool. As the yarn is less tightly wound, it is easier to get level shades throughout than in cop dyeing.

Hank or Skein Dyeing. The hank is the reeled yarn, and presents the form that is familiar to the public in skeins of thread. It requires very simple machinery; in fact, in dyeing yarn in hanks, the only thing to be avoided is the entanglement of the yarn. A typical form of yarn-dyeing machine is the Klauder-Weldon. In this, the yarns are arranged on a pair of rods suspended between a pair of revolving discs, which carry the yarn through the dye liquor contained in a semi-cylindrical vat. The hanks are steadily carried through the dye liquor, and there being no motion of the hanks, there is no chance of any entanglement. The machine works very successfully, is simple in operation, not liable to get out of order, is capable of dealing with large quantities of yarns, and is economical of dyestuffs.



12. CIRCULAR BACK MACHINE (Elkanah Hoyle & Sons)

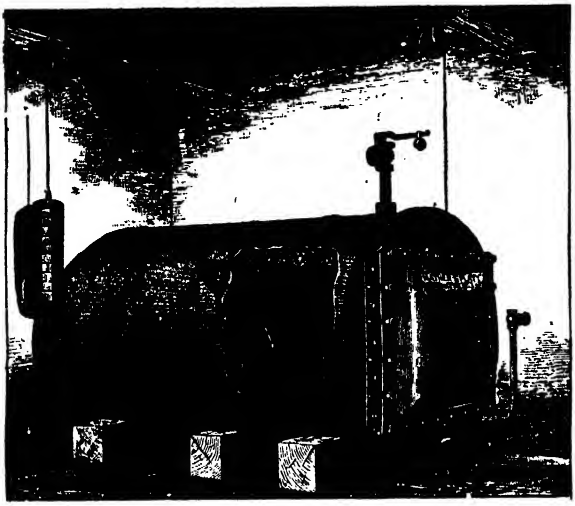
A very ingenious yarn-dyeing machine in that of Corron. In this, a rectangular dye tank is provided, and over it a travelling arrangement which, in passing from one end of the tank to the other, picks up the rods full of yarn, turns them over, and drops them back again.

A perfect hank-dyeing machine would seem to be one in which either the hanks are kept still and the liquor is caused to circulate through them, or one in which the hanks are carried through the dye liquor, but must not, while doing so, be subjected to any rapid movement tending to bring about entanglement of the hanks one with another. The hanks should not be tightly stretched, but hang somewhat loosely, because then the dye liquors can more thoroughly penetrate to every fibre of the hank.

Warp Dyeing. Warps are collections of yarns in long lengths ready for the loom. They come into the dyer's hands in several forms, but usually in large balls of about 12 in. in diameter (ball warps). In the process of dyeing the threads must not be entangled, otherwise they will not lie straight on the loom or pass freely through the eyes of the healds, and so breakages will occur that are undesirable.

The usual plan of warp dyeing is to have a vat with a number of guide rollers at the top and bottom, and to pass the warp round these rollers, and thus, as it passes through from the first to the last roller of the set, it travels several times through the liquor, and by running the warp backwards and forwards, giving it several "ends," it can be effectually dyed. This method works well; the threads of the warps can be kept level and straight, and the dyeing is uniform. It necessitates the unwinding of the ball of warp in the first instance on to a winding roller, and when dyed, rewinding back again into the ball form again, although if the dyer be also the manufacturer, this rewinding may be omitted, and the warp wound ready for use on the warp beam.

The problem comes up whether the warp could be dyed in the ball form, with all the threads in position and undisturbed. If it could be done efficiently and the colour be level throughout, then this method would save the trouble of unwinding and rewinding the warp. Now, simple immersion of the ball of warp into the dye liquor will not do, for it will not come up of a level shade. The dye liquors are found not to penetrate right into the centre of the ball of warp, and so the outside gets dyed the deepest shade while the centre either does not get dyed at all or only a pale tint. This want of penetration is caused by the tightness with which the ball is wound acting as a resist to the penetrative capacity of the liquor; and, secondly, there is no doubt that the air enclosed in the interstices of the warp in the interior of the ball prevents the liquor from getting into the central parts, because the liquor in turn prevents it getting away with sufficient freedom. What is wanted in order to dye a ball warp is some means of forcing the dye liquor right to the centre. Winding the warp into an Obermaier apparatus would do very well and perfect results can be obtained, but, as with the warp-dyeing machine, this necessitates unwinding and rewinding of the balls. Placing the warp into a closed chamber, and circulating the dye liquor through is an improvement, but even then there is much chance of the centre being paler than the

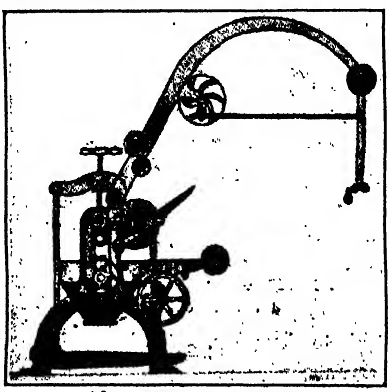


13. "COTTAGE" STEAMER (Mather & Platt)

outer portions. A better plan would be to wind the ball on a spindle in the first instance, and then to put the ball on a hollow perforated spindle through which the liquor can be forced. In this way a modified Obermaier can be used, and good results attained.

Jigger Dyeing Machine. The action of this simple "dye jig" is sufficiently explained in the illustration [10]. The cloth is wound on a roller, round the guide rollers shown at the bottom of the vat, and round a second roller. This is revolved, drawing the cloth through the bath and winding it. When all the cloth wound on it has had "one end" the action is reversed, and it is given as many ends as necessary. Then it is "batched" on to the large roller shown to the left of the figure. This "batching roller" is then removed for subsequent processes, washing, drying, etc. The reversal of the motion of the rollers is automatic, and there are simple arrangements for regulating the tension of the cloth. In dyeing calico and unions in the full width this is perhaps the most universally used machine.

The jigger is used for dark shades, as short strong baths can be used. When heavy drills or thick cloths generally are under treatment, the squeezing rollers are advisable as they drive the liquor into the goods. Only one batching roller is shown, but a similar roller can be mounted on any of the outstretched arms either to the right or left of the vat. For the purpose of attaching the cloth to the rollers it is a common practice to sew a piece of cloth tightly round each roller, leaving a loose end to which the piece can be attached.



14. PADDING MACHINE
(Elkanah Hoyle & Sons)

Spiral Dyeing Machine. In this machine [11] the cloth is not in tension and may be dyed in separate pieces between each peg or stitched together "on the endless system." The dye-beck is of cast iron and the section to the left shows the drain below, the "midfeather" acting as diaphragm, the perforated steam pipe passing into the beck, the peg rail at the top to keep the pieces from entangling, the wince, and the necessary steam fittings. The pieces, or the continuous band, traverse the beck in a spiral, as shown to the left of the figure, the loop at the bottom keeping the cloth fairly slack. This slack loop allows the cloth to remain longer in the liquor and promotes even dyeing. The machine is much used in dyeing on a large scale as the beck can be made of any practicable length, capable, say, of dealing with 30 pieces at a time.

Circular-back Machine. This [12] is a form of the dye-beck and wince for cloth already described. The illustration of the machine made by Elkanah Hoyle & Sons hardly needs description. It will be seen that this has a small cylinder engine attached, and the wince is driven by a reversible eccentric so that the cloth can be run through the bath either way as desired. This is principally used in Leeds and Huddersfield for West of England cloths.

Hawking Machine. This is used in dyeing when it is necessary to keep the cloth under the surface of the liquor throughout the operation to guard it from exposure to the air. It consists of a series of guide rollers arranged in the dye-vat so that they are completely covered with the liquor. The pieces are sewn together in an endless band and drawn continuously at full width through the bath by means of a pair of rollers, also, of course, under the surface of the liquor.

Padding. As the name implies, this is a rapid method of dyeing cloth suitable only for light shades. When one side of the cloth only is coloured this is called "slop-padding," a style of work very suitable for discharge effects. The ordinary padding machine consists of a trough containing guide rollers and with a pair of squeezing rollers above it. The cloth passes through the dye-liquor in the trough, round the guide rollers, between the squeezing rollers and away.

The machine illustrated [14], that of Elkanah Hoyle & Sons, has a pair of cast-iron rollers turned true and ground with emery so that the piece is nipped evenly from end to end including the selvedge. The rollers are wrapped with coarse padding cotton. The wooden trough underneath is for filling purposes, if filling should be required, and also can dye cotton with cold dye tinting, and is very useful should a piece be a little off shade. The machine is made to batch on arms from the top roller, which is of great assistance in keeping the piece well fixed on the roll, as well as for "cuttling down." This is an ordinary form of delivery from dyeing and finishing machines. It will be noted that the long arm delivering the cloth swings to and fro with the revolution of the wheel. This lays the cloth in long even folds on the floor below.

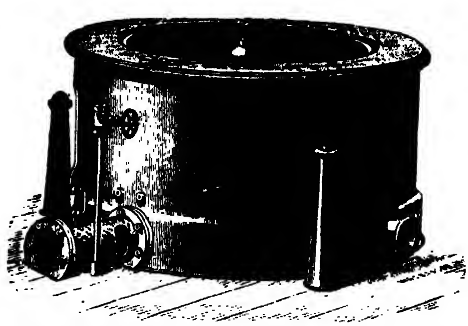
Steaming. After dyeing, some colours—for instance, aniline black, Turkey red, and many of the

alizarines—require steaming under pressure to develop and brighten the colour. The "Cottage" steamer [13] of Messrs. Mather & Platt is universally used. This is a strong wrought-iron cylinder, one end of which gives access by means of a sliding door with counterweights as shown. The section of the shell is removed merely for explanatory purposes. It is used either for yarn or cloth, and the position of the goods round the rollers can be varied from time to time by moving the exterior handle. Any pressure up to 30 lb. per square inch (roughly two atmospheres) may be used.

Soaping and Washing Machine. This continuous open width machine is shown in **15**. It can be made with any number of cisterns from one to twelve. In its most general application it is used as a combined raising or fixing, soaping and washing machine. Besides this use, it can also be employed with advantage for "cutting" indigo-dyed goods, developing naphthol colours, or chroming aniline blacks.

A medium-sized range, with six cisterns, can be used, utilised as follows: Starting from the right (1) raising or emetic cistern, (2) washing cistern, (3 and 4) two soaping cisterns, (5) clean soap cistern, (6) washing cistern with heavy squeezing bowls. The guide rollers are all of solid drawn metal, and the squeezing bowls of brass and rubber, or of brass and sycamore. With the exception of the raising cistern all the cisterns are fitted with beaters of non-corrodible metal placed below the surface of the liquor, and between the vertical laps of cloth. These beaters are driven independently at a high speed, whatever may be the speed of the cloth through the range, and they dash the liquor with great force upon both sides of the cloth, thus thoroughly cleansing it and loosening and removing any thickening matter which may have been used in the colours, and any by-products from the use of mordants or "cuts," while not the slightest injury is done even to the most delicate fabrics.

Wringing, Squeezing, and Hydro-extracting. The wringing-post has a hook or sort of short perch upon which yarn can be twisted by hand to drive off excess of moisture.

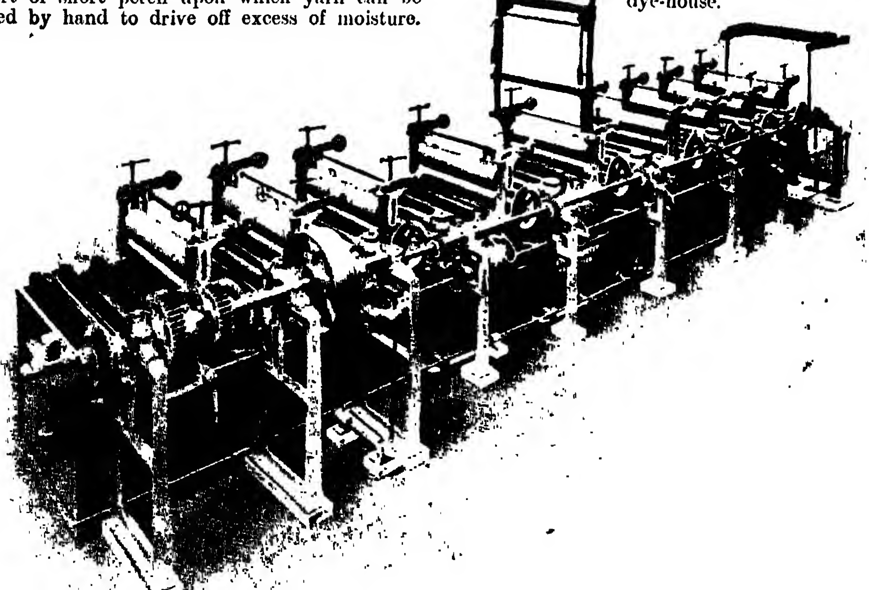


16. HYDRO-EXTRACTOR (Thos. Broadbent & Sons)

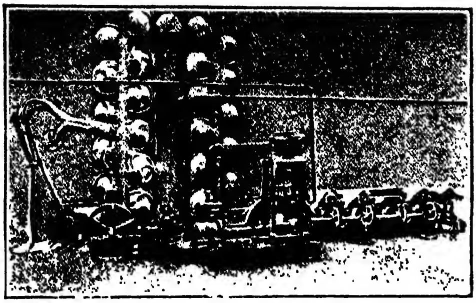
In squeezing, rollers are provided upon many machines, through which the yarn or cloth passes, and the excess liquor runs back into the bath. By taking advantage of the law of centrifugal force much more moisture can be driven off by means of a hydro-extractor. In wringing, less than 50 per cent. of moisture is removed; by squeezing, about 70 per cent.; whereas over 80 per cent. is driven off by "whizzing," as it is familiarly termed. The hydro-extractor is now largely used in the steam laundry, and the economy of this preliminary drying process will be apparent.

The hydro-extractor is a perforated metal basket, mounted in an outer case so that it can be revolved at a high rate of speed. The goods are packed into the inner basket and the machine is set in motion, revolving at the rate of 1,500 revolutions per minute. The water expressed by the powerful centrifugal force is thrown into the case, and escapes by means of a drain-pipe.

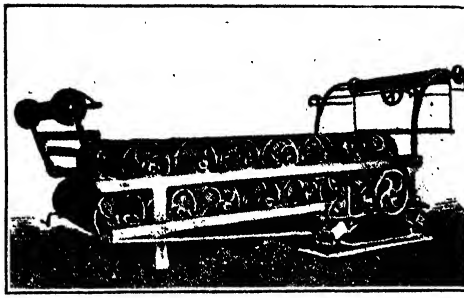
Hydro-extractors vary in detail according to the special use to which they are put. The type shown [16], manufactured by Thomas Broadbent & Sons, Ltd., is that ordinarily used in the dye-house.



15. SOAPING AND WASHING MACHINE (Mather & Platt)



17. DRYING CYLINDERS (Elkanah Hoyle & Sons)



18. DRYING CYLINDERS (Elkanah Hoyle & Sons)

Washing. Thorough washing is one of the most important processes in the dye-house, and it is one that may have to be repeated several times in the stages through which the goods pass before they are ready for the market. All surplus mordant must be washed off before dyeing, otherwise it forms insoluble lakes in the dye-bath, wasting colour and leading to spotty dyeing. As a rule, but not always, the goods must be washed after dyeing to clear the fibre and to freshen the colour. As we have seen, the mordanting, dyeing, and washing may proceed as a continuous operation in a machine with several "holes," or the beck, or jigger, may be cleared of liquor and filled with clean water. Special machinery, however, is useful in some cases.

Drying Cylinders. The machine for drying both sides of the cloth takes the form of a number of cylinders heated by steam. These were all formerly, and are still, as a rule, made of tin-plates, and hence are commonly known to the finisher as "tins." "Drying over tins" is therefore the technical expression when the cloth is dried on both sides, while "drying over cylinders" is used when the cloth is dried on one side only.

The cylinders are heated by steam passing through their hollow axles, and revolve as the cloth passes over them, thus constantly bringing up a fresh heating surface. The machine shown in **18** is that of Elkanah Hoyle & Sons, and each cylinder is fitted with a patent water-bucket, which is emptied of the condensed steam every time the cylinder revolves.

The upright machine [**17**], also made by Messrs. Hoyle, is provided with a "five-holed squeezer," which is exactly similar to the crabbing machine already described, with the exception that there are five pairs of iron rollers and cast-iron troughs. This machine is largely used for all classes of ladies' dress goods, ladies' macintosh mantle cloths, and also for mohairs, and in it a continuous operation can be carried on of scouring, washing, setting, stiffening, and drying.

Steaming and Ageing. The continuous steaming and ageing machine [**19**] is referred to in all technical literature as the "Mather & Platt," a sufficient testimony to its universal application. It is a chamber fitted with a number of copper rollers to guide the piece while passing through. It is used for a large number of colours, which are developed by steaming, and for ageing aniline black, the steam acting as an oxidising agent. In the latest machines two or more "runs" of cloth can pass abreast. This enables a chamber of half the height or length of those constructed for a single run of pieces to turn out the same quantity of cloth. In the older machines it is necessary for the metal rods upon which the cloth hangs, after passing through the chamber, to be transported by hand or by special mechanism outside the chamber to the entering end again. This involves hand labour in every case, and also the exposure of the rods to a much lower temperature outside the chamber. To avoid the condensation which might form on their surfaces and produce stains on the cloth on re-entering the chamber, the rods are re-heated. In the new machine the rods are carried automatically within the chamber, from the point where the cloth leaves, back to the point where it enters the chamber. The machine requires no attention beyond seeing that the cloth enters straight into the chamber. A further improvement consists of an arrangement by which the rods revolve slowly, as they pass from one end of the chamber to the other, in such a manner that no portion of a piece of cloth remains in constant contact with the hot surface of the rods during the whole of the time it is passing through. In the steaming of some colours this is of great importance.

SOLUTION OF RIGHT-ANGLED TRIANGLES

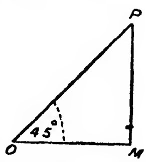
Ratios of 45°, 30°, 60°, 90°, 180°, 0°. Relations between the Ratios of an Angle and its Complement and Supplement. Compound Angles

continued from page 6282

By HERBERT J. ALLPORT, M.A.

18. The Trigonometrical Ratios of Certain Well-known Angles. The ratios of a few angles which are sub-multiples of two right angles can easily be found.

The Ratios of 45°. Let $\angle POM = 45°$. In one of the lines bounding the angle take any point P and draw PM $\perp$ to the other bounding line. Then, since the $\angle$s at O and M make up one and a half right angles, the remaining $\angle OPM$ must be half a right $\angle$. Hence, MP $= OM = m$, say. Therefore, if $OP = x$, we have $x^2 = m^2 + m^2$ (*Prop.* 34).



$$\therefore x = m\sqrt{2}.$$

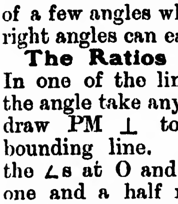
Hence,

$$\sin 45° = \frac{MP}{OP} = \frac{m}{m\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

$$\cos 45° = \frac{OM}{OP} = \frac{m}{m\sqrt{2}} = \frac{1}{\sqrt{2}}.$$

$$\tan 45° = \frac{MP}{OM} = \frac{m}{m} = 1.$$

The Ratios of 60° and 30°. Let OPQ be an equilateral Δ. Then each of its $\angle$s is one-third of 180°, *i.e.*, 60°. Draw PM $\perp$ to OQ. Then



$$\Delta OMP = \Delta QMP \ (\textit{Prop. } 19).$$
$$\therefore \angle OPM = \angle QPM,$$

so that each of them is 30°. Also OM = QM, and OM is therefore half of OQ.

$\therefore$ if $OM = m$, we have $OP = 2m$,

and $MP^2 = OP^2 - OM^2$ (*Prop.* 34)

$= 4m^2 - m^2 = 3m^2$.

Hence, $MP = m\sqrt{3}$.

$$\therefore \sin 60° = \frac{MP}{OP} = \frac{m\sqrt{3}}{2m} = \frac{\sqrt{3}}{2}.$$

$$\cos 60° = \frac{OM}{OP} = \frac{m}{2m} = \frac{1}{2}.$$

$$\tan 60° = \frac{MP}{OM} = \frac{m\sqrt{3}}{m} = \sqrt{3}.$$

Also, since $\angle MPO = 30°$, we have

$$\sin 30° = \frac{OM}{OP} = \frac{m}{2m} = \frac{1}{2}.$$

$$\cos 30° = \frac{MP}{OP} = \frac{m\sqrt{3}}{2m} = \frac{\sqrt{3}}{2}.$$

$$\tan 30° = \frac{OM}{MP} = \frac{m}{m\sqrt{3}} = \frac{1}{\sqrt{3}}.$$

The Ratios of 0°, 90° and 180°. We have already seen, from Arts. 15, 16, 17, that

$\sin 0° = 0$, $\cos 0° = 1$, $\tan 0° = 0$.
$\sin 90° = 1$, $\cos 90° = 0$, $\tan 90° = \infty$.
$\sin 180° = 0$, $\cos 180° = -1$, $\tan 180° = 0$.

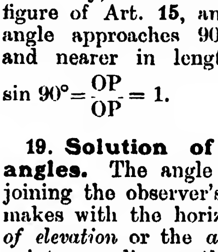
The values of the ratios thus found should be known by heart. Any required ratio is best remembered by thinking of the lengths of the sides of the triangles from which they are obtained. For example, if the value of cos 60° is required, think of the equilateral triangle, and it will easily be remembered that OM is half of OP, and therefore $\cos 60° = \frac{1}{2}$. In the same way, if sin 90° is required, think of the figure of Art. 15, and remember that as the angle approaches 90°, MP becomes nearer and nearer in length to OP, until finally

$$\sin 90° = \frac{OP}{OP} = 1.$$

19. Solution of Right-angled Triangles. The angle which the straight line joining the observer's eye to a distant point makes with the horizontal is called the *angle of elevation* or the *angle of depression* of the point, according as the point is *above* or *below* the observer.

The Trigonometrical Ratios are, in most cases, incommensurable numbers. Their approximate values have been found for all angles, differing by 1′, from 0° to 90°. It will be seen later that this is sufficient to determine the ratios of any angle whatever. [Chambers' Mathematical Tables. 3s. 6d.]

EXAMPLE 1. The angle of elevation of the top of a tower is 30°. From a point 250 feet nearer the foot of the tower the elevation is 60°. Find the height of the tower.



Let PM represent the tower, and let A, B be the points of observation, so that

$$AB = 250 \text{ feet}.$$

Let $PM = x$ feet, $BM = y$ feet.

Then $\frac{MP}{BM} = \tan 60°$,

and $\frac{MP}{AM} = \tan 30°$.

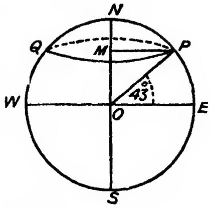
Hence, $\frac{x}{y} = \sqrt{3} \quad . \quad . \quad . \quad . \quad (1)$

and $\frac{x}{y + 250} = \frac{1}{\sqrt{3}} \quad . \quad . \quad . \quad . \quad (2)$

The solution of these two equations gives $x = 216{\cdot}5$ feet.

EXAMPLE 2. Find the distance travelled in an hour, in consequence of the earth's rotation, by a person situated in latitude 43°; given that

cos 43° = ·73135, and that the earth's radius = 4000 miles.



Let NS be the earth's axis, and P a point in latitude 43°, *i.e.*, ∠EOP = 43°. Draw PM ⊥ to ON. Then, owing to the earth's rotation, P describes a circle about M as centre. Also

$$\frac{MP}{OP} = \cos MPO = \cos EOP = \cos 43°$$

$\therefore$ MP = OP cos 43° = 4000 × ·73135 miles
= 2925·4 miles.

Hence, in one hour, the point P travels $\frac{1}{24}$ of the ○^{ce} of the ⊙ which P describes,

$$= \frac{1}{24} \times 2\pi \ . \ PM = \frac{2 \times 22 \times 2925 \cdot 4}{24 \times 7} \text{ miles}$$
766 miles.

20. Complement and Supplement of an Angle. We shall now prove that

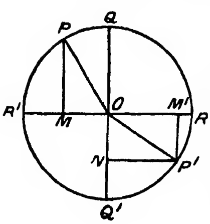
(i.) The sine of an angle = the cosine of its complement.

(ii.) The sine of an angle = the sine of its supplement.

(iii.) The cosine of an angle = – (the cosine of its supplement)

whatever the magnitude of the angle may be.

(i.) Let OP, starting from OR, trace out the angle A; and let OP′ trace out 90° – A, *i.e.*, let it first trace + 90° by turning in the positive direction up to OQ, and then turn back from OQ through the ∠QOP′, equal to – A.



Thus, in whatever quadrant OP lies, the ∠ROP which OP describes from OR is always equal to QOP′ which OP′ describes from OQ in the negative direction. Therefore P′N must always be equal to PM in magnitude, *i.e.*, OM′ = PM in magnitude. Also, by drawing figures in which OP lies in any other quadrant than the one shown, it will be seen that when P is *above* ROR′, P′ is to the *right* of QOQ′, and when P is *below* ROR′, P′ is to the left of QOQ′. Hence PM and OM′ always have the *same sign*.

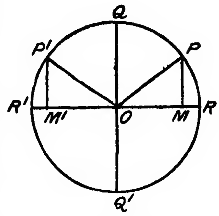
$\therefore$ for all values of the ∠A we have

$$\frac{MP}{OP} = \frac{OM'}{OP'},$$

i.e., sin A = cos (90° – A);

or, the sine of an angle = the cosine of its complement.

(ii.) As before, let one revolving line OP trace out the ∠A, and let the other, OP′, trace out 180° – A, by turning first into the position OR′ and then back through R′OP′, equal to – A.



Hence, since the angle which OP describes from OR is always equal to the angle which OP′ describes from OR′ in the opposite direction, we have M′P′ always equal to MP in magnitude. Also P and P′ must always be both on the same side of ROR′, so that MP and M′P′ have the same sign.

$$\therefore \frac{MP}{OP} \text{ is always equal to } \frac{M'P'}{OP'},$$

i.e., sin A = sin (180° – A).

(iii.) Again, OM and OM′ are clearly always equal in magnitude, and on whichever side of QOQ′ the point P lies, the point P′ will lie on the other. Hence, OM and OM′ are always of opposite sign.

$$\therefore \frac{OM}{OP} = -\frac{OM'}{OP'},$$

i.e., cos A = – cos (180° – A).

21. In the same way, the student can easily prove for himself such formulæ as

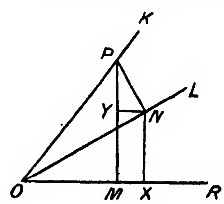
sin A = – cos (90° + A).
cos A = sin (90° + A).
sin A = – sin (180° + A).

22. Trigonometrical Ratios of Compound Angles. The "A, B" Formulæ. To prove that

sin (A + B) = sin A . cos B + cos A . sin B

and

cos (A + B) = cos A . cos B – sin A . sin B.



Let ROL be the angle A, and LOK the angle B. Then ROK is the angle (A + B). In OK, one of the arms of this angle, take any point P, and draw PM, PN ⊥ to OR, OL. Draw NX, NY ⊥ to OR, PM. Then, since ∠s PMO, PNO are right ∠s, ∴ a ⊙ on OP as diameter will pass through M and N (*Prop.* 39, *Cor.* 1). ∴ ∠s MPN, MON are in the same segment, and therefore are equal (*Prop.* 40). Hence ∠MPN = ∠A. Then,

$$\sin (A + B) = \frac{MP}{OP} = \frac{XN + YP}{OP} = \frac{XN}{OP} + \frac{YP}{OP}$$
$$= \frac{XN}{ON} \cdot \frac{ON}{OP} + \frac{YP}{PN} \cdot \frac{PN}{OP} \text{ (Art. 73, page 546)}$$
= sin ROL . cos LOK + cos MPN LOK
= sin A . cos B + cos A . sin B.

Again,

$$\cos (A + B) = \frac{OM}{OP} = \frac{OX - YN}{OP} = \frac{OX}{OP} - \frac{YN}{OP}$$
$$\frac{OX}{ON} \cdot \frac{ON}{OP} - \frac{YN}{PN} \cdot \frac{PN}{OP}$$
cos ROL . cos LOK – sin MPN . sin LOK
cos A . cos B – sin A . sin B.

Continued

MAKING FELT HATS

The Process of Manufacture. "Planking" and "Proofing." How the Shape is Blocked. Pressing and Finishing

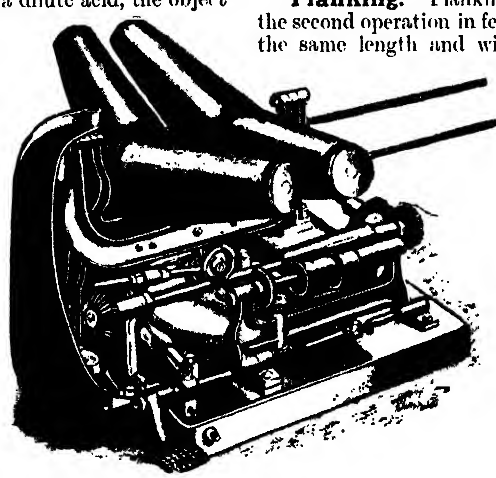
MEN'S HATS continued from page 6042

HUNDREDS of machines have been invented for the manufacture of felt hats, the end in view being to obtain the best machine possible for converting the wool into a good felt hat by the aid of heat, moisture, and friction.

As nearly the whole process of their manufacture is by machinery, we shall here consider the materials used, quantities required, the machinery employed, and so on.

Cleansing the Wool. Felt hats are made from the fur of the rabbit, beaver, nutria, etc., also from the wool of sheep and other animals. After obtaining the wool, it is necessary to give it a thorough washing to free it from the natural yolk or animal grease, or any foreign substance the wool contains, before the felting operation can be begun. It is afterwards passed through a "willow" for the purpose of opening it out.

The carbonising process may be done in a variety of ways by using a dilute acid, the object in view being to destroy all the vegetable matter which clings to the wool, for the presence of any such matter has a tendency to disfigure the appearance of the hats when finished. The wool is then passed through a carding engine, with its several rollers, wire combs and cylinders, which opens it out to an almost cobweb-like texture. It is next taken to the forming card, in front of which is placed the "forming machine" [10], and, as the wool is stripped by the comb from the doffer, it is taken up by the forming cone, which revolves upon four rolling cones. This machine has an oscillating motion from left to right, and vice versâ.

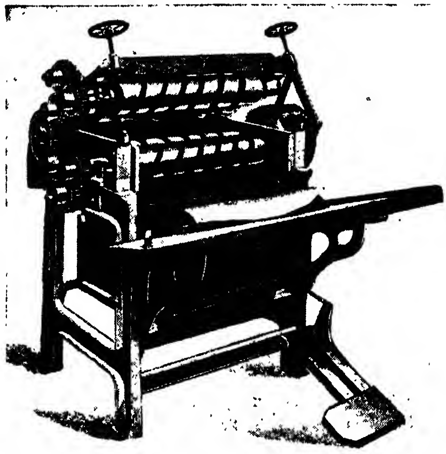


10. THE "FORMING" MACHINE

The "Forming" Process. By this means the wool coming from the doffer is crossed as it is received upon the double cone. This crossing of the wool upon the cone greatly facilitates the felting process. The reader will understand why this is if he refer to the articles on fibres on page 1995 of this work, and notice the structure of the wool fibre, the serrated ends, and the scales overlapping each other, which become interlocked in the operation of felting. When sufficient wool has been delivered upon the double cone, it is cut in two by the insertion of a pair of light shears in a recess which runs round the larger diameter. The forming is conducted by women, whose sensitiveness of touch enables them to determine when a sufficient weight of wool has been delivered on the cone [13]. After leaving the forming department, they are passed on to the hardener. There are two different methods of doing this, called "cup and cone" and "flat" hardening. The "cup and cone" hardener is a machine possessing a slow rotary movement. The wool "forms" are placed on a perforated copper cone, heated by steam: between each form is placed a cone-shaped cloth, to prevent the forms adhering to each other; the cup is then placed upon the cone, and its quick reciprocating movement gives the first operation of felting. The "flat" hardener performs precisely the same function as the "cup and cone" hardener; but in this case the felting is performed by friction between two plates [12].

"Planking." Planking—the next process—is the second operation in felting; the "forms" are the same length and width as when they left the former—14 in. by 21 in., but the soft wool-like appearance they possess has been changed to a cloth-like texture by the first felting process—that of hardening. In the planking department, "batteries" are arranged to accommodate from four to six men, the planks being about 30 in. by 40 in., in the centre of which is a large kettle filled with water, and heated by steam or fire to boiling point. Then the planker takes three or four of the forms, rolls them in a cloth, dips them in the boiling water, and rolls them on the plank to assist the shrinking operation; afterwards taking them from the cloth, to change their position before again repeating the same operation, to keep them in shape and prevent adhesion to each other. They are then taken to the "settler," who rolls the forms in a cloth and places them between the four rollers of the "settling" machine, the rings of which run in a transverse direction, the rings on the front rollers running from right to left, those on the back ones vice versâ [11].

The hat "forms" are felted up by this machine 4 in. or more if required. They are then placed in the "bumpers," which machine contains a



11. THE "SETTLING" MACHINE

pair of large blocks of oak, in the pit of which you place the hat "forms," or "hoods," where they are pounded and milled up to the required size. The finishing touches in this department, so far as machinery is concerned, are given on the "stumping" machine, which is somewhat like the "settling" machine in construction.

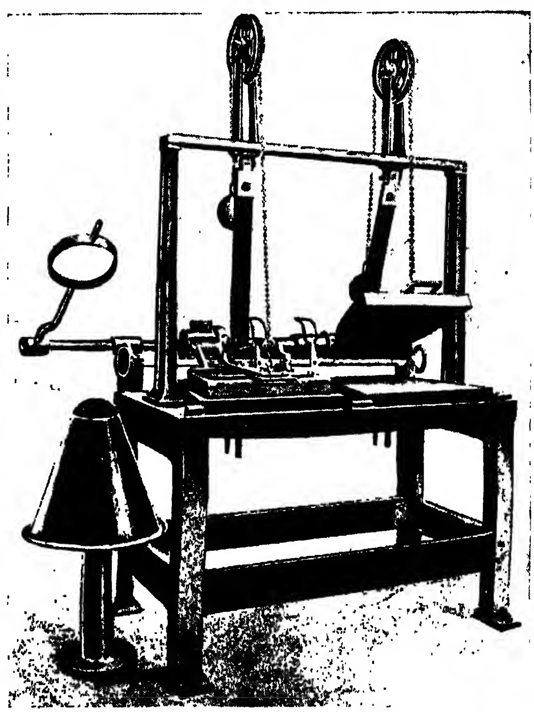
They are now given the finishing touches by hand at the battery, after which they are put into hot water and washed to free them from the sulphuric acid, used in planking to assist the process of felting. Now they are placed on a wooden cone-shaped block to free them from the marks that have been caused by doubling them in planking. They are then placed in the stove to dry. We have now reduced the hat from 14 in. by 21 in. to 9¾ in. by 15¾ in. The best bodies are produced by the subtlest of all machines—the human hand. No machine yet contrived for body-making can equal the fine machinery of the human fingers.

Stiffening the Shape. The next process is that of "proofing," or "stiffening," so that the hat will retain its shape, and become impervious to rain. For this purpose a double-jacketed pan is required, to dissolve the necessary ingredients, heated by steam, in which place 14 lb. of resin, 6½ lb. of borax, 60 lb. of button shellac, and 20 qt. of water. Dissolve the resin and borax in the water before entering the shellac, and after the whole mass has dissolved shut off the steam and allow it to cool down a little; then add water until it is the strength required for the purpose of stiffening the hats. Two large mugs, or troughs, are now required, to be filled with proof of different strengths—the stronger for the brims, and the weaker for the crowns.

The hat bodies are still cone-shaped, and, to start proofing, take hold of the tip or crown with the left hand, immerse about 4 in. in the strongest proof, place it on the bench, and with a piece of wood about 6 in. square held in the right hand draw off the superfluous proof, then croze it, and repeat the operation. Now allow it to set while a few more brims are done. The hats are then dipped bodily into the weaker solution for the crowns, the "draw-board" being used to draw off the excess of proof. Then allow them to drain and set, after which they are placed in an iron steam-chest, containing cone-shaped stands. Put a dozen hats on each stand, cover with a cloth, close the chest, and turn on the steam, which must not be below 30 lb. pressure to the square inch. Allow them to remain 40 minutes, then shut off steam, and spread bodies to cool. Now put them in a stove heated to 120° F., where they remain three hours. Again steam for another 40 minutes at 30 lb. pressure to drive the proof to the interior of the body, so that the surface of the hat will be free from all foreign matter. After taking them from the steam-chest, allow them to cool. Take a stiff brush and brush the hats well, inside and out. Up to this time the hat body is yet of a conical shape; forming, hardening, planking, and proofing have followed each other in turn.

The hat is now taken to the "blocker," and by him the cone-shaped body is pulled out round the edge to develop the brim, and the upper part is widened out to form the tip and side crown.

Next fill a large tub with water, bring it to the boiling point; then dissolve 6 oz. bichromate of potassium, and 6 oz. of copper sulphate. After dissolving these in boiling water, put in 15 dozen hat bodies, keeping them on the move for 30 minutes, afterwards passing them through clean water. The process described is termed



12. THE "HARDENER"

"mordanting," which prepares the hat to receive the necessary colouring matter. By the time "mordanting" is finished the vat or dye-kettle should be ready to receive the hats. Take 36 lb. logwood, place it in a coarse bag, swing it in the dye-kettle, and allow it to boil until the dyeing material is extracted from it; then take it out and put into the vat $1\frac{1}{2}$ lb. verdigris and $1\frac{1}{2}$ lb. iron sulphate. This may be improved by the addition of 2 lb. indigo extract. See that all the materials are dissolved before putting in the hats. After putting in the goods, keep the solution near the boiling point for 90 minutes; by that time the hats should be of a good black. Then take them out of the vat, providing the necessary depth of colour has been got, and place them in a tub of cold water, and allow them to remain some time before washing them in warm water.

The hat is now returned to the blocker—a man working at a battery similar to that described in "planking"—who is provided with wooden blocks, the size and shape the hats are required. He softens the body in boiling water, then pulls it on the block and slips a cord over it to keep in position the part intended for the crown. He then softens the brim part, takes hold of the edge between fingers and thumb, working round the hat, and following with left hand flat on the brim until it is the required shape. He then dips it in cold water, takes it off the block, and allows it to drain before placing it in the stove to dry. When dry, brush it well with a stiff brush. The hats are now taken to the "presser," a man provided with iron moulds or dishes. He places the correct size and shape in a hydraulic press, puts the hat in a steam or gas oven to soften, then places it in the "dish," closes the press, and turns on the pressure of 400 lb. to the square inch. The presses are provided with indiarubber bags containing the pressure, so that it may be evenly distributed over the whole surface of the hat.

13. PUTTING THE WOOL ON THE CONE

14. HYDRAULIC CURLING MACHINE

The Finishing Process. The "finisher" then takes the hat in hand, and on a quickly-revolving lathe smoothes its surface with glass-paper, afterwards polishing with tallow, dissolved by a gas heater and applied with a velure.

The rough edge is then cut from the brim by the rounding machine. Up to this time the hat brim is perfectly flat, but is now taken in hand by the curler, and placed on a steam baker, so that the brim only is softened, then put on a "split" frame, which is placed in the hydraulic curling machine [**14**]. After closing, the pressure is turned on from the accumulator, entering an indiarubber bag, by which it is distributed over the surface of the brim at the rate of 400 lb. to the square inch. The frames are made in all the shapes and sizes required, and being made in sections, they can be taken from the brim without altering the shape or breaking the curl. A hot iron is now run over the edge so that it will retain its shape; then cut the rough edges from the curl until it attains its proper dimensions.

It is next sent to the "trimming" department, where the brim is wired, the banding tied in a bow and fastened to the band of the hat, the binding sewn round the curl, and the leather and lining stitched and fastened in their respective positions by women, after which they are velured.

For illustrations **10**, **11** and **12**, we are indebted to the courtesy of Messrs. Turner, Atherton & Co., Ltd., Denton.

DEFECTIVE VERBS

THOSE verbs that want some tenses or persons are called "defective." They are:

Angere (poet.), to grieve
Ind. Pres. (third pers. sing.).—*Ange.*

Ardire, to dare
The forms that might be confounded with the corresponding forms of the verb *àrdere,* to burn, as *ardiamo, ardente,* etc., are not used.

Arrogere, to add
Of this verb only the form *arroge* (imperat.) is now used.

Atterrire, to terrify
The forms that might be confounded with the corresponding forms of *atterrare,* to cast to the earth, as *atterriamo, atterriate,* are not used. This verb has no present participle.

Calére (impers.), to matter
Ind. Pres. (third pers. sing.).—*Cale.*
Imperf.—Caleva.
Past Def.—Calse.
Subj. Pres.—Càglia.
Imperf.—Calesse.
Gerund—Calendo.
Past Part.—Caluto.
Of this verb only the third persons of the present, imperfect, and past def. are sometimes used.

Capére, to hold [see page 4504]
Ind. Pres. (third pers. sing.).—*Cape;* plur., *càpono.*

Colere, to worship
Ind. Pres.—Coli, cole (poet.).
Past Part.—Colto and *culto.*

Gire (poet.), to go
Ind. Pres.—Gite.
Imperf.—Giva and *gìa.*
Past Def.—Gisti, gì, gimmo, giste, gìrono.
Subj. Imperf.—Gissi.
Future—Girò.
Condit.—Girei.
Past Part.—Gito.

Ire (poet.), to go
Ind Pres. and *Imperat.* (second pers. plur.).—*Ite.*
Imperf.—Ivo, ivi, iva; third pers. plur., *ìvano.*
Past Def.—Isti, ìrono.
Past Part.—Ito (gone).
The compound tenses are formed with *èssere*—as, *Se n'è ito,* He has gone.

Licere (poet.), to be allowed
Ind. Pres.—Lice (*lece*).
Imperf.—Liceva, licèvano.
Subj. Imperf.—Licesse, licèssero.
Past Part.—(*Lìcito*) *lècito.*

Lucere, to shine
Ind. Pres.—Luce, lùcono.
Imperf.—Luceva, lucèvano.
Pres. Part.—Lucente.

Molcere (poet.) to mollify, to mitigate
Ind. Pres.—Molci, molce.
Imperf.—Molceva.
Subj. Imperf.—Molcessi.
Gerund—Molcendo.
This verb has no past participle.

Olire (poet.), to smell sweet
Ind. Pres.—Olisci, olisce.
Imperf.—Oliva.
Pres. Part.—Olente.

Redire, to go back
Imperf.—Rediva, redivano.
Past Part.—Redirono.

Riedere, to go back
Ind. Pres.—Riedo, riedi, riede, rièdono.
Subj. Pres.—Rieda, rièdano.
Subj. Imperf.—Riedesse, riedèssero.

Sèrpere, to wind about
Ind. Pres. (third pers. sing.).—*Serpe.*
Instead of *sèrpere,* the verb *serpeggiare* is generally used.

Solére, to be accustomed
Ind. Pres.—Soglio, suoli, etc.
Subj. Pres.—Sòglia.
Past Part.—Solito [see page 4504].

Sùggere (poet.), to suck
This verb has no past part. Instead of *sùggere,* in colloquial language, *succhiare* and *succiare* are used.

Tàngere (poet.), to touch
Ind. Pres. (third pers. sing.).—*Tange.*
Subj. Pres.—Tanga.
Pres. Part.—Tangente

Urgere (impers.), to urge
Ind. Pres.—Urge, ùrgono.
Imperf.—Urgeva, urgèvano.
Subj. Imperf.—Urgesse, urgèssero.
Future.—Urgerà, urgeranno.
Condit.—Urgerebbe, urgerèbbero.
Pres. Part.—Urgente.
Gerund—Urgendo.
In familiar language the verb *èssere* followed by the pres. part. *urgente* is used.

Vertere, to be question of
Ind. Pres.—Verte, vèrtono.
Imperf.—Verteva, vertèvano.
Pres. Part.—Vertente.
Gerund—Vertendo.

Vigere, to be extant
Ind. Pres.—Vige, vìgono.
Imperf.—Vigeva, vigèvano.
Future—Vigerà, vigeranno.
Subj. Imperf.—Vigesse, vigèssero.
Pres. Part.—Vigente.
Gerund—Vigendo.
All the forms of this verb belong to the official language.

PROPOSITIONS

Attributive and Appositive Propositions. Attributive and appositive propositions are constructed with the relative pronouns *che, il quale, la quale,* etc., and they generally require the indicative, as: *Le accludo la lèttera che ho ricevuta,* I enclose you the letter that I have received.

But when the attributive proposition has the meaning of a final or consecutive proposition, the subjunctive must be used, as: *Si era comprato un ombrello, che le servisse* (*affinchè le servisse; tale che le servisse*) *anche da parasole*, She had bought an umbrella which she could also use as a sunshade.

Temporal Propositions. Temporal propositions are constructed with the conjunctions *quando, allorchè, appena, finchè, qualora*, etc., and they require the indicative if a fact is expressed as real or past; and the subjunctive (or the future of the indicative), if they refer to a possible or future fact, as: *Quando si è commesso un errore, bisogna pensare a rimediarvi*, When one has made a mistake, one must think of how to correct it; *Appena sentì il campanello, si precipitò giù ad aprire*, As soon as she heard the bell, she rushed down to open [the door]; *Aspetterò finchè fàccia* (or *farà*) *giorno*, I shall wait until it is day; *Capii tutto prima che aprisse bocca*, I understood everything before he opened his mouth.

Instead of the conjunction *quando*, we sometimes use the past participle followed by *che*, and the auxiliary verb, as: *Giunto che fui* (*quando giunsi*) *domandai di lui*, When I arrived I asked for him; *Finito che ebbe di mangiare* (*quando finì* or *ebbe finito*) *andò a fare una passeggiata in giardino*, When he had finished eating, he went for a walk in the garden.

These propositions are also constructed with the gerund or the infinitive preceded by prepositions, as: *Lo incontrammo andando* (*mentre andavamo*) *a teatro*, We met him while we were going to the theatre; *Nel fare una cosa* (*mentre fàccio*) *dimèntico l'altra*, In doing one thing I forget the other; *Detto ciò* (*avendo detto ciò; dopo che ebbe detto ciò*) *andò via*, After he had said this he went away.

Note. In Italian the gerund is never preceded by prepositions.

Local Propositions. Local propositions are constructed with adverbs of place, *dove, dovunque*, etc. They require the indicative, and, if the meaning is indefinite, also the subjunctive, as: *Vado dove mi pare e piace*, I am going where I like; *Dovunque batte* (*batta*) *cuor di popolo, i pòsteri leggeranno Garibaldi* (*Bovio*), Wherever the heart of a people beats, posterity will read of Garibaldi; *Dovunque il guardo io giro* (*giri*), *Immenso Dio ti vedo*, Wherever I turn my glance, I see Thee, Almighty God!

Causal Propositions. Causal propositions are constructed with the conjunctions *perchè, giacchè*, etc., and they require the indicative, and sometimes the conditional, as: *Non scherzare col fuoco, perchè altrimenti ne resterai* (or *ne resteresti*) *bruciato*, Do not play with the fire, because otherwise you will be burned.

The subjunctive is used when the subordinate proposition depends upon a negative, as: *Lo fàccio, non perchè ne àbbia voglia, ma perchè sono costretto a farlo*, I do it, not because I wish, but because I am compelled.

When a causal proposition has the same subject as the principal one, and the verb is in a past tense, the infinitive or the gerund may be used, as: *Per volèr troppo* (*perchè voleva troppo*) *non ebbe nulla*, He had nothing, because he wanted too much; *Avèndolo visto così afflitto* (*perchè lo vidi*) *credetti opportuno di non dirgli niente*, Seeing him so afflicted, I thought it wise not to tell him anything.

Final Propositions. Final propositions are constructed with the conjunctions *acciocchè, affinchè, perchè, che*, etc. The verb must always be in the subjunctive. If the verb of the principal proposition is in the present, past indefinite or future, the verb of the final proposition is in the present or past indefinite; if the verb of the principal proposition is in the imperfect or conditional the verb of the final proposition is in the imperfect or pluperfect. Examples: *Lo dico a te, perchè tu lo dica a lui*, I tell it to you, so that you may tell him; *Il ragazzo fingeva di dormire, affinchè la madre non lo sgridasse*, The boy pretended to be asleep in order that his mother might not scold him.

When the principal and the final propositions have the same subject, the aim is expressed by the infinitive preceded by *per*; so if we turn the final proposition of the above example into the passive, we must say: *Fingeva di dormire per non èssere sgridato da sua madre.*

Comparative Propositions. Comparative propositions are constructed with *che non*, or with *di quello che*, and they may be used with either the indicative or the subjunctive: as, *Ho guadagnato più che non sperassi* (or *di quello che sperassi*), I have gained more than I hoped; *La nèbbia divenne più spessa che non era prima* (or *che non fosse prima; di quello che era*, or *fosse prima*), The fog became thicker than it was before.

Note. *Che non* is used only before a verb, as in the above examples; in any other case the *non* is omitted: *Uccide più la gola che la spada*, Gluttony kills more than the sword; *Egli ha speso più parole che danaro*, He has spent more words than money.

After the relative superlative, the subjunctive is used: *È la più bella donna che io àbbia mai veduta*, She is the most beautiful woman I have ever seen; *Questo è il più gran ponte che sia mai stato costruito*, This is the largest bridge that was ever built.

Conditional Propositions. Conditional propositions are constructed with *se, purchè, caso mai, qualora, quando, dove*, etc. With the conjunction *se*, the verb is in the indicative if the condition is assumed to be real; and in the subjunctive if the condition is only imaginary: *Se avete volontà di lavorare, vi prenderò nel mio ufficio*, If you are willing to work, I will take you into my office; *Se lo sapessi, ve lo direi*, If I knew it, I would tell you.

With other conjunctions and adverbs, the subjunctive is generally used: *Quando tutto vada bene, non avrò guadagnato nulla*, If everything goes well, I shall have earned nothing; *Noi non vogliamo fargli del male, purchè àbbia giudìzio*, We do not wish to do him any harm, provided he is (be) reasonable.

Conditional propositions may also be constructed with the infinitive, preceded by prepositions, with the gerund, and the past participle: *A dire il vero* (*se vogliamo dire il vero*) *non ci aspettavamo tanto successo*, To tell the truth, we did not expect so much success; *Vedèndolo* (*se lo vedi*), *digli che l'aspetto*, If you see him, tell him that I am waiting for him; *È una spècie di mùsica che, eseguita bene* (*se fosse eseguita bene*), *potrebbe passare*, It is a kind of music that, if well executed, might pass.

Concessive Propositions. Concessive propositions are constructed with *benchè, sebbene, quantunque, non ostante che, per quanto, se anche, quando anche, con tutto che*, etc.

The verb is in the subjunctive: *Egli ha sempre qualche cosa da dire a tutti, quantunque nessuno gli voglia dare ascolto*, He always has something to say to everyone, although no one wishes to listen to him: *Quando anche dovessi pèrdere tutto quello che ho, non abbandonerei l'impresa*, Even if I had to lose all I possess, I would not give up my enterprise.

Consecutive Propositions. Consecutive propositions are constructed with *che, a segno che,*

tanto che, di maniera che, di guisa che, etc. The verb is in the indicative if the consequence is expressed as a fact, and in the subjunctive if the consequence is only considered as possible: *Ha insistito tanto, che ha ottenuto quello che voleva,* He has insisted so much that he has obtained what he wished: *Disponete le cose in modo che vi sia un certo òrdine,* Arrange the things in such a way that there may be a certain order.

Consecutive propositions may also be constructed with the infinitive preceded by the preposition *da: Gli mìsero tanta paura addosso, da farlo stare rinchiuso in casa per un mese intero,* They frightened him so much, that he remained indoors for a whole month.

NOTE. With *troppo,* the preposition *per* is generally used: *Egli è di cuore troppo nòbile, per scéndere a una tale bassezza,* He has too good a heart to descend to any such meanness.

KEY TO EXERCISE LV.

1. I heard someone knocking; I opened [the door], but I did not see anyone. 2. "May God bless you," said the poor mother. 3. When Mr. N. returns to the office, I will tell him that you called. 4. If you had told me the truth, I would have forgiven you. 5. We offered him five hundred francs, but he did not wish to accept. 6. If you do not mind going up to the fourth floor, I will show you the violin of which I spoke to you the other day. 7. Tell your cousin to come to me to-morrow, because I want to speak to him. 8. You cannot believe how much that unhappy man has suffered! 9. This bridge was constructed four hundred years ago.

Participial Adjectives

PASSIVE VOICE

The passive voice in Esperanto is formed by the addition of the participial endings *ata* (present), *ita* (past), and *ota* (future) to transitive verbs. Intransitive verbs are incapable of receiving these.

The rules for the formation of the compound tenses of the passive voice are exactly the same as those for the active voice. When used predicatively the participles accord with the noun or pronoun in number only. When used to qualify, they agree in number and case.

Nine compound tenses may be obtained by combining the three passive participles with the three tenses of the auxiliary verb *esti.* (These three participles may also be combined with *esti, estus* and *estu.*)

Mi estas lavata, I am (being) washed; *mi estas lavita,* I have been washed (lit. I am having been washed); *mi estas lavota,* I am about to be washed.

Mi estis lavata, I was (being) washed; *mi estis lavita,* I had been washed (lit. I was having been washed); *mi estis lavota,* I was about to be washed.

Mi estos lavata, I shall be (being) washed; *mi estos lavita,* I shall have been washed (lit. I shall be having been washed; *mi estos lavota,* I shall be about to be washed.

Mi estus lavata, I should be (being) washed; *mi estus lavita,* I should have been washed (lit. I should be having been washed); *mi estus lavota,* I should be about to be washed.

The present, past, and future infinitives are: *Esti lavata,* to be (being) washed; *esti lavita,* to have been washed; *esti lavota,* to be about to be washed.

The complement of the passive voice is introduced by *de* (by) to indicate the agent, and by *per* (by means of, with) to indicate the instrument:

Mi estis lavata de mia patrino per sapo, I was (being) washed *by* my mother *with* soap.

The distinction of these prepositions is sometimes a little obscure, but if it be remembered that *de* must be used to introduce the performer of the action, and that *per* indicates the means or method used, a little forethought will determine which preposition must be used.

Example: *Mi estis kovrita de la knaboj per koto,* I was covered with mud by the boys. *La leteroj estis skribitaj de ŝi per plumo,* The letters were written by her with a pen.

The simple tenses will show more clearly the *agent* and the *instrument:*

The boys covered me with (*per*) mud; She wrote the letter with (*per*) a pen.

Suffixes

AD denotes the continuation or repetition of an action.

Example: *Promeni,* to walk; *promenadi,* to walk about; *instrui,* to instruct; *instruado,* instruction; *pafo,* a shot; *pafado,* a fusillade.

ID denotes a child or descendant, also young of animals.

Example: *Princo,* prince; *princido,* prince's son; *princidino,* prince's daughter; *koko,* cock; *kokido,* chicken.

IST denotes a person following the occupation indicated by the root-word.

Example: *Paroli,* to speak; *parolisto,* a professional speaker, a lecturer, an orator.

Note the customary habit here. An occasional speaker would be indicated by the use of the participles *parolanto, parolinto,* or *parolonto,* according to whether the time referred to be present, past or future.

ESTR denotes a chief or leader (not a master).

Example: *Ŝipo,* ship; *ŝipestro,* captain; *klubo,* club; *klubestro,* leader of a club.

Master of an hotel is *hotelmastro,* not *hotelestro.*

Vocabulary

anas', duck
anser', goose
art', art
benk', bench
buĉ', butcher (v. t.)
ĉarpent', carpentry
ĉerp', draw, extract
denunc', denounce
esplor', explore
fleg', nurse, take care of
forĝ', forge (v.t.)
juĝ', judge (v.t.)
komerc', commerce, trade
komiz', clerk
kondamn', condemn
kort', courtyard
kugl', bullet
kurac', treat, cure
paŝt', pasture, feed cattle
pot', pot (earthen)
predik', preach
rab', rob
rajt', right
rekomend', recommend
rigl', bolt (v. t.)
rimed', remedy, means
ring', ring (subst.)
sang', blood
sap', soap
sat', satiated
seĝ', seat, chair
serv', serve
sever', severe
situaci', situation
skulpt', sculpture (v.t.)
sonĝ', dream
spec', kind, sort
stel', star
suker', sugar
suspekt', suspect (v. t.)
ŝaŭm', foam
ŝpin', spin (threads)
ŝtat', state (country)
teks', weave
tent', tempt
traduk', translate
ver', true
verd', green
verk', work (literary)
vers', verse

Exercise XVII.

1. Servistino, kokidaro, kuracisto, rabistestro, ŝpinisto, tentado, ĉarpentisto, buĉisto, servado, flegistino, anasido, esploristo, paŝtisto, artistino, hundido, ĉevalidino, skulptisto, kuracistino, predikado. La rabistaro estis kondamnita de la juĝisto. Verkisto verkas librojn kaj skribisto simple transskribas paperojn. Ili aŭdis la pafadon kaj la kuglojn flugantajn. La komizo estas konfesinta, ke li prenis la ringon, kaj nun li estas juĝota de la juĝisto. Kiam la ŝpinistino estis malsana, la kuracisto vizitis ŝin, sed, post iom da tempo ŝi mortis. La fero estis forĝata de la forĝisto.

2. This is the remedy which is recommended by the sailor. The door was locked against the robber. The suspected person has been denounced by the clerk, and he will certainly be severely punished. These verses were extracted by the translator (professional) from the works of the best writers. Some stood on chairs and benches in order to see better, but the orator could not be heard. It is not possible to see a flying bullet. He was dreaming about his far away home, which, possibly, he would (will) never see more. Nobody has the right to judge. Remember that he who judges will be judged. Now it is night, and we can see the shining stars above the foaming sea. Friends seldom seen are friends forgotten.

Note. The participles to be used in translating.

Participial Nouns and Adverbs

Active Voice

In the two foregoing lessons the formation of adjectival participles, active and passive, has been explained. There remain, however, two other participial forms, obtained by substituting *o* or *e* for the final *a*, by which change we get substantives and adverbs respectively. Examples:

Lavanto, the person or thing that is performing the action expressed in the root.

Lavinto, the person or thing that *has performed* the action expressed in the root.

Lavonto, the person or thing which is *about to perform* the action expressed in the root.

Lavante, while washing.

Lavinte, after having washed.

Lavonte, when about to wash.

The term adverb in Esperanto has a much wider application than in English. Not only roots, but their derivatives can be made into adverbs by the addition of the adverbial termination *e*. Thus, a phrase may be represented by one word, as. *elirinte*, having gone out.

The adverbial form, being exceedingly convenient and expressive, is much used in Esperanto, but its functions must be carefully noted, as the adverbs so constructed may only relate to the subject of the sentence in which they actually appear.

Example: *Lavinte sin, la knaboj iris al la teatro*, Having washed themselves, the boys went to the theatre; *Estante saĝaj, ili tuj konsentis*, Being wise, they at once consented.

But when, however, such an adverbial phrase in English does not relate to the subject of the sentence, then the meaning must be expressed in Esperanto in a different manner. The sentence: "I having been wounded, the doctor visited me," cannot be translated by *Vundite, la kuracisto min vizitis*, because here the subject of the sentence is *la kuracisto*, by which it would appear that *la kuracisto* was wounded. Such a sentence must be translated *Ĉar (aŭ kiam) mi estis vundita la kuracisto vizitis min*, "As (*or* when) I had been wounded, the doctor visited me."

In English sentences the word *after* is very often placed before the gerund: "After eating, I slept well." The Esperanto past participle, however, fully expresses time, and consequently *after* must not be translated: say *Manĝinte, mi bone dormis.*

The word "without" before the participles is rendered by *ne*.

Ne pensante, mi sendis la leteron, Without thinking, I sent the letter; *Ne pentinte, li mortis*, Without having repented, he died.

Extraneous Words

There exist, in use throughout the world, a large number of words, principally scientific and technical, which, derived from a common source, have already become international. The fundamental vocabulary of Esperanto need not, therefore, be swollen by their inclusion, inasmuch as a very slight phonetic and orthographic adjustment turns them into suitable Esperanto words. But since Esperanto is primarily intended for those who have not acquired foreign languages, and, therefore, are not in a position to judge what words are international, nor to discriminate between concurrent cognate words, the best dictionaries are gradually including these words in their approved forms.

Such words are:

telefono, telephone
markonigram-e, by marconigram
omnibus-i, to go by omnibus
helium-o, helium
teleskop-o, telescope
aŭtomobil-e, by motor-car
telefon-inda, worth telephoning
mikrofon-a, microphonic

Vocabulary

acid', acid, sour
anim', soul
atest', attest, affirm
azen', ass, donkey
buton', button
dec', becoming, decent
desegn', design, draw
difin', define
drap', cloth, woollen goods
ekscit', excite
embaras', embarass
fend', split, rive
fleks', bend (v.t.)
fundament', foundation
hered', inherit
kadr', frame
komod', chest of drawers
kompost', compose (printing)
konscienc', conscience
lang', tongue
lign', wood (substance)
mason', build with stone
maŝin', machine
mebl', piece of furniture
migr', migrate
ornam', adorn
ost', bone
pik', prick, sting
plad', dish, plate
plat', flat
porcelan', porcelain
prefer', prefer
prepar', prepare
prezent', present (v. t.)
privat', private
prudent', reasonable
rand', edge
reg', rule, govern
rilat', relate to
rost', roast (v.t.)
sag', arrow
sankt', sacred
senc', sense
sid', sit
signif', signify, mean
societ', society
sonor', give out a sound (as bell)
sort', fate, end, lot
spert', expert
sprit', wit
stat', state, condition
ŝpar', spare save

Exercise XVIII.

I shot an arrow into the air, but having lost it, I conclude that I am not an expert. This set of exercises, after having been printed by a linotype machine, is now ready. In painting that picture, and drawing this design, he attracted much attention. You have spoken (a piece of) nonsense. Having admired the beauty of the furniture and ornaments, they presented a silver coin to the doorkeeper. Steel is flexible, but iron is not flexible.

All the emigrants wasted their money, and having arrived in a pitiable state, they excitedly complained about their misfortune. That singer is worth neither hearing nor seeing. The writer of this letter is the first witness. After finishing his meal, he rang. Here is the roast beef. Do you prefer veal, mutton, or lamb, sir? That sort of wittiness signifies nothing. Take away this sour stuff. When the mason was about to die, his inheritors came to receive his blessing and divide his fortune. Their rapidity afterwards pricked their consciences. It is better to die poor than unloved. The proposal was carefully prepared, and afterwards presented to the society-membership. You would be much embarrassed if you knew how imprudent he is. The tree was split by the woodman with an axe. I can conscientiously affirm that.

Participial Nouns and Adverbs

PASSIVE VOICE

The participles in the passive voice may, in the same way as those in the active voice, take the substantival and adverbial forms:

SUBSTANTIVES:

Lavato, the person or thing *being washed*.

Lavito, the person or thing (*having been*) *washed*.

Lavoto, the person or thing *about to be washed*.

ADVERBS:

Lavate, in being washed.

Lavite, having been washed.

Lavote, being about to be washed.

These adverbial participles must always relate to the subject of the sentence in which they appear.

Examples: *Vundite, li alvokis helpon*, On being wounded, he called for help; *Kaŝite, la ringo ne povas esti trovata*, Having been hidden, the ring cannot be found; *Batote de l'patro, la infano ploris*, About to be beaten by the father, the child cried.

The remarks on the construction and general use of participial adverbs in the active voice apply equally to the adverbs in the passive voice.

KEY TO EXERCISE XVI.

Forte blovas ekstere. Kiam li estis faldinta la fakturon kaj skribinta sian adreson sur la koverton, li donis ambaŭ al mi. Kia stranga vetero estas hodiaŭ! Jen neĝas, jen hajlas, jen fulmas kaj tondras. Oni neniam povas esti certa pri ĝi. Tiu ĉi ĉeno havas tridek sep ĉenerojn, ĉiu el oro. Li ne ŝatas la frostan veteron, kaj estas ĉiam feliĉa kiam ekdegelas. Li estis defendanta. Ili estas melkontaj. Mi estos ŝanĝinta. Ni ne estas pretendantaj. Vi estos savinta (aŭ savintaj), Li estis defendonta. Mi estis ofendinta. Ili estos ripozintaj. Mi estas ordoninta. Ŝi estas spiranta. Tiuj kiuj estas mortontaj vin salutas. Ili estas ofendintaj min. Ili estis tuj savontaj ŝin. La vilaĝanino estis melkinta siajn bovinojn. La policano estas trankvile dormanta. Mi sentas min kvazaŭ mi esti mortonta. Se mi havus ombrelon, mi estus povinta (aŭ, povus) viziti vin malgraŭ la pluvo. Polvero estis falinta en ŝian okulon. Ŝi estis tremanta, kaj apenaŭ povis spiri. Se ili scius la regularon, ili ne estus farintaj (aŭ, farus) dufoje la saman eraron. La blindulo estis falonta en la flamojn, kiam tiu kuraĝulo savis lin.

GREEK

Continued from page 6240

By G. K. Hibbert, M.A.

SECTION I.—PREPOSITIONS

The prepositions in Greek, as in English, were originally adverbs, and this adverbial use is clearly seen when prepositions appear in composition with verbs—*e.g.*, *κατα-βαίνω*, I go down. The Greek prepositions govern various cases, as will be seen from the following scheme:

I. GENITIVE ONLY: *ἀντί*, *ἀπό*, *ἐκ* (*ἐξ* before a vowel), and *πρό*.

ἀντί, instead of, for the sake of—as: *ἀντί σου*, instead of you, *or* for your sake. In composition with a verb it means *against* (*ἀντειπεῖν*, to speak against); *instead* (*ἀντιλαμβάνειν*, to receive instead); *in return* (*ἀντιδίδωμι*, I give in return).

ἀπό (Latin *a, ab*; English *off*), from, away from—as: *ἀπὸ τούτου τοῦ χρόνου*, from this time; *ἀφ' ἵππου μάχεσθαι*, to fight from a horse—*i.e.*, on horseback. In composition with a verb it means *from, away, in return*—as: *ἀποστέλλω*, send away ("apostle").

ἐκ (Latin *e, ex*), from, out of—as: *ἐκ ταύτης τῆς πόλεως φεύγει*, He is banished from this city; *ἐκ τοῦ νῦν*, from the present (time); *Ὄναρ ἐκ Διός ἐστιν*, The dream is from Zeus. In composition, it means *out, away*—as: *ἐκπίπτω*, I am driven out (lit. I fall out, used as the passive of *ἐκβάλλω*, I expel).

πρό (Latin *pro*), before, on behalf of—as: *πρὸ τοῦ νεώ*, before the temple; *πρὸ τῆς μάχης*, before the battle; *πρὸ πατρίδος μάχεσθαι*, to fight for fatherland; *πρὸ τούτων*, in preference to this. In composition it means *before, forth*—as: *προκαλέω*, call forth.

II. DATIVE ONLY: *ἐν* and *σύν*.

ἐν (Latin *in* with ablative), in—as: *ἐν τῇ νήσῳ*, in the island; *ἐν τούτῳ*, meanwhile (understanding *τῷ χρόνῳ*); *ἐν δήμῳ λέγειν*, to speak among the people. In composition it means *in, on* (*ἔγκειμαι*, I lie on).

σύν or *ξύν* (Latin *cum*), together with, with the help of—as: *σὺν τοῖς θεοῖς*, with the help of the gods; *σὺν Ξενοφῶντι ἐπορεύετο*, He went with Xenophon. In composition it means *with, together*—as: *συμμάχομαι*, fight along with. (This preposition appears in our English words beginning with syn, sym, syl, sys, etc.).

III. ACCUSATIVE ONLY: *εἰς* or *ἐς*, into, to (Latin *in* with accusative)—as: *εἰς Ἀθήνας ἔφυγον*, They fled to Athens; *εἰς νύκτα*, till night; *εἰς ἕκατον*, up to a hundred; *χρήσιμος εἰς πόλεμον*, useful for war.

The form *ὡς* is sometimes found, but only with persons: *ὡς Κῦρον εἰσιέναι*, to go to visit Cyrus.

IV. ACCUSATIVE AND GENITIVE: *διά*, *κατά*, *ὑπέρ*.

διά, through. 1. With accusative *on account of*: *διὰ τοῦτο*, on this account; *διὰ τὴν νόσον*, on account of the disease. 2. With genitive *through*; *διὰ νυκτός*, through the night; *διὰ τῆς χώρας*, through the country; *δι' οὐδένος ποιεῖσθαι*, to value at nothing; *δι' ὀργῆς ἔχειν*, to be in anger (*ἔχειν* is often used intransitively = to be).

In composition it means *through, in different directions, mutually*—as: διαρρίπτω, throw in different directions.

κατά, down. 1. With accusative *down along, at* (of time), *according to, by* (distributively)—as: κατὰ ῥοῦν, down stream; οἱ καθ' ἡμᾶς, those at our time; κατ' ἐμέ, according to me; καθ' ἡμέραν, day by day; κατὰ τρεῖς, by threes. 2. With genitive *down from, below, against*—as: κατὰ γῆς, below ground; κατὰ τῆς πέτρας ἅλλεσθαι, to leap down from the rock; κατά τινός λέγειν, to speak against someone In composition *down, against:* καταβαίνω, go down; καταψεύδομαι, tell lies against.

ὑπέρ, over (Latin *super;* note that a rough breathing in Greek is often represented by *s* in Latin: ἕξ, sex; ἑπτά, septem; ἅλς, sal). 1. With accusative *beyond*—as: ὑπὲρ δύναμιν, beyond one's strength. 2. With genitive *above, on behalf of*—as: ὑπὲρ τῆς κεφαλῆς, over his head; μάχεσθαι ὑπέρ τινος, to fight for someone. In composition *over, exceedingly, on behalf of.* (English *hyper*, as in "hyper-critical").

V. Accusative, Genitive, and Dative: ἀμφί, ἐπί, μετά, παρά, περί, πρός, ὑπό (and very rarely ἀνά).

ἀμφί, about (Latin *amb-, both*), on two sides of. 1. With accusative *about* (time, space, number, or circumstances)—as: οἱ ἀμφὶ Πλάτωνα, those about Plato (*i.e.*, the Platonists); ἀμφί τι ἔχειν, to be busy about a thing. 2. With genitive *about* (of subject matter), rare in prose; usually περί. 3. With dative *about* (of place), *for the sake of, owing to*—as: ἀμφ' Ἑλένῃ μάχεσθαι, to fight for Helen; ἀμφὶ φόβῳ, for very fear.

ἐπί, on, upon. 1. With accusative *on to, to, towards, against*—as: προελθεῖν ἐπὶ τὸ βῆμα, to come forward on to the platform; πλεῖν ἐπὶ τοὺς Ἀθηναίους, to sail against the Athenians. Also in phrases like τὸ ἐπ' ἐμέ, as far as I am concerned; ἐπὶ τοῦτο, for this purpose; ἐπὶ τὸ πολύ, for the most part. 2. With genitive *on, towards, in the time of*—as: ἐπὶ βήματος, on a platform; ἐπὶ Σάμου πλεῖν, to sail towards Samos; ἐφ' ἡμῶν, in our time. 3. With dative *on, at, on condition of, in the power of, in addition to*—as: τὸ ἐπ' ἐμοί, so far as is in my power; ἐπὶ τούτοις, on these terms, *or*, in addition to this; μέγα φρονεῖν ἐπί τινι, to be proud of a thing.

μετά, among, with (akin to Latin *medius*). 1. With accusative *after*—as: μετὰ τὸν πόλεμον, after the war; μετὰ ταῦτα, thereafter. Also rarely (in poetry) it = into the midst of—as: μετὰ στρατόν, into the midst of the host. 2. With genitive *with, on the side of* (implying closer union than σύν)—as: μετά τινος πάσχειν, to suffer with someone; μετ' Ἀθηναίης, with the help of Athena. 3. With dative *among* (only used in poetry)—as: μετὰ κύμασι, among the waves (Homer). In composition μετά often denotes *change*—as: μεταμόρφωσις, transformation; μετανοέω, I change my mind, repent.

παρά, near, alongside. 1. With accusative *to the side of, along, during, because of, contrary to, compared with*—as: καταφυγὴ παρὰ φίλους, a flight to one's friends; παρὰ τὸν βίον ἅπαντα, during the whole of life; παρὰ τοῦτο γέγονεν, It has happened because of this; παρὰ φύσιν, contrary to nature; παρὰ πολύ, by far. 2. With genitive *from the side of, from*—as: ἄγγελος παρά τινος, a messenger from someone. 3. With dative *at the side of, near*—as: στῆναι παρά τινι, to stand by someone. In composition παρά often means *beyond, over, wrongly*—as: παρανομέω, I transgress the law.

περί, around, about. 1. With accusative *about, near* (practically the same as ἀμφί)—as: οἱ περὶ Κῦρον, Cyrus and his attendants. 2. With genitive *about, concerning* (Latin *de*), *above* (in poetry)—as: περί τινος λέγειν, to speak about someone; also the common phrase: περὶ πολλοῦ ποιεῖσθαι τί, to reckon a thing worth much. 3. With dative *around, about, by reason of* (rare in Attic prose)—as: θώρακα περὶ τοῖς στέρνοις ἔχειν, to have a breastplate round the breast; περὶ δείματι, for fear (Latin *præ*). In composition περί often denotes excess—as: περικαλλής, very beautiful; περιδείδω, I fear exceedingly (*cf.* Latin *permagnus*, exceeding great).

πρός, in front of, at, by. 1. With accusative *to, towards, against, in reference to*—as: κλαίειν πρὸς οὐρανόν, to cry to heaven; πρὸς Θεὸν ἐρίζειν, to strive against God; πρὸς ἑσπέραν, towards evening; πρὸς τὸν λόγον, in reference to the argument; and often adverbially—as: πρὸς βίαν, = βιαίως, forcibly. 2. With genitive *from* (rare), *by* (of agent), *in the eyes of*, and in oaths—as: τετιμῆσθαι πρός τινος, to have been honoured by someone; πρὸς ἀνθρώπων, in the eyes of men; πρὸς Θεῶν, by the gods (I swear); also in sentences like Οὐ πρὸς ἰατροῦ σοφοῦ θρηνεῖν, It is not the part of (*or* it is not fitting) a wise physician to wail. 3. With dative *at, near, in addition to*—as: τεῖχος πρὸς τῇ θαλάσσῃ, a wall near the sea; πρὸς τούτοις, in addition to this, furthermore.

ὑπό (Latin *sub*), under, by. 1. With accusative *to under, towards* (of time)—as: ἰέναι ὑπὸ γαῖαν, to go under the earth (*i.e.*, to die); ὑπὸ νύκτα, towards night (Latin *sub noctem*). 2. With genitive *from under, through* (causal), *by* (of agent, after passive verbs; Latin *ab*)—as: λύειν τοὺς ἵππους ὑπὸ τοῦ ζυγοῦ, to loosen the horses from under the yoke; ὑπὸ δέους, through fear; τιμᾶσθαι ὑπὸ τῶν πολιτῶν, to be honoured by the citizens; also in such phrases as: ὑπ' αὐλοῦ, to the accompaniment of the flute. 3. With dative *at, under* (place and circumstances)—as: εὕδειν ὑπὸ πέτρῃ, to sleep beneath a rock. In composition ὑπό often means *secretly*, or *slightly*, or *gradually*—as: ὑποθέω, I make a secret attack; ὑπόλευκος, somewhat white.

ἀνά, up (opposite of κατά). 1. With accusative *up, along*—as: ἀνὰ τὸν ποταμόν, up the river; ἀνὰ νύκτα, all night through. Distributively—as: Ἔστησαν ἀνὰ ἑκατόν, They stood in hundreds; ἀνὰ πεντήκοντα, by fifties. 2. With genitive, only in the phrase ἀνὰ νηὸς βαίνειν, to go on board ship (Homer). 3. With dative *on, upon* (only in poetry)—as: ἀν' ὤμῳ, upon the shoulder. In composition ἀνά denotes *up, back, repetition, strengthening*—as: ἀναχωρέω, I retreat.

In addition to the above, which are the prepositions proper, there are some adverbs used as prepositions. These cannot be compounded with verbs, and are called improper prepositions. They are: ἄνευ and ἄτερ, without; ἄχρι and μέχρι, as far as, until; μεταξύ, between; ἕνεκα,

for the sake of; πλήν, except. These all govern the genitive.

AUGMENT OF VERBS COMPOUNDED WITH PREPOSITIONS. In the case of a verb compounded with a preposition, the augment follows the preposition—as: προσλαμβάνω, προσέλαβον; ἐκλείπω, ἐξέλιπον; εἰσακούω, εἰσήκουσα; συγκρίνω, συνεκρίθην; συλλαμβάνω, συνέλαβον; συμβάλλω, συνέβαλον; συ-στέλλω, συνέσταλκα.

Prepositions that end in a vowel drop the final vowel before the augment ε, except περί and πρό—as: ἀποβάλλω, ἀπέβαλλον; but περιέβαλλον and προέβαλλον. (πρό is usually contracted with the augment—as: προὔβαλλον for προέβαλλον.)

A few verbs take the augment before the preposition—as: καθίζω, ἐκάθιζον; while some have both augments—as: ἀνέχω, ἠνειχόμην.

ὑποπτεύω, suspect, makes ὑπώπτευον; and παρανομέω, transgress, makes παρηνόμουν (very irregular).

The Irregular Verbs εἰμί, Be, and εἶμι, Go.

εἰμί (stem ἐσ-, Latin *es-se*), be.

Indicative

Present	*Imperfect*	*Future*	*Present Subj.*	*Present Optative*	*Present Imperative*
εἰμί	ἦν or ἦ	ἔσομαι	ὦ	εἴην	—
εἶ	ἦσθα	ἔσει or ἔσῃ	ᾖς	εἴης	ἴσθι
ἐστί	ἦν	ἔσται	ᾖ	εἴη	ἔστω
ἐστόν	ἦτον	ἔσεσθον	ἦτον	εἴητον, εἶτον	ἔστον
ἐστόν	ἤτην	ἔσεσθον	ἦτον	εἰήτην, εἴτην	ἔστων
ἐσμέν	ἦμεν	ἐσόμεθα	ὦμεν	εἴημεν, εἶμεν	—
ἐστέ	ἦτε	ἔσεσθε	ἦτε	εἴητε, εἶτε	ἔστε
εἰσί	ἦσαν	ἔσονται	ὦσι	εἴησαν, εἶεν	ἔστωσαν, ἔστων, ὄντων

Present Infinitive: εἶναι, to be.

Present Participle: ὤν, οὖσα, ὄν (*gen.* ὄντος, οὔσης, ὄντος; *nom. pl.* ὄντες, οὖσαι, ὄντα), being.

Future Infinitive: ἔσεσθαι.

Future Participle: ἐσόμενος.

Verbal Adjective: ἐστέον.

There is also a future optative, ἐσοίμην, ἔσοιο, ἔσοιτο, etc., quite regular.

εἶμι (stem ἰ-, Latin *i-re*), go.

Present Indicative	*Imperfect Indicative*	*Present Subj.*	*Present Optative*	*Present Imperative*
εἶμι	ᾔειν or ᾖα	ἴω	ἰοίην	—
εἶ	ᾔεις or ᾔεισθα	ἴῃς	ἴοις	ἴθι
εἶσι	ᾔει or ᾔειν	ἴῃ	ἴοι	ἴτω
ἴτον	ᾔειτον or ᾖτον	ἴητον	ἴοιτον	ἴτον
ἴτον	ᾐείτην or ᾔτην	ἴητον	ἰοίτην	ἴτων
ἴμεν	ᾔειμεν or ᾖμεν	ἴωμεν	ἴοιμεν	—
ἴτε	ᾔειτε or ᾖτε	ἴητε	ἴοιτε	ἴτε
ἴασι	ᾔεσαν or ᾖσαν	ἴωσι	ἴοιεν	ἴτωσαν or ἰόντων

Infinitive: ἰέναι, to go.

Participle: ἰών, ἰοῦσα, ἰόν (*gen.* ἰόντος, etc.).

Verbal Adjective: ἰτός and ἰτέον.

NOTE. The present εἶμι has usually a future sense, I shall go, and is used as the future of ἔρχομαι. The two εἶμι's are liable to be confused by the beginner, and there is a third verb, οἶδα, know, which is somewhat similar in parts. Thus—

οἶδα, I know.

(οἶδα has no present, being a second perfect from the stem ἰδ-; see εἶδον in dictionary.)

Perfect Indicative	*Pluperf. Indicative*	*Perfect Imperative*
οἶδα	ᾔδειν or ᾔδη	—
οἶσθα	ᾔδεισθα or ᾔδεις	ἴσθι
οἶδε	ᾔδει or ᾔδη	ἴστω
ἴστον	ᾔδειτον or ᾖστον	ἴστον
ἴστον	ᾐδείτην or ᾔστην	ἴστων
ἴσμεν	ᾔδειμεν or ᾖσμεν	—
ἴστε	ᾔδειτε or ᾖστε	ἴστε
ἴσασι	ᾔδεσαν or ᾖσαν	ἴστωσαν

Perfect Infinitive: εἰδέναι, to know.

Perfect Participle: εἰδώς, εἰδυῖα, εἰδός, knowing.

Verbal Adjective: ἰστέον.

Subjunctive: εἰδῶ, εἰδῇς, εἰδῇ, etc.

Optative: εἰδείην, εἰδείης, εἰδείη, etc.

Future Indicative: εἴσομαι, εἴσει, εἴσεται, etc.

SECTION III.—TRANSLATION

THE FIRST GLIMPSE OF THE SEA

[This is from Xenophon's "Anabasis," one of the most fascinating books in the world. Xenophon has led a body of Greeks into Persia to help Cyrus to wrest the crown from his elder brother Artaxerxes II. Cyrus is slain, and the Greeks have to retreat. It is a time of terrible danger and hardship, and when one day in February 400 B.C. the vanguard catch sight of the Black Sea in the distance and call out "The Sea! The Sea!" the joy of the whole army is unbounded. Let the gallant leader tell the story in his own words.]

Ἐντεῦθεν ἐπορεύθησαν διὰ Χαλύβων καὶ ἦλθον (1) πρὸς πόλιν μεγάλην, ἣ ἐκαλεῖτο Γυμνίας. ἐκ ταύτης τῆς πόλεως ὁ τῆς χώρας ἄρχων πέμπει ἡγεμόνα τοῖς Ἕλλησιν· ἐλθὼν δὲ ἐκεῖνος εἶπεν ὅτι ἄξοι (2) αὐτοὺς εἰς χωρίον ὅθεν ὄψοιντο (3) θάλασσαν. ὁ δὲ ἡγεῖτο (4) αὐτοῖς· καὶ ἀφικνοῦνται ἐπὶ τὸ ὄρος τῇ πέμπτῃ ἡμέρᾳ· ἐπεὶ δὲ οἱ πρῶτοι ἐγένοντο (5) ἐπὶ τοῦ ὄρους καὶ κατεῖδον τὴν θάλασσαν, κραυγὴ πολλὴ ἐγένετο. ὁ δὲ Ξενοφῶν καὶ οἱ ὀπισθοφύλακες ἀκούσαντες ᾠήθησαν (6) πολεμίους ἐπιτίθεσθαι τοῖς ἔμπροσθεν. ἐπειδὴ δὲ βοὴ πλείων ἐγίγνετο, καὶ οἱ ἀεὶ ἐπιόντες (7) ἔθεον δρόμῳ ἐπὶ τοὺς ἀεὶ βοῶντας, ἐδόκει δὴ τῷ Ξενοφῶντι μεῖζόν τι εἶναι· καὶ ἀναβὰς ἐφ' ἵππον καὶ ἀναλαβὼν τοὺς ἱππέας, παρεβοήθει. (8) καὶ τάχα δὴ ἀκούουσι τῶν στρατιωτῶν βοώντων 'Θάλασσα, θάλασσα', καὶ παρακελευομένων ἀλλήλοις. ἔνθα δὴ πάντες ἔθεον· ἐπεὶ δὲ ἀφίκοντο ἐπὶ τὸ ἄκρον, ἐνταῦθα δὴ περιέβαλλον (9) ἀλλήλους καὶ στρατηγοὺς καὶ λοχαγοὺς δακρύοντες· καὶ εὐθὺς οἱ στρατιῶται φέρουσι λίθους καὶ ποιοῦσι κολωνὸν μέγαν. μετὰ ταῦτα οἱ Ἕλληνες ἀποπέμπουσι τὸν ἡγεμόνα δῶρα δόντες (10) αὐτῷ, ἵππον καὶ φιάλην ἀργυρᾶν καὶ σκευὴν Περσικὴν καὶ χρήματα· ὁ δὲ δείξας (11) αὐτοῖς κώμην, οὗ ἔδει σκηνεῖν, καὶ τὴν ὁδὸν ἣν πορεύσοιντο, ᾤχετο τῆς νυκτός.

NOTES. (1) Irregular aorist of ἔρχομαι (participle ἐλθών). (2) Future optative of ἄγω. (3) Future optative of ὁράω. (4) Governs the dative (from ἡγέομαι). (5) Second aorist of γίγνομαι. (6) Aorist of οἴομαι. (Note that verbs beginning with a diphthong take the temporal augment on the first vowel of the diphthong, αι becoming ῃ, and οι becoming ῳ—*e.g.*, αἰτέω, I ask, ᾔτησα; οἴχομαι, ᾠχόμην, as below ᾤχετο τῆς νυκτός.) (7) Present participle of ἔπειμι, come near. (8) and (9) Imperfect of παραβοηθέω and περιβάλλω respectively. (10) Aorist participle of δίδωμι. (11) Aorist participle of δείκνυμι.

TEXTILE DESIGN

The Work of the Textile Designer. Making Patterns for Axminster, Brussels, and Wilton Carpets. Reversing Patterns

Continued from page 6277

By H. NAPPER

IN the following articles, containing practical knowledge necessary to the maker of patterns for all materials that require a pattern, it is intended to give, without being severely technical, just the amount required by the designer to make a design suitable for showing to a manufacturer; and also to serve the purpose of connecting the course on DESIGN with the practical articles of weaving in all its branches, which are included in this work [see TEXTILES, pages 2939, 3153, 3357, 5507].

Drawing for Textiles. The designer of to-day must, if he wish to be successful in his calling, be able to make patterns for all materials that require them, be they carpets, tapestries, silks, muslins, cretonnes, velvets, wallpapers, etc. He should also interest himself in furniture and carving for wood or stone, otherwise he will soon find that to limit his invention to one branch becomes irksome; but by taking up others he will return refreshed, and probably with ideas suggested by the change of thought.

The great difficulty in the way of the young designer is how to acquire this knowledge. Although we have schools for design, the practical side seems to be ignored. This is a great mistake. Moreover the ordinary productions of to-day are generally held in contempt. To give an instance. In looking at a collection of designs exhibited by young designers from any school of art it will be found invariably that they are only suitable for working in the most expensive cloths, and are costly in production because the same effect could be realised by the design being half its length, or by the reduction of the amount of warps and wefts.

The same remarks apply to wallpapers, where nearly all the designs could be produced only by block—that is, by hand—whereas this process of production represents only about one-tenth of the output by other processes used for wall-covering.

Market Requirements. The manufacturer depends for his ideas on the designer, and for his best work invariably buys from the designer who is working for himself—that is, for the general market, and not for any particular firm. There is generally a large staff of designers kept by the manufacturer; the majority of these are busy with the technical side—re-colouring, re-arranging, and adapting ideas, and the consideration of new effects in weaving and printing. If possible, the young man who can spare the time to go thoroughly into one branch, and feels inclined to specialise, should endeavour to get into a factory.

It is very necessary that the designer should keep himself in touch with what is being produced for the market. He should look around at the principal shops and take note of the class of goods, not with a view to copying the designs, but for the purpose of seeing what other people are doing and the kinds of cloths that are in demand, and also with the view of getting some notion of the scale of pattern; one year the fancy may be for large pattern, another for small, full or empty in material. These are all points the designer must take into consideration if he wish to be successful. Do not try to force your ideas on the manufacturer; he will come probably to your way of thinking in time.

There are so many hands for the design, when in the material, to go through, before reaching the ordinary buyer, that even the manufacturer cannot see his way to produce novelties without consulting others.

Axminster Carpets. Our object in taking the carpet as the first of this series of woven goods is because of its importance in the field of design, its variety, and also its difficulties. The fact of the carpet being looked at from above, unlike other woven fabrics, increases the difficulty of making a satisfactory pattern [see also TEXTILES, page 3357].

Axminster is the most interesting from the designer's standpoint, especially if he be a good colourist. In fact, it is not much use doing designs for it unless he is, for colour is its main feature, drawing counting for very little. This will be seen plainly by referring to the illustrations of a design transferred to the ruled or "point" paper [1, 2, and 3].

When the size of these blocks of colour which represent your outline—and these are the sizes generally used—is considered, it will be understood that delicacy of drawing, small detail, etc., would be unintelligible when woven, and get more so by constant repetition. The best method to start with Axminster is to find out the "pitch," or range of points used to the square inch by the manufacturer for whom the design is required. The variety is so great that it is imposible to give them all, but from five to seven to the inch are the pitches most generally used. Sketch the rough idea on this paper, say, in charcoal; experiment with the outline by filling in the squares along the line—this will enable you to get the "scale" required; it will also show, what is a necessity in all carpet work, how to get "roundness," or, in another word, "fatness," into the drawing. Having experimented on the ruled paper, and brought the idea into shape, the next question that will occur is the length of the pattern.

The width of the material and the drawing is always 27 in.; borders from 13 in., 18 in., or 22½ in. For length there is no fixed rule, but from 27 in. to 36 in. should be sufficient. Of

DESIGN FOR BRUSSELS CARPETS

course, if it be necessary to make a pattern which drops in the 27 in. or width of material, the designer can go up to 54 in. in length. These large sizes are not much used to-day, probably owing to a better understanding of design by the public and the improvement in design generally.

Manufacturers have seen that a large repeat does not give the most artistic result, or make a more serviceable carpet. The number of colours for Axminster is unlimited, but for all practical purposes thirty to forty will be found sufficient.

Preparing the Design. There are various methods of preparing carpet designs. The best, of course, is to put the drawing direct on to the ruled paper, thus making a practical drawing ready to go into the machine-room. It has its disadvantages, however; to the novice it would take a long time to cover, say, a square yard, keeping the colour exactly in these small squares, thinking at the same time of the drawing and colour. His time also would be in a great measure wasted, because colourists employed by the manufacturer would be able to do it in a third of the time, and see that the ranges of colour come within their collection.

Should it be decided to work it out this way, see that the design is complete in drawing before starting to paint. First put in the outlines, afterwards the ground, and then the filling in of the shapes. Be careful to use solid colour—that is, dry powdered colours mixed with gum. This is very necessary to cover over the squares, so that only the indentation made by the printing of the lines remains. No uneven or transparent effects should be seen, and every colour used in gradation or shading must keep a definite shape, which will be repeated exactly in the cloth.

Do not start colouring with primaries; break them well up, and mix various ranges of green, red, etc., by adding white or yellow, so that a perfect set is obtained, definite in tone, of each.

A splendid scheme can be made in this way of black, raw umber, burnt umber, and burnt sienna, broken with white only, giving the effect when massed together, of the richest reds, greens, and blues.

Making the Sketch. Some manufacturers buy small sketches made to scale, say one-fourth of the full size, or one-sixth, the latter preferred. This method is very unsatisfactory, both for the designer and manufacturer; it is impossible to give the right effect in such a small space of the detail, colouring, etc. But a great deal can be done in this way by repeating it roughly several times, and experimenting with border, etc., before drawing it full size.

The best method to make a satisfactory drawing is to start by considering the masses of colour [4]. After having decided on the length of pattern, take a piece of ordinary brown or tinted paper, and rule it out in square inches, with pencil, so that they can just be seen; then draw in either body colour or pastel. The latter is the better, as it can be taken out easily with bread; it also gives a certain amount of texture, which helps to realise the effect of the cloth.

Set the rough planning of flowers and leaves, and if the pattern is to repeat, say twice or three times in the 27 in., the squares will help to plan the colour arrangement without the trouble of tracing. Place the drawing as often as possible on the floor, and look at it from different points of view. Do not be afraid of making the design look hard, but endeavour to cultivate "definiteness," so that nothing is left to chance. The material being thick, with a rich pile, tends to soften both the colour and design when woven [5].

Axminster Borders. Borders for Axminster can be drawn in the same way as the filling or body [5]. They should be constantly put on the floor by the side of it to obtain the necessary contrast. Always make the border design larger or smaller than the main design, and get a good outer and inner guard, so that there is some plain colour near the floor and a definite line to separate it from the filling. A greater contrast can be made by having an entirely different scheme of colour, for the border in the usual make is woven separately from the filling.

There are other uses to which the same design can be applied—for staircase, landings, hearthrugs, etc.; but it is better not to consider these at first. The manufacturer usually has these arranged by the copyists or designers kept in the firm. There are other kinds of Axminster in which the borders are woven with a part of the filling; others with the complete design—that is, filling, borders, and corners woven together. The colours in these are generally limited, and, owing to the technicalities, the design also becomes limited, and can be produced only by designers with a complete knowledge of the working of the loom.

Brussels and Wilton Carpets. In preparing designs for Brussels or Wilton carpets, it is not necessary to make any difference in the appearance of the designs, for they are practically woven in the same way. The difference in effect is given to the cloth by what remains in a finished Brussels—the loop or thread, which fills the square in the design. This loop is cut through, making a tuft, thus making the Brussels into a Wilton; this gives a pile similar to an Axminster, but with a limited number of colours.

The sizes of Brussels—that is, width for borders, fillings, etc.—are precisely the same as Axminster; the great difference is the size of the points or loops. The point paper is ruled to about 85 points to the square inch, or 9 by 9½, nearly. Ordinary Axminster runs usually from 27 to 70. It will at once be seen that this gives a better chance for the expression, by drawing in the design.

Drawing, or the design, plays a very important part in Brussels, owing to the limited colour, which must be made up for in other ways by richness of material or by the careful disposition of the colours one against another. Sometimes by reversing them the same colours can be made to give a totally different effect. There is a new feature which can be introduced in this fabric—that is, by changing one colour (sometimes more) by *planting*. This we will endeavour to explain more fully. The top

surface of a Brussels is usually composed of five layers of worsted threads, which are called frames; these run the lengthway of the material, and are looped over wires to form the pile, the different colours required to form the pattern coming to the surface in a row of loops, each loop making the size of the points on the ruled paper.

Colour Arrangement for Brussels Carpets. The designer must not use more than these five decided colours. Now, if one of these be taken for outline purposes, there will be four only for ground, leaves, and flowers, or whatever material is used in the design. It follows, then, that any method by which any one of these colours can be changed gives an advantage to the designer. Care must be taken to start with this idea, for to do it satisfactorily entails an amount of thought and trouble not obvious to the ordinary buyer of carpets. These five colours running along the carpet are decided only in their number; one can change as many times as required so long as one keeps always to five colours in one line. This is called "planting" The designer can use it to give gradation if the design is planned for it; but the best method is to reserve it for giving bright effects in small parts of the pattern, so that the great error of making colours look like stripes is avoided. This will not be an easy matter at first, but after a while it will be found that in nearly all woven fabrics these technical difficulties often result in giving character to the work.

A good method is to make a strip of paper, with the range of colours marked in the line in which they are to be used, so that one can pass it up and down the design, and be certain the colours do not overlap. Another great point with regard to Brussels is that with the change of ground colour only the manufacturer can get an entirely different effect, in some cases making it look like a fresh design. This is a detail which should be always borne in mind, for, strange as it may seem, a design woven with a dark ground may not sell at all, but with a light ground may have an enormous success.

Reversing and Other Carpets. There is a great variety of other makes of carpet which cannot be explained by writing or illustration, owing to the complicated method of weaving. Tapestry carpet is one. This is a very common effect, usually woven in squares, and of a very cheap quality. In nearly every case, the cheaper the material, the more difficult it is to make a pleasing or satisfactory design outside the factory.

There are exceptions, however. The cheapest and best is what is generally called a "Roman" carpet, woven in squares of varying sizes, in two colours, giving, when reversed, the same pattern [6]. It is almost impossible to make a bad floor covering in this material, owing to its simplicity. The chief points to be noticed are that the filling must repeat with the border, both ways; that the detail must be always on the large or coarse side; and that the effect of it when repeated must be borne in mind so that a good effect on both sides is obtained. Sometimes a third colour is introduced. This serves to make a better or thicker material, and helps to give a bloom of colour, but obviously makes it more difficult, and generally destroys its use for reversing.

In illustration 6 the repeat of borders and filling and the method of making corners are roughly suggested, as well as the reversal of the grounds to make the border stand out distinct from the filling. The hearthrug contains the whole of its design in one quarter, but, by reversing exactly in the centre both ways, economy is obtained in design and weaving. This also applies to the stair carpet, in which the design, instead of reversing, is turned over. These methods of saving in production are more fully described in articles on woven fabrics.

There are at the present time a great many hand-made carpets to be seen. These, owing to their cost and primitive method of weaving, are generally used for special purposes. They contain no special technical limitations, such as repeats or limited colour. The designer, having a free hand, can carry his idea with variations all over the surface or change the colour in any way he may wish.

Examples of Carpet Design. In referring to illustrations of carpets it will be seen in the case of Axminster and Brussels [1, 2, and 8] that any small breakings or serrations of outline in the drawing become meaningless or impossible to express when placed upon the ruled paper. The hardness is, of course, slightly modified when the design is woven, owing to the tuft spreading a little. This is more noticeable in Axminster and Wilton.

The illustration of a Brussels [9] gives a piece of the complete carpet with border, with a detail of filling nearly full size. In the filling the method of planting in the full width of material is explained. Although it is marked in four different colours, it is possible to introduce changes again, and give a graduated effect of the same colour.

The method of planting the border is also shown. In this more contrast can be obtained, as it will not again repeat as in filling. Brussels and Axminster are made up to size of room by mitring the corner of the border and joining to strips of filling. If the length of filling repeat is long, some parts will have to be cut away and consequently wasted, in making up [10].

Hearthrugs and stair carpet are made in Brussels and Axminster with the border and filling complete, as in the illustration to reversing carpets [6].

We would advise the young designer to take every advantage of the collections of Indian and Persian carpets in the museums for purposes of study. Their perfect colour, invention, and planning make them for all time the ideal to be aimed at in a floor covering. There is always a market for designs of this class, not necessarily copies, but with the spirit, and the designer cannot do better in making a style for himself than learn from the great craftsmen of the past.

MINERAL WATERS

Principles and Process of Aerating Waters. Bottle and Syphon Filling. Making the Gas. Aerated Waters Made While the Customer Waits

Following WINES AND CIDERS from page 8266

By CLAYTON BEADLE and HENRY P. STEVENS

MINERAL waters may be divided into two classes—natural and artificial. The natural waters are taken from some spring or other source of supply, and consumed on the spot or bottled for delivery direct to various countries. Artificial waters are prepared by the addition of saline substances and impregnations with carbonic acid gas.

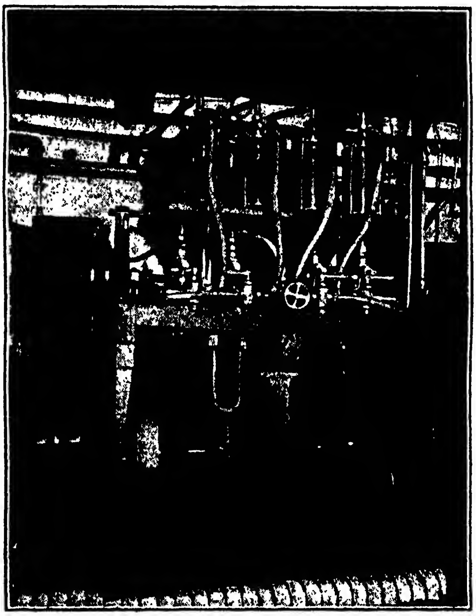
There are also waters which stand midway between these two classes—those which already contain some salts or other dissolved substances having medicinal or other qualities, and which are fortified by the addition of further salts or carbonic acid gas.

Principles of Manufacture. Water such as is got by artesian wells from the chalk below the green sand formation in the London Basin is perhaps the best adapted for the manufacture of "minerals." It is soft, slightly alkaline, and very free from organic impurities. The analysis of such a London water made by a well-known expert showed only 0·0004 parts per 100,000 of organic ammonia, 5° of hardness, and six bacteria per cubic centimetre. Such water is practically sterile.

Aeration, as it is called, consists in saturating water under pressure with carbonic acid gas. Water at ordinary temperature, say 60° F., absorbs about its own weight of this gas (if cold, it absorbs more; if warm, less). All bottling is done at ordinary temperatures with cold water. If the pressure on the gas be doubled, the volume is approximately halved; if doubled again, the volume is again halved; but no matter what the pressure, one pint of cold water (60° F.) absorbs one pint of the gas. If, then, we double the atmospheric pressure by applying 15 lb. per square inch, we get twice the amount of gas into the water. On releasing the pressure, the excess of gas escapes into the air. As ordinary bottling is done at from 60 lb. to 100 lb. per square inch, a large amount of the gas is absorbed by the liquid.

The principles of manufacture, which we will describe in some detail, are chiefly in accordance with those adopted by Camwal, Limited, where the work is conducted under scientific supervision.

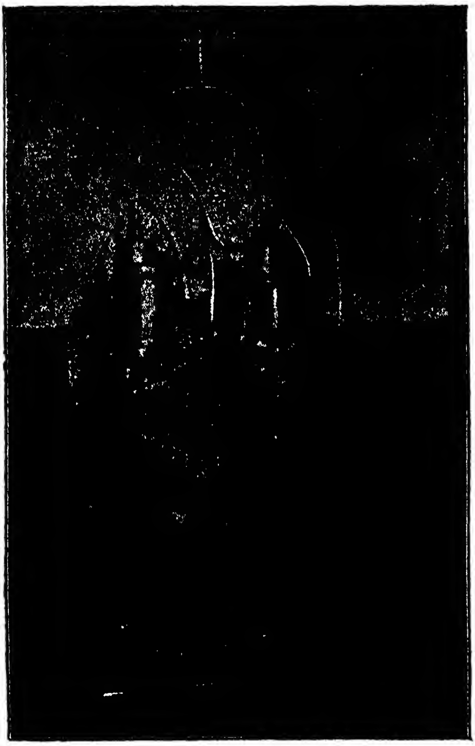
Mixing the Gas. Carbonic acid gas used in these works is a natural gas obtained from Germany, where it is compressed as a liquid in steel cylinders under a pressure of 800 lb. per square inch. These cylinders are stood on end, and connected up, six at a time, with a receiver resembling a miniature gas holder. By discharging into this holder, the gas is obtained under a few inches of water pressure. The rate of evaporation from the cylinder causes a portion of the liquid to freeze to a solid, which makes itself evident by frost on the outside. The cylinders are then removed and others attached. The warmth of the air, or of warm water, converts the solid gas back into a liquid, and the cylinders are again placed in contact with the receiver, and the gas completely absorbed by the aid of a warm water jacket.



1. AERATING MACHINE

The gas from the receiver then passes through pipes to the aerating machine. Here it is washed as a final precaution, by bubbling through glass cylinders containing water. As the gas contains 99·4 per cent. of pure carbon dioxide, this precaution does not appear to be necessary. The gas then passes through three-way cocks, where it meets with water. These cocks can be so regulated as to supply any proportion of water and carbonic acid gas. The water, the composition of which has already been referred to, is pumped from the deep well into a tank, where, for the manufacture of soda-water, it is rendered alkaline by the addition of pure carbonate of soda. The water has a natural temperature of 56° F. Each mixing tank holds exactly 200 gallons. Bicarbonate of soda is added by means of a suspended filtering bag through which the water flows and dissolves it into the tank. The chemist checks every mixing by analysis, as a check to the weighings, the figures of which are carefully recorded.

The alkaline water then passes through silver-plated connections and tin pipes to the various aerating machines above described. It first enters a small feed tank with a glass front, provided with a ball-cock, and then goes to the three-way taps, from whence the mixture of gas and water passes into the carbonating chamber. This machine is made of gun-metal, and is lined inside with tin, ¼ in. thick. With a large machine, the cylinder has a capacity of 80 gallons, and is worked under a pressure of 180 lb. per square inch, the cylinder being half full of water and half full of gas.



2. SYPHON-FILLING MACHINE

Agitation is promoted by a longitudinal shaft provided with triangular perforated paddles, and revolving at 60 to 80 revolutions per minute. The gas and water are pumped into the cylinder by four pumps and four sets of pipes, pairs of which can be worked independently [1].

The water which has thus been ærated thence passes to the filling machine at a pressure of about 180 lb. if required for filling syphons, and 120 lb. for filling bottles and "plain goods"—that is, not containing syrup or sugar—and about 90 lb. for sweet drinks. The actual pressure in the syphons or bottles is about half that at which the water is forced into the vessel. The biggest carbonating cylinder will fill about 1.800 30-oz. syphons per hour.

Filling Aerated Water Bottles. In filling bottles fitted with glass marbles as stoppers the marble is forced into the neck of the bottle by the pressure of the gas inside the bottle.

With screw-stoppered bottles, the stopper is screwed loosely into the neck of the empty bottle; it is then placed under the machine, which removes the stopper, fills the bottle, and screws the stopper in firmly.

Bottles fitted with ordinary corks are held in position by the machine and the cork is placed in a holder. When the machine is started working, the bottle is filled, the cork dropped into position, and rammed into the neck by means of a small ram. By the thrust of an arm, the bottle is thrown out of position and pushed down a chute. To avoid "cork dust," the corks are previously washed in water, but as an extra precaution, the ram delivers a spray of aerated water, so as to further cleanse the cork at the moment of insertion. In all the machines, the aerated water is forced into bottles by the pressure of the carbonating cylinder. If syrup is to be added, as in the case of lemonade, ginger ale, etc., it is admitted to small pumps from the tanks above, which deliver at each stroke the requisite quantity to the bottle, which is made up at the same time with the proper proportion of aerated water. All the modern filling machines are fitted with a syrup and aerated water saving device. By this means, no water or syrup can flow unless the bottle to be filled is fixed in its place. In this way, a great deal of unnecessary waste is saved.

When the aerated water is forced into the bottles the air in the bottle is driven out. This is called "snifting." In the case of syphons, the "snifting" gases are collected and used again, as they consist of pure carbon dioxide left from the last filling, but in the case of bottles they are allowed to escape, as they contain a large percentage of ordinary air.

Syphons. Syphons are filled through the spout. They are fixed so that the spout is pressed against the pipe through which the water is to be admitted. The lever is then pressed down, by means of a small arm actuated by means of a pedal, and the soda-water is forced in so that the pressure in the syphon is equal to that at which the water is entering. The water valve is then closed automatically, and the "snift" valve is opened to allow the gas inside to escape. The "snift" valve then closes again, the water valve is opened, and the syphon is filled up [2]. The gas in the best soda-water syphon contains about 0·6 per cent. of air, the rest carbonic acid. There must not be more than 2 per cent. of air, or the syphon cannot be properly emptied. After the syphons have been filled the tops are burnished by means of a revolving calico disc, and then the body of the syphon is washed and the labels stuck on. The syphon tops of the Camwal Co. are made of pure tin, with only sufficient antimony and bismuth to give the requisite hardness. Some are silver-plated, but this is merely to give them a better appearance, as the tin is absolutely safe.

There are two sorts of syphon tops—*viz.*, those with the long lever, and those with the short ones [4]. With the long lever tops, the lever is raised to deliver the liquid, while with the short valve, the valve is depressed. The former work against a spring, which must be strong enough to prevent leakage; but in the latter, the pressure forces the valve against its rubber setting, and so makes its own joint. Opinions differ as to which is the better, but the public seem to like the long lever, as it gives better control when pressing. The sudden spirt when starting a new syphon is due to the valve sticking and coming away suddenly. The Idris

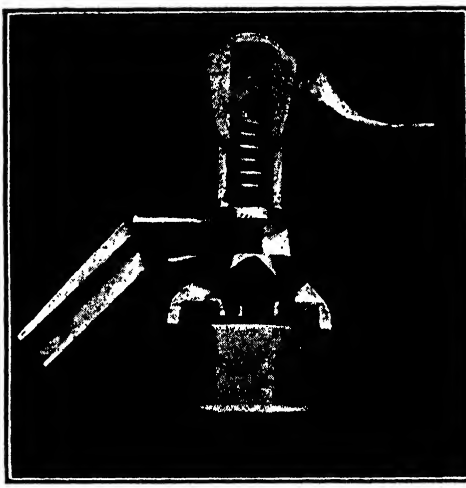
3. SYRUP COOLERS AND FILTERS

Company make a china plug and nozzle fitted inside, so that none of the liquid comes in contact with the metal top. Metal contamination results from the use of unsuitable metal tops.

The Preparation of Syrups. The best crystallised cane sugar is boiled in a steam-jacketed copper. The strength of the syrup is made up to from 40° to 50° Tw., 2 cwt. of sugar being used at each boiling. The syrup is then run into a cooler [3], and fru t acid essences are added to give it the necessary flavours. The mixture is then filtered through a bag to the tank, whence it is led to the various filling machines.

Soda-water varies in strength between 5 gr. and 30 gr. of bicarbonate per pint. The British Pharmacopœia formerly gave soda-water at 30 gr. per pint. Prosecutions are usually instituted where the amount is under 5 gr. per pint. The strength is largely a matter of taste. The amount in the case of lithia is 10 gr., according to the British Pharmacopœia, 1885. Potash is 5 gr. to 15 gr. Seltzer water, properly prepared, is a mixture of sodium bicarbonate, sodium chloride, and magnesia, but, as generally sold, means nothing. There are, in addition, aerated distilled water and carbonated water.

Preparation of Ginger-beer. The water is first boiled in a steam-jacketed copper, and is then passed into a mash-tun, where it is mixed with crushed Jamaica ginger. The whole is then run into a settling tank where fruit acids are added, and the liquid, after reduction to proper temperature, is drawn off into the fermenting vat, where it is mixed with sugar (1 lb. per gallon), and allowed to ferment for twelve hours. It is then run off and filled into stone bottles in special filling machines, after which it is stored for about a fortnight, during which time the proper aeration is promoted as a result of the fermentation which takes place. Ginger-beer so prepared contains from 0·6 per cent. to 1·4 per cent. of alcohol. The extreme legal limit is 3 per cent., but manufacturers are warned if 2 per cent. is exceeded.



4. CAMWAL SYPHON TOP

Preparation of Carbonic Acid Gas. Many firms still make their own carbonic acid gas by adding sulphuric acid to whiting or sodium bicarbonate. To a large cylindrical tank, half full of water, a charge of 2 cwt. of bicarbonate is added. Sulphuric acid is then run into it from a reservoir situated at the top, and carbonic acid gas, so called, is drawn off by a pump to the aerating machine. On its passage it is purified free from nitrates by passing through alkaline potassium permanganate solution, which also removes any spray of sulphuric acid wh ch might be carried over mechanically. This method of producing carbon dioxide gives trouble on account of the amount of air it is liable to contain, hence the use of pure natural gas.

Large quantities of sulphuric acid, in jars, surrounded with whiting, are shipped to India and the Colonies for the production of carbon dioxide to be used in the manufacture of aerated waters. If these jars should break during shipment the acid is absorbed by merely converting the whiting into plaster of Paris. The empty jars are cleansed, refilled with Indian pickles, and shipped back to this country. Carbon dioxide is also produced during the process of fermentation in breweries, where it is compressed into cylinders and sold to makers of mineral waters.

Perhaps the most advanced method of producing the gas is from coke, according to Stead's and Leslie's patents. A very ingenious process (Stead's patent) has been installed by the Idris Company, whereby gas of the highest degree of purity is produced. The process consists in the main as follows: The products of combustion of special coal or coke are forced, under pressure of 20 lb. to 30 lb. per square inch, into carbonate of potash solution, which is thereby converted into bicarbonate, after which it is heated with the evolution of pure carbon dioxide, and the re-formation of ordinary carbonate.

Domestic and Automatic Aeration. Retailers of mineral waters can now prepare their own if they so choose. Attempts have been made from time to time to introduce a machine for this purpose. From the description already given of the manufacture of "minerals" on a large scale, the principle of the ingenious "multum in parvo" machine known as the "Consol" (British Automatic Aerators, Ltd.) [6] will be grasped readily.

It enables the retailer to deliver at the point of consumption an aerated water of good quality, freshly made for each customer, and also enables him to dispense with the cumbrous boxes of bottles formerly needed for his business.

This machine occupies a space only slightly exceeding 1 sq. ft., and can be fitted to any bar or shop counter. In addition to ordinary aerated water, it can be made to produce soda, potash, lithia, lemonade, ginger-beer, ginger-ale, etc., by adding the necessary amount of soluble constituents, according to well-known recipes.

It differs from other "draught apparatus," such as soda fountains, various forms of draught arms, etc., in that it manufactures each drink as required, whereas ordinary apparatus has to draw from a previously manufactured store, which deteriorates on keeping. The entire operation is performed by a right and left movement of the handle, which occupies a period of not more than five seconds, so that it is possible to draw on draught the equivalent of 60 dozen bottles per hour.

A filter should always be fitted where any doubt exists as to the purity of the water, and in all cases where it is desired to produce the highest class of "minerals." Suitable germ-proof filters have been designed for special use with the aerator, all that is necessary being to introduce the filter at any convenient point in the water supply.

Aerated Water in Open Jugs. It is claimed by some that aeration on a small scale produces a different result to aeration in bulk. It is

said that it so saturates the water with the gas (CO_2), that it is actually held in solution, and not given off in a violent eruption upon the removal of outside pressure. The experiment described below may be taken as showing that water aerated in bulk does *not* retain the gas for any length of time after opening the bottles We cannot undertake to sift the evidence on this point, and as "minerals" from bottles and syphons, especially the latter, are consumed almost immediately after opening, we need hardly concern ourselves with it Nevertheless, domestic aeration makes it possible for aerated water to be served in open jugs, without detriment to its sparkling qualities, a point which should prove of decided gain to the public

The following simple experiment illustrates this A tumbler of aerated water is drawn from the small hand machine, and a similar tumbler is filled from a bottle or syphon supplied from an ordinary mineral water factory. The two are left side by side for half an hour or longer, each is then gently stirred with a thin rod or knitting needle. That from the bottle will be comparatively flat, whereas that from the small machine will "bead" round the rod and effervesce freely

Although the aerator has been designed primarily to make and supply aerated water straight into the glass, yet both screw - stoppered and corked bottles can be easily and rapidly filled Where it is desired to bottle under pressure, an attachment is added for filling any description of bottle, particularly suited for ball stoppered bottles (known in the trade as cod bottles). This is attached to the aerator by removing the delivery vessel. The illustration [5] shows the attachment.

Another Simple Machine for Bottling Only. Another machine, worked somewhat differently, is shown in 9. In this case the bottles have first to be filled with the water to be aerated. They are then clamped on to the attachment communicating with a tin ball full of gas under pressure By pulling up the lever, the bottle is inverted, causing the water to flow into the ball, where, by the aid of shaking, it becomes aerated. The lever is then lowered, so that the bottle is the right way up, when the aerated water finds its way back into the bottle. The machine is of cheaper construction, but slower in its action than the "Consol," and it will not deliver direct into the glass. It appears to answer its purpose.

Sparklet Aeration. We will conclude our account of mineral waters with a short description of the Sparklet syphon (Aerators, Ltd.). By means of this ingenious system anybody can make at any time and in any place as much freshly aerated water as desired The principle of the system consists in the sale of carbonic acid gas strongly compressed in small steel bulbs which are fitted on to the syphon and pierced by turning a screw, which allows the gas to escape and saturate the water with which the syphon is previously filled The bulb containing the carbonic acid gas, and the bulb - holder into which it is slipped neck downwards, are shown in 8 and 10 The vase of the syphon, the upper part of which is shown in 7, is filled with water to a red mark near the top, the glass tube is inserted, and the head screwed down without employing undue force. The bulb - holder, containing the bulb, is held with the thumb on the bulb so that the neck of the latter protrudes slightly below the bottom of the holder The protruding neck of the bulb is now inserted centrally into the hollow formed by a washer and gently screwed down Inside this hollow and projecting outward is a pin, which enters the end of the bulb and pierces it, in this way admitting the gas from the bulb into the syphon. The bulb holder is screwed down gradually, shaking the syphon well from time to time and continuing alternate screwing and shaking until no more bubbles of gas are given off. The syphon is now ready for use, but the aeration is improved if the syphon be allowed to stand a few minutes before drawing off the contents.

The glass vases are covered with a metal wire, and are tested to a pressure of 220 lb. per square inch

Either plain water alone can be aerated or small quantities of soda, potash, lithia, or fruit crystals may be previously added in the form of "sparkloids," thus producing soda, potash, or lithia water, or other effervescing drinks of various descriptions.

HAND & MACHINE-MADE PAPERS

Plant and Processes in Making Paper by Hand and by Machine. Uses of Wood Pulp. Representative Papers

continued from page 6285

By CLAYTON BEADLE and HENRY P. STEVENS

THE process of making paper by hand is the same to-day in principle as it was long before the Christian Era. The Chinese and Aztecs, independently and without knowledge of one another's craft, employed a rough frame covered with hair or fibres through which the water drained, leaving a wet film of paper on the surface to be transferred for drying. To-day not more than 1 per cent. of the output of this country is made by hand, the rest being made by machinery. There is none made by hand in the United States and Canada, but considerable quantities on the Continent.

All hand-made papers in this country and on the Continent are made from cotton and linen rags and hemp. In the East they are made from the native fibres. In a "hand mill," as it is called, the preliminary processes of dusting, hand sorting, boiling, bleaching, "breaking-in," and beating are conducted in a similar manner to the treatment of rags in a machine mill, as already described, only, of course, on a smaller scale. As only the best papers are made by hand, the best rags have to be selected, and every care has to be exercised that they are free from dirt. The beating engines are nearly always of the "Hollander" type and of small capacity, the most convenient sizes being such as will take 105 lb. to 250 lb. dry weight of rags.

Tub-sizing. The general principles of tub sizing paper are more or less common both to machine and hand made papers but hand-made papers —at least all those worthy of the name—are always tub sized with gelatin to make them ink bearing. The tub-sizing process is, perhaps, the most difficult branch of paper-making to master in all its multifarious details.

Waterleaf, or unsized paper, in addition to being porous, has little or no wearing qualities, and is deficient in strength. It lacks what is appropriately but vulgarly described as "guts." Up to the waterleaf stage, for ninety-nine purposes out of a hundred such paper would be useless. The gelatin supplies it with additional strength, its original strength is very often more than doubled, it makes it inkproof, gives it firmness, "rattle," "feel," and such desirable qualities. In the trade language, it puts guts into it. There is as much difference between waterleaf and sized paper as there is between glazed and unglazed earthenware.

The Sizing Solution. The size solution can be made by extracting wet hide pieces, etc., with warm water—a complex industry in itself, but one which up to recently the paper-maker had to conduct on his own premises; now frequently he buys sheets of ready-made gelatin or glue, according to his requirements.

In the latter case the sheets of gelatin are soaked in water for twelve hours, the cold water being then run off, and hot water introduced to dissolve the gelatin. Alum is almost universally added as a preservative and means of control. This is then reduced to the necessary consistency or strengh with or without the addition of soap. The solution is introduced into the sizing trough [34], which, at one time, was a mere tub—hence the name of the process—but now consists of a vat heated either by steam coils at the bottom or by a jacket, and is preferably made of copper. The temperature is maintained at 100° F. to 120° F.

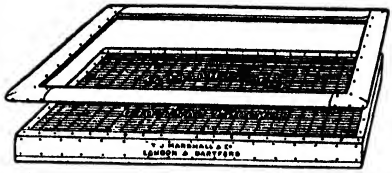
The "sizeman" has to control the quantity of gelatin entering the paper. This object is to get the best sizing effect with the least quantity of gelatin. The addition of small quantities of alum has the effect of thickening the size, and so reducing its penetrating qualities, although, curiously enough, if too much alum is added, the size is said to be killed; it becomes thin, and, in consequence, will readily penetrate the paper. This, however, is an effect to be carefully avoided. Alum, nevertheless, affords the chief means of controlling the quantity of gelatin that enters the paper. Increase of temperature means decreased viscosity and increased penetration. The temperature may be varied only within certain limits.

The soap in the size—which, by the way, must be of special composition—renders it opaque, somewhat improves its colour, and imparts to the paper special qualities, the chief of which, perhaps, is in reendering the paper more easily cut under a guillotine. If no soap were used the knife might go through with a bang. Soap also helps the glazing and surfacing under the action of the calender rolls, to which reference will be made later. Alum, if added to the chest, causes the waterleaf to be less easily penetrated by the size. As the penetration takes time, the immersion in the sizing vat must be prolonged to complete the penetration to the centre—that is, if hard sizing is required. The squeezing after immersion removes a part of what has penetrated according to the pressure applied, but assists in the removal of the air from the centre, which air is replaced by gelatin. If the sheets come gradually into the solution between perforated felts running nearly horizontal in a shallow trough, the saturation takes

31. SINGLE VAT

place from the under side, slowly driving the air to the top side. This is the modern mode of sizing hand-made sheets or cut sheets of machine-made paper. The sheets, fanned out in bunches in three rows abreast, are placed on a table, whence they are fed on to a travelling felt, which slowly carries them through the size. The upper felt holds the paper down. The paper, rising out of the vat thoroughly saturated, passes between the squeezing rolls, from which it is removed for drying.

Drying. The proper drying of the sized sheet is no easy task. It is here that the paper-maker frequently fails. The sheets are removed to a loft and hung in bunches over strings or laths until air-dry; the arrangement is somewhat like that used for drying the hand-made waterleaf, copper rollers, should rise vertically upwards and pass through the "nip" of the bronze rolls. This keeps the inside of the paper air-locked, and so retards penetration.



32. LAID HAND MOULD AND DECKLE

Making Hand-made Paper. The bleached and beaten stuff, containing, as a rule, no size or mineral, but starch, and sometimes colouring matter, is now emptied into the stuff chest. From this it is raised by lifting buckets to a small box at the head of the vat, with overflow back to chest. This gives a constant head of stuff for supply to the vat.

The vat [31] in which the hand made paper is produced, may be of wood or stone, but is usually of iron, lead lined and rectangular in shape, and smaller at the bottom than at the top.

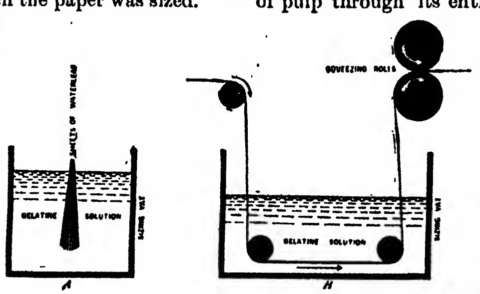
except that the temperature is kept down. To produce a perfect result it is imperative that the temperature should be below that of the melting point of the jelly with which the paper was sized.

Tub-sizing Machine Papers. With machine-made papers the sizing vat is either a continuation of the paper machine itself, coming next to the drying cylinders, or the operation is conducted in a different room by attaching a reel of waterleaf paper removed from the machine to the sizing vat. The reel is unwound and passed through the vat containing the size, then through a pair of bronze squeezing rolls, which remove any surplus, after which the sized paper is usually re-reeled. If only surface sizing is required, the web should dip vertically downwards into the vat [34B], and after passing round two immersed wooden or



34. TUB-SIZING MACHINERY

In it is a "hog," so called from its turning up and disturbing function, revolving horizontally near the bottom to secure uniformity and consistency of pulp through its entire depth in the vat. The heating arrangements by steam, as well as the regulation of flow to the vat, are under easy control by the vatman, who stands against the middle of the front side of the vat, a leaning board being provided for his support. The strainer is on his right hand, and just in front of him, resting on the ends of the vat, lies the *bridge*.

The bridge, made of wood, has several uses; upon its top side half round brass strips enable the mould to pass easily and rapidly to and fro. It also forms a rest for the mould, ready to the vatman's hand, and, further, being provided with a curved support at its lower end called an

"ass," the mould with the freshly made sheet upon it, rests and drains until taken away by the "coucher"

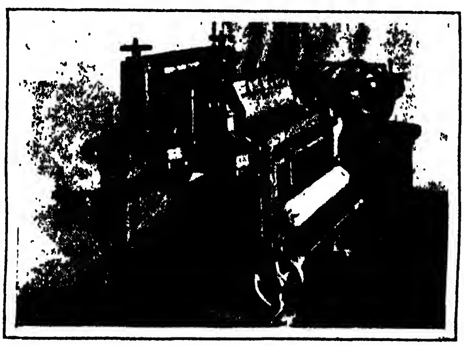
The mould [32] next occupies our attention. There are two to each vat, and each is a mahogany frame about 1½ in. deep, as light, true, and rigid as possible, and of the size of the required sheet of paper. Transverse brass wires passing through and over light wooden bars help to keep the frame taut, and form a support for the top wire which covers its entire surface. The covering wire determines the markings of the sheet of paper, and, as with machine-made paper, are described as "laid" [32] or "wove." These are called "face" wires and upon them the device, name, date, etc., are fixed by fine wire, and this forms the watermark. Fitted to each mould is the "deckle," also a light mahogany frame, having a rebated edge which accurately fits over the mould frame and forms a raised edge above the face wire all the way round. Only one deckle is in use to a pair of moulds, and it is in the hands of the vatman practically all the time.

35. SET OF STUFF CHESTS

The "coucher," or the man who turns off the sheet of paper from the mould, stands at the bottom end of the vat and opposite to the vatman, and the "layer," usually a lad in his apprenticeship, is still further away from the vat and practically in line with the vatman. These three are a "vat's crew."

36. LECHLER'S SPRAY

The Vathouse. The vatman, taking a mould with its deckle in position, dips it into the pulp which, flowing over the deckle edges, forms a regular stratum on the upper or wired face of the mould. As the mould is lifted clear of the pulp a partial vacuum draws the stratum of pulp on to the wire, and then with an individuality separate and distinct from all other vatmen he weaves and interlaces the fibres by shaking the mould and contents transversely and longitudinally, and finally by a fillip throws the surplus water from off the mould; and within the deckle edges lies the sheet or sheets of paper. There may be two, three or even four sheets on one mould, but usually only one. It is just here that the secret of "hand mades" lies. No mechanical device can, or will, adapt itself to changing conditions and perform similar and equal work.



37. CUTTER

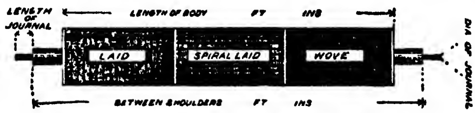
The Coucher. Meanwhile the coucher takes the resting mould with its paper and turns it edge downwards on to a pile of soft felts, slightly larger than the mould itself. With a rolling motion, also peculiar to each man, the mould is pressed face downwards, and, as it is again lifted, it leaves the paper on the felt. The mould is returned to the bridge, another felt is laid over on the paper just deposited, and then the operation of couching a second is repeated. This goes on, paper and felt alternately, until a "post"—that is, a certain number of felts—are piled upon an equal number of layers of paper, the pile supported upon an elm plank, which, with its load, is placed under a pressure of 200 tons between head and table of an hydraulic press.

The effect is that enough moisture has been removed from paper and felt as will enable the sheets to be taken safely from the felts, and yet not to crush the paper. Again the post retraces its steps, this time to the layer, who takes each sheet of paper with both hands, and evenly and exactly places them one upon each other, and with his right hand throws the felt for the coucher to use. In this way with perfect regularity of time and motion, the sheets of paper are made, couched, and laid, and instead of a post, the wet sheets of paper are laid together and called a *pack*. The day's work, however, is reckoned by posts—a certain number of posts corresponding to a given size and sort is mutually agreed upon between the trade and the employer.

The pack, as we now describe the sheets of paper in bulk, is pressed between zinc plates, and then taken to pack sorting-room. Here, women and girls sort again every single sheet, keeping each pack intact, and these are now sent to the drying loft.

Drying Lofts. The drying of hand-made papers is usually done on "cowhair lines," which are found to be cleanly, and leave no stain—an important consideration. The "dry workers" take the packs, and with these rows of cowhair lines overhead, pick up several sheets of paper with the left hand, and, holding a wooden tee in the right hand, catch the suspended sheets as nearly as possible in the middle of their lengths, and raising them by the tee, pass up one end over the hair line. Two men work side by side, and these lines are in frames holding 15 to 25 lines, long enough to take from six to eight widths of paper. When filled as described, the frames are lifted up on the shoulders of the dry workers, who stand on ladders, and the vertical posts, four to each frame or "room," as it is called, are fitted with movable pegs, which support the weight and enable tier above tier to be fixed.

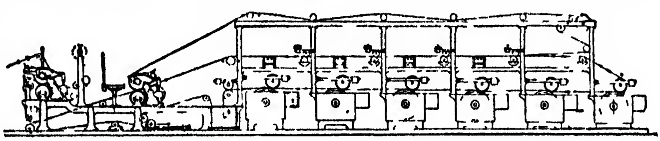
The lofts are usually high and narrow; two rooms in width are rarely exceeded, but in length any convenient number. When filled, thousands of sheets hang in these lofts, tier above tier regularly in rows and even in line. The heat for drying is obtained from steam pipes on the floor, ventilation by "louvre" windows and other methods. Under the roof, all lofts should be ceiled, and wooden partitions effectively divide lofts. When dried, the paper is taken down from the lines, and it is called "waterleaf"—that is, it is absorbent, really a blotting paper—and before it can be used for writing and printing it must be sized.



38. MARSHALL'S DANDY ROLL

When successfully sized, the sheet of paper may be written on and erased, written over and erased again, still opaque and resisting the ink to the last thread. The sizing process has already been described. The hand-made sheet, after tub sizing, is dried on lines in the same manner as the waterleaf, but a continuous web is treated differently.

Skeleton Drum and Festoon Driers. For the production of a continuous web the drying is effected by passing it over skeleton drums in the centre of which small fans revolve at different speeds according to the condition of the paper. These cause the cool air to impinge on the surface and accelerate the drying. A long dryer may be sufficient to accommodate three-quarters of a mile of continuous web. Perhaps the more modern method is to dry paper by means of a festoon machine. The latter permits free shrinkage of the paper, and does not cause a "quiver," as with the skeleton drums.

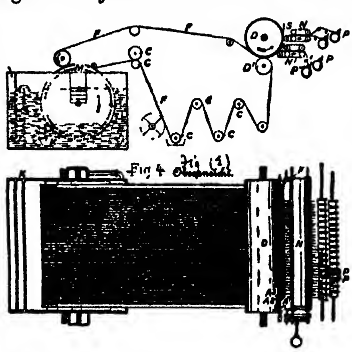


39. ELEVATION OF TRIPLEX CARDBOARD MACHINE
(James Milne & Son, Ltd)

When the sized paper is dried it passes over a cutter. If necessary, it is slit longitudinally with circular knives, and then cut transversely into the sizes required by the wholesale stationer.

Single-sheet Sizing of Machine-made Papers. To obtain the best possible results with machine-made papers the waterleaf can be cut into sheets before immersion in the sizing trough, when it is treated by one or other of the methods employed for sizing and drying hand-made papers.

An excellent method of providing heat for single-sheet drying is by turning the steam boiler economiser into an air heater. This is done either by entirely replacing the ordinary economiser or by putting down a supplementary air-heater. Hot air so produced can be used for drying either waterleaf or sized sheets.



40. MACHINE FOR MAKING PAPER YARN BY TÜRK'S PROCESS

Paper Machine. Up to 100 years ago all paper was made by hand. The paper machine was the invention of a Frenchman, Louis Robert, who brought his invention to England, where, with the assistance of Henry and Sealey Fourdrinier, the help afforded by Gamble and Didot, and the ingenuity of Bryan Donkin, the invention was ultimately made a success. We have already traced the progress of the beaten stuff to the stuff chests. These are large reservoirs made of wood or metal, and provided with mechanical agitators [35].

The pulp from the stuff chest is raised by means of a stuff pump to a constant head, whence it is delivered by an automatic control arrangement to a mixing-box, where it is diluted with water, and, if necessary, heated by steam. The stuff in the chest contains, say, 5 per cent. fibre and 95 per cent. water. After passing the mixing-box, it contains, say, from ½ per cent. to 1 per cent. fibre and the rest water. It then flows over a sand table, a wide trough fitted with numerous cross-pieces of wood at intervals of about 3 in.; in between these cross-pieces any heavy impurities, such as sand, grit, particles of buttons, etc., settle.

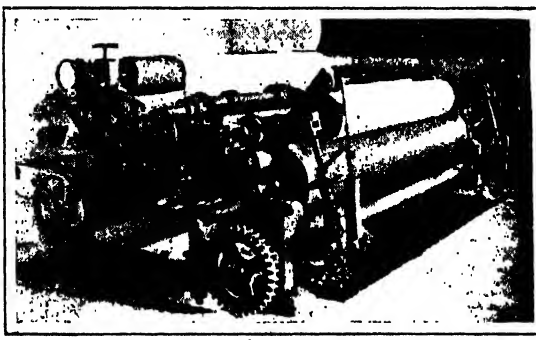
The Strainer. The stuff then passes to the "knotters" or "strainers." These are of different forms. A common form is the bellows strainer. A substantial plate of brass or gunmetal perforated with numerous very narrow parallel slots, and having sides to it — in old types provided with lugs — is fastened to an outer frame of iron, the bottom of which consists of a movable plate attached to the frame by an indiarubber connection. The plate, when in operation, lies horizontally. The movable plate forming the bellows is actuated by an eccentric on a shaft, or by a toggle joint, which gives to it a very rapid up-and-down motion or quiver, causing the stuff in the "knotter" to vibrate and to draw at lightning speed in and out of the slots. The principle is this. All fibres tend to point in the direction of the current. As the current is promoted in and out of the slots, the fibres pass through end on, whereas all knots, untreated stuff, and other particles too large for the slots are retained on the surface of the "knotter." The "retained knotted stuff," as it is called, was formerly removed by hand by scooping it out from time to time, but is now automatically removed by an arrangement which scrapes the surface at regular intervals. It would be impossible without such contrivances to make clean paper. The progress of the stuff from start to finish is shown in 38.

The stuff next passes to the breast-box of the machine, where it overflows a lip on to an endless wire band, which latter, in addition to travelling forward at from 40 ft. to 500 ft. per minute according to circumstances, receives a lateral shake to promote the felting of the fibres. The wire cloth is supported on a number of tube rolls, which are actuated by the wire passing over them. The formation of foam often gives much trouble on the paper machine, detached particles come away and spoil quantities of paper. Many remedies, both mechanical and chemical,

have been suggested and tried from time to time. Perhaps the most effective method of destroying the foam is to direct a fine spray on to the breast-box or between the sieves, as shown in 36. A large amount of water drains through the wire into the "saveall," a tray placed beneath to catch it, whence it is returned by auxiliary pumps to the mixing-box to be used over again.

In between two of the suction boxes is sometimes fixed a "dandy roll" [38], by means of which the "laid" and the "wove" texture, as also the water-marking, is imparted to the web. The dandy roll rests on the surface of the wet stuff, and is revolved by contact with the moving wire. It is made of brass or gunmetal, and consists of two spindles, one inside the other, to which are fitted at regular intervals numerous thin discs or flanges as support to the wire gauze which covers the roll. It is necessary to provide that just sufficient water remains in the stuff as it reaches the dandy: this is controlled by the suction boxes. On the surface of this gauze is fastened the watermark, consisting of lettering and design. In place of vacuum pumps a vacuum ejector is often used whereby an absolutely uniform vacuum can be maintained.

After the suction from the last box, which makes all the difference between a "wet" and "dry" surface, the wire bearing the web of partially-formed paper dips down and passes between the "couch rolls," the top roll of which is covered with a thick specially manufactured felt jacket, made all in one piece so as to fit on without a seam. Pressure exerted by this upon the lower roll bearing the wire further removes the water. On the top of the "couch roll" is a "doctor," consisting of a cross-piece of wood covered with felt, pressing tight against the surface so as to form a channel along which water can be made to flow to remove any dirt or loose material. The paper, which can now move without a support, passes from the couch rolls to the first wet felt, which is a continuous web of felt passing between squeezing rolls where more water is removed, and thence to the second wet felt and squeezing rolls, and sometimes to a third. The web of paper is manœuvred so that first the under-side and then the top side comes into contact with the wet felts, thus insuring that both sides receive as far as possible equal treatment. The web now contains, say, 27 per cent. dry weight of fibre and 73 per cent. water. This water has to be driven off by heat, as pressure has removed all that it possibly can. This is accomplished by leading the web in zig-zag fashion over cylinders usually heated by exhaust steam from the engine which drives the paper machine. The web is kept in contact with the cylinders by the "dry felts," and when perfectly dry is either passed over the calenders, reeled and sold in the rough, or taken to the sizing room. The dry felts are kept dry by additional cylinders (felt dryers) kept straight by autoguides and kept taut by autostretchers.



41. LUMSDEN'S PATENT REELER

Finished paper generally reaches the cutter [37] or reel [41] in an over-dry condition—that is, containing less than its normal moisture. On storage or exposure the paper, of course, regains its normal moisture.

Board Machine. In 1809 Dickinson invented a machine for making paper on an entirely different principle to the Fourdrinier. It consisted essentially of a cylinder covered with wire gauze revolving vertically immersed in a trough of beaten pulp. The water passes through the gauze, leaving a film of paper on the surface, which was pressed against an upper roll revolving in contact with the gauze-covered cylinder, and then passed by means of an endless felt to the couch rolls and afterwards dried over steam cylinders. These first machines were, and still are, used for making special papers; but the principle is applied in the modern board machine. Figure 39 shows a machine on the above principle which will make triplex boards. Each cylinder gathers up its quota of pulp and transfers it to a felt which moves in the direction of the arrows. The mass on the felt, from being one thickness or ply at the first cylinder, becomes successively 2, 3, 4, 5, 6 ply. The two outside cylinders constitute the outside surfaces, which may be of different colours and composition. The four middle cylinders build up the "middles." The middles is all of one composition, and is reckoned as one, so that the board is called triplex because it has three distinct layers. Three cylinders are enough for a thin board, but five are needed for a thick one, and as the thickness of the "middles" is often much more than half the total thickness, more cylinders are required to build it up. The outer cylinders often give merely a thinnish coating of superior material, the middles being often made of mechanical, broke, and very cheap materials.

Uses of Wood Pulp. There are a number of ways in which wood pulp is used outside that of making "news" and other cheap papers. One of these, which is likely to attain considerable importance in the future, is the manufacture of paper yarn. This, as the name indicates, consists of continuous threads of paper which can be woven into the form of a material either with or without the addition of a small quantity of cotton, wool, "shoddy," etc., and the resulting products are likely to prove valuable substitutes for jute baggings, coarse tailoring stuffs, etc.

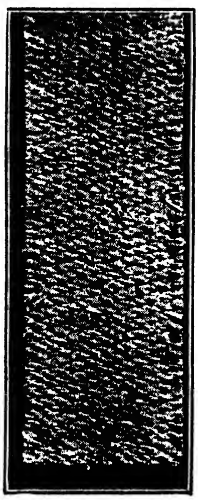
If we refer back to the different fibres used in paper-making it will be remembered that the length varies very much, cotton, linen, and some wood fibres being an inch or more in length, while straw and esparto fibres measure only a small fraction of an inch. Although the ultimate fibre of jute is short, the filaments, the real spinning units, are long. The paper-maker can use any of these fibres, but the spinner only the longer ones. This is largely owing to the different methods employed in the two industries.

In the manufacture of paper yarn, two qualities are combined—namely, the felting and spinning

qualities. The fibres are first treated so as to make paper, which is then cut into long strips. These strips are then treated in spinning machinery, similarly to "sliver" [see page 1723], with the formation of threads. Although the process is a new one, it has already undergone quite a number of modifications and improvements. We shall confine ourselves to a description of the most recent.

How Paper is Prepared for Spinning. Of the modern methods there are two, known respectively as Türk's and Kron's processes. Both of these start by making a thin sheet of unsized pulp, and the fibrous material is usually wood-pulp, preferably chemical wood. Although it is quite possible to introduce rag, hemp, linen, or other fibres, it has yet to be proved whether the advantage gained would compensate for the extra cost. It is considered necessary to form the thin sheet of pulp into a number of individual strips, to avoid the expense of cutting a ready-framed wide web into continuous narrow strips, as well as to give the natural or deckle edge which, to a paper-maker, has obvious advantages. Türk, who uses a cylinder or board machine, fixes to the wire cloth a number of parallel metal strips encircling the cylinder. As the water cannot permeate the cloth where it is covered up by metal strips, no fibre is deposited on these points, and the sheet of pulp, when formed, is already separated into a number of strips corresponding to the distance between the strips of metal, or, in other words, to the available width of exposed wire cloth. The general arrangement is shown in **40**. M is the cylinder of the board machine, F′ the endless felt, DD′ couch rolls, and N the condenser. [For a description of the action of a condenser, see page 1546.]

Kron proceeds by a somewhat improved method. He uses an ordinary Fourdrinier machine, and divides the thin sheet of pulp by numerous fine jets of water directed on to it, so that a sheet is obtained divided into strips and held together only here and there by stray fibres. It is partially dried by passing round a big steam-heated drying cylinder, and is then wound up to form a reel. By working with the Fourdrinier machine it is claimed that thinner pulp sheets can be produced, the machine can run more rapidly, and there is less waste space on the wire cloth than in Türk's process. A sheet produced on a wide machine may be divided into as many as 400 strips.



42. PAPER YARN SACKING

Paper Strips Spun. A reel of strips still damp—that is, containing 30 per cent. to 40 per cent. of moisture—is now taken to a spinning frame, by the aid of which each thin strip is twisted into a thread. The twisting of the strip greatly increases its strength.

As the strip contains 30 per cent. to 40 per cent. of water, when twisted into threads the resulting threads have to be dried before final reeling. For this purpose the material is placed in special drying rooms supplied with hot air.

The chief use of pulp yarn, or "silvaline," as it is called, when prepared by Kron's process will probably be to replace jute for preparing coarse sacking, jute bagging, etc. Figure **42** is a piece of sacking made from paper yarn; **43** shows samples of cord made from the same material. The yarn can be dyed as easily as paper, either by adding colour to the pulp or by dyeing the woven or spun material. Figure **44** is an example of a woven design.

Papers in Common Use. Even to enumerate in an article of considerable length the different kinds of papers now manufactured would be an impossibility. The classification below is merely one to give the student some general idea of those kinds of paper which must be more or less familiar to him. We have, furthermore, generally omitted such kinds as have been already referred to when dealing with the actual manufacture of paper.

BLOTTING PAPER. Formerly made entirely from soft rags, but now often made from special kinds of wood pulp and other fibres. Should be soft to the touch and handle well, and possess spongy, pliable qualities. Should be capable of being used repeatedly without smudging the writing.

BANK AND LOAN PAPERS. These are generally made of rags with a preponderance of linen. Beaten a long time with dull tackle and well sized with gelatin. Thin papers with good rattle.

"BROWNS." The best are made from rope sized with glue or gelatin and "loft dried." The commoner are made with a mixture of jute bagging, and unbleached wood pulp. Sized with resin and dried over cylinders. Should fold well and have good strength and stretch. Improve on keeping.

BOOK PAPERS. *Edition de luxe*, hand-made rag papers sized with gelatin, leaving deckle edge untrimmed. Less expensive, made with a mixture of wood pulp on machine. The best printing qualities got by addition of esparto pulp. Common printings made with mixtures of chemical and mechanical pulps. The commonest for cheap literature, little better than "news."

BIBLE AND INDIA PAPERS. Monopoly of one firm in this country, who make the finest Bible paper in the world. Excellent substitutes in Italian and German makes. Pleasing surface, and very thin and smooth. Highly opaque to prevent printed matter from being seen through. A thousand pages of thinnest occupy a little over ½ in. thickness, and yet hardly show printed matter through when read. Composition and mode of manufacture a profound secret.

CARTRIDGE. Thick papers of various composition. Must have good resistance to penetration and stand contact with powders. It has recently been discovered that nitro-glycerine exudes through some papers—rendering the cartridge useless—but not through others.

COUPON. Best hand-made with linen, well sized. Special water-mark designs. Such paper must be specially beaten to give a clear water-mark.

CELLULOID PAPER. Very thin tissue, specially made with pure cotton for nitration and conversion into celluloid.

CORPSE WRAPPING. Very tough, black paper. Retains strength when wetted; very lasting qualities. Suitable for wrapping and conveyance of fish, fruit, and other perishable articles that require protection from damp.

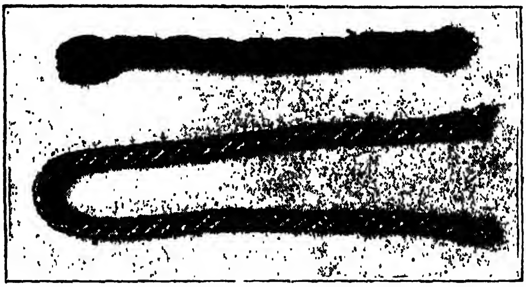
COPYING PAPER. Thin tissue, usually made from rags. Must stand wetting and take transfer of ink. Generally British; but sometimes Japanese manufacture from native fibre.

CHART PAPER. Must retain its dimensions and surface under changes of atmosphere.

CUTLERY PAPERS. Usually strong manilla; rough texture, good strength and stretch. Must be free from all substances calculated to rust or tarnish cutlery. Specially made.

CIGARETTE PAPERS. Foreign manufacture. Best made from rice straw. Thoroughly freed from encrusting matter, ash, or trace of chemicals. Must possess proper wrapping qualities.

DRAWING PAPERS. The best are hand-made from rags. Must possess special "tooth," which improves with storage and age. Some dates of "Whatman's" are specially prized by artists on account of pleasing surface. Cheaper drawings machine-made from rags; suitable for draughtsmen, engineers, and others. All tub-sized with gelatin. Should take the wash properly and show small but regular expansion when wetted so that the sheet stretches uniformly flat on drying.



43. PAPER YARN CORD

DUPLEX PAPERS. Made on cylinder machines one-half one colour and the other half a different colour, according to requirements. Suitable for box-making. *Triplex* made similarly in three layers or plies.

Usually made of commoner material such as "mechanical" or "broke" papers. The outside surface is sometimes made of mixtures of straw and chemical pulp; with or without colouring.

FILTER PAPERS. Made somewhat like blottings, but with special texture so as to retain sufficient strength when wetted. Made mostly from rags. For chemical work specially treated with hydrochloric and hydrofluoric acids to get rid of ash. Largely of foreign manufacture. Good filter paper now made with wood pulp.

FEATHER - WEIGHT PAPERS. Popular with publishers of books. Can be made of bleached sulphite or of esparto. Bleaching done quickly. Machine tackle must be manipulated to give large "bulk." "Wet felt" must be of close texture to avoid felt mark. Press rolls and couchers should be hung a little so as to give "bulk."

44. WOVEN PAPER YARN

INSULATING PAPER. For wrapping round wires for cable insulation. Large quantities used. The best made from manilla or hemp. Very strong, thoroughly thick and pliable. Mostly sized with resin. Prepared so as to ensure the greatest possible durability. Some now prepared from wood pulp.

"KRAFT." Unbleached paper, mostly Swedish manufacture, prepared from a particular kind of wood pulp. A large firm are about to make this paper in England. Good rattle, hardness and stretch. Much in favour for wrapping, etc.

METALLIC AND SIMILAR PAPERS. The fibres of papers are sometimes incorporated with metallic particles, and used for book covers or the surface is coated with aluminium, bronze powder, etc., for fancy purposes

MARL PAPERS. Brown papers with "marl," or mottled effect, produced by use of material specially manipulated. Strong and excellent.

MOTTLED AND MARBLED PAPERS. Made with cotton, linen, cotton and union rags, or with specially and separately dyed cotton, jute, wood or sulphite wood fibres. The *Silurian* writing papers are made in this manner.

"NEWS." By far the greatest output of all kinds, and lowest in price. Formerly made with rags, esparto, but now from mixtures of mechanical and chemical wood. The cheapest news made in England contains 80 per cent. mechanical and 20 per cent. sulphite, sized with a little resin. The custom of adding about 10 per cent. of clay is largely abandoned. The better qualities contain larger proportions of sulphite.

PARCHMENT PAPER. Made by passing an endless web of paper through a bath of sulphuric acid, which is washed out and the paper dried. Special qualities, strong when wet, water resistant, suitable for protecting foodstuffs against damp and air, as for tops of jam-pots and similar purposes. Takes the place of real parchment for such purposes, where moderate strength only is required.

PHOTOGRAPHIC PAPERS. Specially made from rag. Manipulation of fibres a secret. The best is of foreign manufacture. The plant used is of special construction so as to render fibres free from all injurious metallic and chemical substances. Must have suitable surface and stand the washing. Good photographic now made in England.

TYPEWRITING PAPERS. Suitable composition for high class, 40 per cent. bleached sulphite, 60 per cent. strong linen, well beaten and passed through refiner. Some American papers are mostly sulphite and are very well milled. Sized slightly with resin. With or without mineral.

WRITING PAPERS. Made formerly entirely of rags; well sized with gelatin, and coloured where necessary with ultramarine or smalts. Loaded with pearl hardening, and sized with resin and gelatin. Now increasing quantities of wood pulp in admixture. Some writings contain esparto with other fibres. Commoner writings contain "broke," some "mechanical," the rest chemical and clay. Sized with resin only.

WILLESDEN PAPER AND CANVAS. Treated in solution of copper dissolved in ammonia, which makes the paper strong and rot proof. Suitable for building purposes, and for use where great durability is required. Colour generally of greenish cast, due to presence of copper, which, however, can be obviated by substituting zinc for the copper.

EARTH & THE INNER PLANETS

The Motions of Mercury and Venus inside the Earth's Orbit round the Sun. Measuring the Sun's Distance. Weighing the Earth

By W. E. GARRETT FISHER

THERE are two known planets which move round the sun in orbits smaller than that of the earth, and as this leads to certain peculiarities in their appearance, which distinguish them from the other planets to human eyes, we may deal with them before passing on to the earth. These two, of course, are Mercury and Venus. More than once the discovery of a planet still nearer to the sun than Mercury has been announced, and this supposed planet has even been christened Vulcan, but it is almost certain that the alleged observations of it are misleading. There might, indeed, be a planet nearer to the sun than Mercury without our being sure of its existence, since its light would almost always be drowned in the solar radiance. Certain peculiarities in the movements of Mercury have been attributed to perturbations caused by the attraction of an inner planet, but the careful search made for this planet during eclipses of the sun has hitherto proved unsuccessful.

Mercury. Mercury, the inmost of the known planets, moves round the sun at a mean distance of about 36,000,000 miles. It is the smallest of the major planets, being only 3,030 miles in diameter, or a little more than one-third the size of the earth. The plane of Mercury's orbit is inclined at an angle of 7° to the ecliptic, which is more than the inclination of any other planetary orbit. The Zodiac had to be made 16° wide in order to include the apparent movements of Mercury.

The year of Mercury, or the time in which it completes its revolution round the sun, is equal to 88 of our days. Mercury certainly rotates on its axis, but it has been extremely difficult to determine the period of this rotation, owing to the lack of definite markings on the planet's surface, which, as it is seen by us, probably consists of a mass of clouds. The latest conclusion is that Mercury rotates on its axis in the same time as it completes a revolution in its orbit—88 days. In other words, its day is equal to its year, and it always presents the same face to the sun, just as—and probably for the same reason—the moon always presents the same face to the earth.

When the Day is Equal to the Year. As will be shown when we come to study the case of the moon, there are reasons for supposing that this will be the ultimate condition of all the planets, including our own—namely, that their period of rotation and of revolution round the sun will become the same. At that very distant date the dwellers on the earth (if they be not extinct) will find their planet divided into two nearly equal zones, one of which enjoys perpetual day whilst the other is sunk in everlasting night. The sun, instead of moving regularly round the earth, will only vibrate backwards and forwards in the sky for a comparatively short distance. All life will necessarily congregate on the side of the earth which faces the sun, since the opposite side will be chilled down to a temperature nearly approaching that of interstellar space. As a matter of fact, one side of the earth would thus probably become too hot for habitation and the other would certainly be too cold. The only chance for man's continued existence would then be that he should retire, as Mr. Wells supposes the inhabitants of the moon have long ago done, into vast caverns and underground cities, or possibly eke out a lingering existence in the narrow temperate zone which might still exist near the meeting place of eternal day and night. As far as Mercury is concerned this state of things has already been reached, and there is little doubt that this planet is entirely unfitted for the abode of any kind of life which we can mention. Mercury possesses no satellites. Its apparent movements and orbit will be described along with those of Venus.

Venus. Venus, which is the brightest and most beautiful star in the heavens, is our nearest planetary neighbour, coming at times within about 25,000,000 miles of the earth. Its distance from the sun is 67,200,000 miles, and it therefore receives just twice as much heat and light as the earth. Its orbit is almost exactly circular, and the length of its year is 225 days. Its orbit is inclined to the ecliptic at an angle of 3½°. The diameter of Venus is about 7,700 miles, or very slightly less than that of the earth.

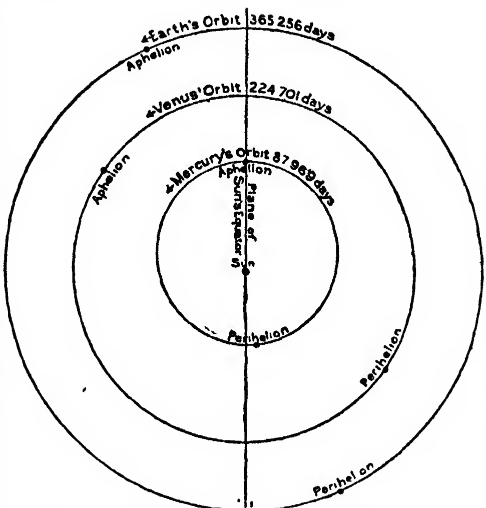
The planet rotates on its axis, but here again, as in the case of Mercury, there is great difficulty in measuring its angular velocity, owing to the apparent covering of the planet with clouds which afford no definite fixed point for our telescopes to watch. The best modern opinion is that Venus, like Mercury, has a day of the same length as its year, and continually presents the same face to the sun. If this be the case, Venus, like Mercury, must be unfitted to be the abode of life, and it is, to say the least, doubtful whether the proximity of these planets to the sun ever allowed life, which seems to us to be limited to a very moderate range of temperature, to be developed upon their surface. Venus appears to be surrounded by an atmosphere of considerable density, and possesses no known satellite.

Morning and Evening Stars. The apparent motions of Mercury and Venus present great similarity, and may conveniently be described together. They are both visible at different times of the year as morning or as evening stars. Venus is pre-eminently known as the Evening Star, or Morning Star, on account of its resplendent beauty, "sweet Hesper-Phosphor, double name." Mercury, though very nearly as bright as Venus, is very much less easy to perceive, on account of its greater proximity to the sun. The great astronomer Copernicus is said to have passed his whole life in unavailing endeavours to perceive Mercury—though this is perhaps an exaggeration. The planet can be seen several times a year by those who know where to look, but it is generally drowned in the sun's radiance. Everyone, however, is familiar with the brilliant appearance of Venus, whether shining as the Evening Star after sunset

or as the Morning Star which heralds the appearance of the sun.

Apparent Motions of Mercury and Venus. The essential peculiarity of the motions of Mercury and Venus is that they are never seen very far away from the sun. Mercury never remains visible for more than an hour or so after the sun has set, and Venus is always seen as an evening star in the west or a morning star in the eastern sky. They are never visible, like others of the planets, right overhead. If we study the motions of Mercury or Venus from night to night, we very soon begin to perceive their regular changes. Venus, being so much easier to perceive, offers a very good object for the young astronomer to watch from week to week.

After a while it becomes apparent that this planet moves backwards and forwards on either side of the sun, within a limited range. Suppose that at the time of beginning our watch Venus is shining as the brilliant Evening Star after sunset. For a time it seems to travel farther and farther eastward, or away from the sun, and consequently to remain visible for a longer time each evening. But the time soon comes when we notice that it ceases to go farther away from the sun; it remains stationary for a night or two, and then it begins to travel back towards the sun until it is entirely swallowed up in the solar radiance and is invisible for a time. After a short period of invisibility, Venus emerges on the other side of the sun and consequently becomes visible in the morning shortly before sunrise. As it continues to move to the west of the sun, it rises earlier and earlier, till again it reaches the limit of its western motion, remains stationary for a short time, and then again starts on its eastward journey back toward the sun, ultimately to emerge on the eastern side of the sun and again become the Evening Star.



22. ORBITS OF VENUS AND MERCURY

At the dawn of astronomy the Morning and Evening Star were supposed to be distinct bodies, which were named Phosphorus and Hesperus; one of the first astronomical discoveries was that they were really the same star, which journeyed backwards and forwards from one side of the sun to the other. The apparent motion of Mercury is precisely similar, though less easy to watch because it is confined within much narrower limits. The angular distance of these planets from the sun on either side is known as their *elongation*. When they are in a straight line with the sun and earth, they are said to be in *conjunction*.

The Orbits of the Evening Stars. The real explanation of these motions is not difficult to comprehend. Venus and Mercury both move round the sun in roughly circular orbits inside that of the earth [22]. Consequently, the effect of perspective shows them to us as if they moved in a straight line backwards and forwards from the sun [23]. If the earth were at rest, each planet would complete its double oscillation in the period of its year. Venus, for instance, would pass from her farthest eastern to her farthest western elongation in 225 days. But as the earth is also in motion round the sun this simple motion is complicated by our own motion. Instead of the easterly and westerly motions of Venus or Mercury being completed in the same time, the westward swing appears to be completed much more rapidly than the eastward, because in the former case the earth's motion assists that of the planet, but in the latter it detracts from it. Thus, Venus moves rapidly from its easterly elongation as the Evening Star to its westerly elongation as the Morning Star, and travels back again much more slowly.

Its *synodic* period, or the period in which it completes this cycle with reference to the earth, is 584 days; more than three-quarters of this period is occupied in the slower half of the journey. The synodic period of Mercury is 116 days. The greatest elongation of Venus, or its apparent distance from the sun, varies from 47° to 48°, which means that when it is farthest away from the sun it may be visible for more than three hours after sunset or before sunrise. Mercury's greatest elongation varies from 18° to 28°, so that under the most favourable circumstances it is visible for less than two hours before sunrise or after sunset.

Phases of Mercury and Venus. One of the first discoveries made by Galileo's telescope was that these two planets, Mercury and Venus, exhibited phases like those of the moon. The other planets always shine with a full circular disc, though it varies in apparent size with their varying distance from the earth. But Venus and Mercury, when seen through a telescope, present the phases with which we are so familiar in the moon. These phases will be readily understood by a glance at the diagram [23]. They depend, of course, upon the fact that the planet derives its light by reflection from the central sun, and moves round the sun between it and the earth. When at *inferior* conjunction the planet is between us and the sun; we see only its dark side, or, in other words, do not see it at all. As a matter of fact, it is then swallowed up in the sunbeams, and the only occasion when we have an opportunity of testing the truth of this part of the theory is when Venus or Mercury passes right between us and the sun. It then appears in *transit* as a circular black spot on the sun's disc.

At the *superior* conjunction it is beyond the sun, and nearly in a straight line with it from the earth. At these times we cannot see it at all, because of the solar brilliance; but if we could see it we should see its disc fully illuminated like that of the moon. At the times of greatest elongation the planet appears like a half-moon; a good field-glass or small telescope will clearly show these phases when Venus is shining as the Evening Star, from two to three hours after sunset. At other times the

planet exhibits various lunar phases, being gibbous as it passes from one elongation to the other beyond the sun, and waning to a crescent as it completes the other half of its orbit. The same explanation applies to Mercury, though its proximity to the sun makes its phases less easy to follow.

The Earth as a Planet. The third planet in order of distance from the sun is by far the most interesting of all, because it is the earth on which we live. Some explanation must here be given of the way in which astronomers have measured the size of the earth's *orbit*, or annual path round the sun, which affords a basis for all our measures of celestial distances. In the first place it must be said, though the explanation of the fact must be looked for in more advanced treatises, that the mathematical theory of astronomy, based on Newton's law of gravitation, gives us all the *relative* measurements of the solar system with great accuracy, but does not determine any one of them *absolutely*. That is to say, if we know any one of these measurements, we can easily calculate all the others in terms of it. The most obvious measurement to use as a basis or unit is the distance of the earth from the sun. The early Greek astronomers made ingenious but futile attempts to calculate this by geometrical constructions, but the problem was too complicated for them. Modern researches have been carried on by means of two distinct methods, which have yielded results practically similar, and have enabled us to measure the earth's mean distance from the sun within a very small margin of error.

The Sun's Parallax. The first and older of these methods depends on what is called *parallax*. Parallax is a name given to the difference between the directions of a celestial body as seen from two different points. It is the same principle which is utilised in the trigonometrical operations of ordinary surveying. The surveyor measures the base line AB of a triangle [**25**] in order to determine the position of a third point C. He then sets up his theodolite first at A, and then at B, and measures the angles CAB and CBA—or, in popular language, the difference of direction of C, as seen from A and B. When the length AB and any two of the angles of the triangle ABC are known, it is a simple trigonometrical calculation to find the length of the other sides CA and CB [see MATHEMATICS, pages 6231 and 6373]. In celestial surveying, or astronomy, we begin by measuring a base line on the earth.

We can now understand the principle on which the measurement of the sun's distance by its parallax is based. In the diagram let A and B represent two stations on the earth, separated by a known distance AB, and let C represent the sun or planet whose distance it is desired to measure. If two observers simultaneously observe the direction of the sun or planet, and combine their observations, we then have a triangle in which the length AB and the angles CAB and CBA are all known, and it then becomes possible to calculate the distance AC or BC.

This is merely a rough illustration of the method used, which is really much more elaborate, and involves a great many minute corrections which we have no space to explain. But the principle of it will now be clear. Such measurements require to be made with the greatest accuracy, because the distance of the sun from the earth is so great in comparison with the longest base that can be drawn on the earth that the difference between the directions from which it is seen from any two points at the same time is exceedingly small.

There is, however, another quite independent method of estimating the distance of the sun. It will be clear that we could measure the distance from London to Edinburgh with considerable accuracy if we knew that a motor-car, built so as to run uniformly at twenty miles an hour, had taken a specified time over the journey. We have a messenger of this kind, warranted to move with a perfectly uniform speed, in the ethereal vibrations which constitute light. It was discovered 200 years ago that light did not traverse space instantaneously, but took a definite time in completing a journey of a given length. In the course of its yearly journey, the earth moves from end to end of the diameter of its orbit—a gigantic base line of more than 180,000,000 miles.

The Sun's Distance Measured by the Speed of Light. The Danish astronomer Roemer found that his observations of the eclipses of Jupiter's satellites, whose motions are so well known that the times of these eclipses can be calculated in advance, varied as much as sixteen minutes from one another at different times of the year. Some of his observations showed that these eclipses happened about eight minutes sooner than the predicted time. Six months later the observation was eight minutes behind the time given in the tables. It is from such discrepancies between calculated events and observations made as accurately as possible that a great many of the most valuable scientific discoveries have arisen, since they always point to the existence of some previously unsuspected cause which modifies the phenomena under study.

Roemer, on thinking it out carefully, saw that the only difference in the conditions between the two sets of observations was that the earth was at opposite ends of its annual journey; in other words its distance from Jupiter, which does not move far in six months, varied in that time by about the diameter of the earth's orbit, or twice the distance from the sun to the earth. He then saw that if he assumed that light took about 8 minutes to travel from the earth to the sun, the discrepancies between his observations and the predicted times of eclipses might be satisfactorily explained. These eclipses having been calculated with the sun as starting point, when the earth was at its nearest approach to Jupiter light from that planet, bearing the message of the eclipse, would reach it eight minutes sooner than the sun, and, consequently, the eclipse would seem to happen eight minutes too soon. Similarly, six months afterwards, when the earth had rushed to the other end of its orbit, the light would have to pass the sun and travel on as far again, and the eclipse would appear to happen eight minutes later.

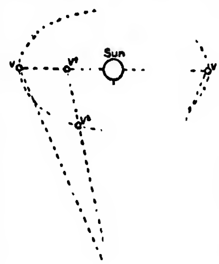
The Fundamental Astronomical Unit. It is possible with the exact instruments of modern science to measure the velocity of light in our laboratories, and from such observations as those of Roemer can be measured, with equal accuracy, the time which light takes to travel from the earth to the sun. This physical method of measuring the sun's distance is quite independent of the parallactic or astronomical one, and the two give results closely in accordance with one another. From these various methods the earth's distance from the sun is known to be about 92,900,000 miles, the probable error not being greater than 100,000 miles either way. This distance of the sun is the fundamental unit of astronomical measurements, in terms of which all others are calculated, though we shall see when we come to the fixed stars that another and larger unit has there to be adopted.

When the actual distance of the earth from the sun has been found by either of these methods, all the other dimensions of the earth's orbit and the rest of the solar system can be calculated from it. Another very important unit is the earth's *mass*, which is found by experiment, and from which the laws of dynamics enable us to calculate the mass of all other bodies which compose our system. There are various methods of weighing the earth, which all depend on the same principle as that by which the mass of any comparatively small quantity of matter is determined.

The Mass of the Earth. The most trustworthy of these is that used by Cavendish, the famous chemist of the eighteenth century, and generally associated with his name, though later workers have obtained still more accurate results from its use. The law of gravitation tells us that two masses attract one another with a force which is always proportional to the product of their masses. The *Cavendish experiment* consists in measuring the attraction which a massive globe of lead has for a small pith ball, and comparing this attraction with the weight of the pith ball. The weight of a body is simply a convenient way of measuring the attraction which the earth has for it; we are, therefore, able to say that the mass of the earth is to the mass of the leaden globe as the weight of the pith ball is to the force with which the leaden globe would attract it if placed at the same distance away from it as the centre of the earth, from which terrestrial gravitation is measured. The observation is a very delicate one, as it involves measuring forces not greater than the weight of the millionth part of a grain; but considerable reliance is placed on its results, and the density of the earth is known with fair accuracy to be about $5\frac{1}{2}$ times that of water.

Other methods used for determining the mass of the earth, such as the Schehallien and the Harton experiments, are much less trustworthy, but on the whole lead to the same result. From the known size of the earth we can calculate its volume, and its mass being determined by the Cavendish experiment gives us its mean density. The actual mass of the earth is 6×10^{21} tons—or 6 with 21 noughts after it. This gigantic mass cannot be realised by any mental process of which we are capable. In astronomical work the mass of the earth is taken as the unit to which the mass of other celestial bodies are referred. Thus, the mass of the sun is given as 332,000 times that of the earth; and Jupiter, the largest of the planets, is 317·7 times as massive as the earth. The smallest of the telescopic planets is probably much less than $\frac{1}{10000}$th part of the earth's mass.

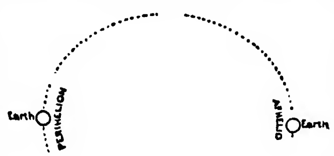
The Orbit of the Earth. The earth's orbit, as we have already seen, is an ellipse of which the sun occupies one focus. This orbit is very nearly circular, the eccentricity of the ellipse being only about $\frac{1}{60}$th [24]. The points in the orbit at which the earth is nearest to and farthest from the sun are respectively known as the *perihelion* and the *aphelion*. The earth reaches its perihelion about December 31st, and its aphelion early in July. It would seem at first that the earth should be nearest to the sun in summer and farthest from it in winter. But our seasons depend upon the fact that the earth rotates about an axis which is inclined to the plane of its orbit at an angle of rather more than 23°. This axis always remains pointing to the same points in the sky, which are known as the celestial poles.



23. APPARENT MOTION OF VENUS

When the earth is in perihelion its north pole is inclined away from the sun, whence it follows that in the northern hemisphere the nights are then longer than the days, and the total quantity of light and heat which that hemisphere receives from the sun is a minimum, while in the southern hemisphere these conditions are exactly reversed. Consequently when the earth is in perihelion it is mid-winter in the northern and mid-summer in the southern hemisphere; when it is in aphelion it is mid-summer in the northern and mid-winter in the southern.

A Model of the Season Changes. The student will find it quite easy to understand why this is the case if he will make a rough model of the earth by running a knitting-needle through the core of an apple, and trace the equator round the middle of the apple at right angles to this axis. If he then takes a lighted candle to represent the sun and moves this model earth round it, taking care to keep the axis inclined at an angle of about 23° to the plane of the table on which the lighted candle stands, he will get a very good idea of the seasonal changes which are a necessary consequence of such physical arrangements.



24. THE EARTH'S ORBIT

He will also see that there are two, and only two, points in the earth's orbit at which the plane of its equator passes through the sun. When the earth is at these points both hemispheres are equally illuminated, and day and night are of equal length, whence these points in the orbit are known as the vernal (or spring) and autumnal *equinoxes*. The points in the orbit at which the northern hemisphere has respectively its maximum and minimum illumination are the summer and winter *solstices*, because at these points in the orbit the sun has reached its highest place in the sky and appears to stand still for a day or two before beginning its reverse journey. The sun's apparent motion in the sky is compounded of the earth's rotation and its revolution in the annual orbit. Every day it travels across the heavens from east to west, because the earth is rotating from west to east and carrying the observer with it. Every year the point where the sun *culminates*, or reaches its highest place at noon, travels steadily upwards in the sky from mid-winter to mid-summer and then sinks down again at the same rate.

SHIP MANAGEMENT continued from page 6366

THE DUTIES OF A SAILOR

The Apprentice Sailor. Making Knots and Hitches. The Management of Sails. Rules of the Road. Signalling at Sea

By J. P. LORD

THE basis upon which the whole calling of a sailor rests is a sound knowledge of seamanship and navigation. Seamanship must be learnt first, for there is little benefit in being able to find out the position of a ship and the direction in which she is to sail if one cannot make her take that direction. For this reason the Board of Trade insists that the candidate who fails in seamanship shall go to sea for six months prior to presenting himself again for examination.

First Duties. The first matter that will engage the attention of the apprentice or boy on board a sailing vessel will be to make himself acquainted with the names and positions of the several sails, and more particularly the numerous ropes pertaining to or in the management of them—namely, the *yards* on the masts, and the *braces* by which they are trimmed to the wind. Then the *halyards* and *downhauls* and *reef-tackles* by which they are controlled will have to be learned. The majority of these ropes are led through *fairleads* attached to the *shrouds* and *backstays* on each of the masts, but some lead down by the sides of the masts themselves. The names and position of these ropes are not difficult to learn, but this knowledge is of more importance than almost anything to which a boy can give his attention. His duties during his watch on deck will be concerned with certain articles of ship's furniture—namely, the deck-buckets, brooms and scrubbing brushes, swabs and cloths, etc. These he will have to get ready for the daily wash down of decks and paintwork, and see to their being put carefully away after this operation is finished. The boatswain's gear, such as marlin-spikes, serving-boards and mallets, spunyarn and marline, tar and grease-pots, used when repairs or renewals of ship's running or standing rigging are going forward, will have to be fetched and returned by the young sailor. He will be in attendance on the seamen engaged on this work either on deck or aloft, and in this manner gains a knowledge of how a ship's equipment is kept in working order, and the chafing of gear prevented as much as possible. As youngest apprentice or boy, his place in his watch on deck at night will be on the lee side of the poop, handy to the officer of his watch; he will keep the time and strike the bell every half-hour, and see that the binnacle lamps are kept burning brightly. There is a good deal of drudgery for the beginner, but if his heart is in his work he will soon be given more responsibility.

Knots. The principal knots that a sailor must be able to tie are as follow:

OVERHAND KNOT, OR SIMPLE KNOT [1]. Pass the end of the rope round the standing part, and through the bight. The standing part is supposed to be the fixed part of the rope, the end is the free end, and the bight is a loop formed by the rope.

FIGURE OF EIGHT [2]. Pass the end of the rope round the standing part, under its own part, and through the bight. Its own part is where the end first meets a portion of itself which has been used.

HANDSPIKE HITCH [3]. Rope fastened at each end. Make a bight in it. Pass handspike down through bight, under underneath portion of the rope, and force it up till the end, lifting the rope, passes over the other side of bight. On pulling out the handspike the rope is again free.

COMMON SHEET BEND [4]. Two ropes. Form bight with 1. Take end of second rope, pass through bight of 1, and round both parts of 1, and then under its own part. This will jam against the edge of the bight.

COMMON BOWLINE [5]. One rope Some little distance from the end form a bight in rope with a half twist, making a loop. Pass end up through this loop, round standing part and down again through loop

REEF KNOT [6] Joining two ropes Make bight in 1, with end and standing part side by side. Pass end of 2 up through bight, round both parts of 2 and down through bight again. Or pass end of 1 round end of 2, then bring two ends back to their standing parts, passing one part round the other so that two parts of each rope pass through the bight in the same direction.

CARRICK BEND [7]. Two ropes Cross bight of 1. Pass end of 2 through bight, over end of 1, round standing part of 1, over its own part, and through bight again, both parts coming out of bight at different sides.

SLIP KNOT. This is the common slip noose of the schoolboy.

FLEMISH LOOP [8] Make slip knot, and then with end make overhand knot round standing part, away from loop.

CHAIN KNOT AND TOGGLE [9]. Chain knot is a succession of slip knots, known to schoolboys as the drummer's knot or rat's tail. The toggle is a short bar passed through the last loop The chain knot is made by making a bight on the rope and crossing it Pass hand through bight and catch standing part. Pull this through, forming loop Repeat this for as many slip knots as may be required Pass toggle through last loop, and haul on end to tighten up.

BOWLINE ON A BIGHT [10] Place bight over the two end parts, and form loop with bight through, pass bight under the two end parts, and bring it back, through which reeve the bight formed by the double parts.

SHEEPSHANK [11]. This is a form of hitch used for shortening a warp. A piece of the middle of the rope is taken up so as to form three parallel strands, or two bights. Round the end of each bight a hitch is made with the part leading to the end. As long as the strain is maintained the knot holds. When it is desired to let out the rope one of the long sides of the bight can be prised out, or one of the hitches slackened and the end of the bight withdrawn.

CATSPAW [12]. Take a bight of rope, and from this form two bights, holding one part in each hand. Now twist each of these bights several times, with the result that you will have two small loops, each of which terminates in a twisted double rope. A spike, bar, or hook of a tackle can then be passed through the loops.

Hitches. These are used for securing pieces of timber, for attaching a rope to a hook or shackle, and for making fast cargo and weights to be hoisted. They must be mastered thoroughly, for on their security much depends.

HALF HITCH [13]. Pass the end round the spar and its own standing part, and then reeve under its own part.

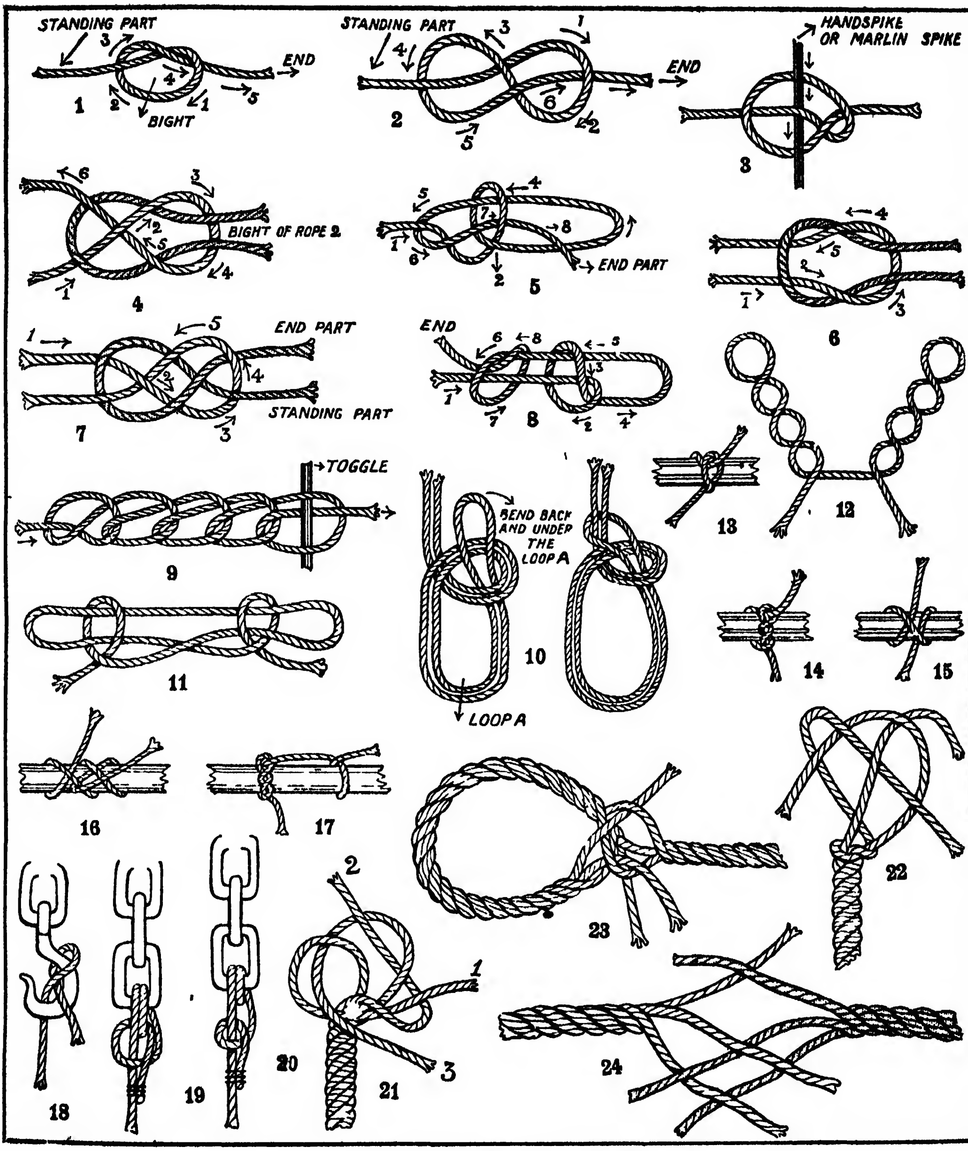
TIMBER HITCH [14]. Similar to above, but reeve several times round its own part.

CLOVE HITCH [15]. Pass the end round the spar, crossing the standing part. Then pass round spar again, and bring end through between the end part and standing part, under its own part.

ROLLING HITCH [16]. Pass end twice round spar, crossing standing part each time. Then hitch end round the spar on the opposite side to the two turns.

TIMBER AND HALF HITCH [17]. Make half hitch first, and then make a timber hitch with the end part.

BLACKWALL HITCH [18]. This is used for suspending cargo from a crane hook. Pass the end round the back of the hook, and under its own part, taking care that the two parts of the rope are on opposite sides of the hook.



SAILORS' KNOTS AND HITCHES

1. Overhand knot 2. Figure of eight 3. Handspike hitch 4. Sheet or common bend 5. Common bowline 6. Reef knot 7. Carrick bend 8. Flemish loop 9. Chain knot and toggle 10. Bowline on a bight 11 Sheepshank 12. Catspaw 13. Half hitch 14 Timber hitch 15. Clove hitch 16. Rolling hitch 17. Timber and half hitch 18. Blackwall hitch 19. Fisherman's bend 20. Round turn and half hitch 21. Wall knot 22. Crown knot 23. Eye splice 24. Crutching or marrying a splice

FISHERMAN'S BEND [19]. This is used for fastening a cable to a shackle or ring. Pass the rope twice round the ring, and put the end through the turns. For security the end must be tied to the standing part with fine cord, or "stopped back," as the proper term is.

ROUND TURN AND HALF HITCH [20]. Used for the same purpose. Pass end twice round the ring, and make half hitch round standing part. Stop end back to standing part.

WALL KNOT [21]. This is a neat method for finishing off ropes, and preventing them from unlaying. It is made in two stages, as follows:

(1) Untwist the three strands of the rope for a distance sufficient to give you three cords about eight inches long each. Call these strands, 1, 2, and 3. Make a bight with strand 1 and pass 2 round the end of it. Then pass strand 3 round end of 2 and through bight of 1.

(2) Haul ends taut, shaping the knot evenly with the fingers.

CROWN KNOT [22]. This is a further completion of the wall. Make wall and then take strand 1 over centre of wall. Place strand 2 over 1 and 3 over 2, and under 1; pull these taut. Shaping with fingers is necessary, and the crown is complete.

With a sound knowledge of these knots the sailor will be able to make his way as far as knotting is concerned; but to join ropes permanently he must be able to splice, which we shall now explain.

Splicing. Splicing is the art of interlacing the strands of ropes so as to make them practically

one cord. To separate the strands a marlinspike, which is an exaggerated steel needle, is necessary.

Eye Splice. This [23] is the method of making a permanent loop at the end of a rope. Take the end of the rope and unlay the three strands for about 4 in. Then place these against the standing part at the spot which will give a loop of the desired size. Take the middle strand and after prising up one of the strands of the standing part pass the free strand beneath it. Pass the other two strands, one on each side, under the other strands of the standing part, and work the loop up tight. Slightly taper the strands, by pulling off a little of the hemp (the usual practice is to cut one or more of the yarns composing the strands of the rope), after first tuck has been completed with all strands, and pass them under the strands of the standing part again, taking care that each free strand passes over one of the standing strands before entering beneath the next strand. The ends are now again further tapered and the process repeated a third time. All ends are now clipped off short, after the splice has been well hammered, and then fine spunyarn is bound round the joint. Binding with spunyarn when done the reverse way to the lay of the rope is called *serving*.

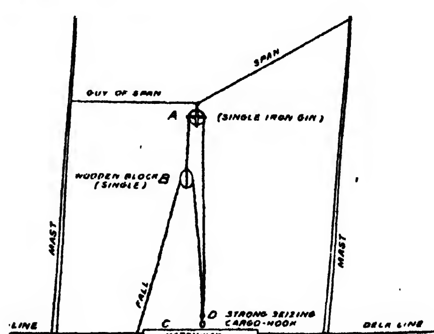
Short Splice. To make a short splice, or join between two ropes, the ends of each must be unlayed, or unravelled for a few inches. Then fit the ends of each rope accurately together, so that the ends of one lie between the ends of the other. This is called *crutching* or *marrying* the ropes [**24**]. Now pass each strand over one strand of the opposite rope and tuck it under the next strand. When this has been done once with each strand of each rope, taper the ends a little and repeat the process a second time. Clip off the ends, and if necessary serve with spunyarn.

Long Splice. This is used where no increase in the circumference of the rope is required. To begin with, each rope must be unlayed about three times further than for a short splice. Then the parts are married. Now take one of the strands of the right-hand rope and unlay it still further, filling up the groove thus made with the corresponding strand of the left-hand rope. This must be done till only a short end of the left-hand strand remains free. Repeat the operation on the left-hand rope, filling up with the corresponding right-hand strand. You will now have two long strands in the middle, and at some distance on each side of them there will be a very long strand and a very short one. Deal with each of these three points separately. Divide the strands at each point and tie the corresponding divisions together. Then take the ends at each point thus formed and tuck them under the second strand, having passed over the first one. Taper the ends and tuck them a second time over a strand and under the second from it. Hammer and stretch the rope well and cut off all loose ends.

Worming and Parcelling. *Worming* is filling in the grooves of a rope with spunyarn so as to make the surface absolutely smooth, and to prevent water from reaching the heart of the rope. It must be done in the direction of the lay of the rope. *Parcelling* is bandaging the rope with strips of tarred or oiled canvas about two or more inches wide, according to size of the rope dealt with. This must be done with the lay of the rope, and each lap must overlay the one prior to it. In parcelling rigging, parcel from below upwards, so that the overlays shed the water. Serving is done against the lay, as we have indicated. The rule is easily remembered:

" Worm or parcel with the lay,
Turn and serve the other way."

Purchases and Tackles. For lifting heavy weight, and obtaining increased power for hauling on the various ropes in a ship a number of combinations of blocks and ropes are used. The simplest is a *single whip*, which consists of a single pulley over which the rope runs. The pulley is made fast to a spar or to some portion of the rigging. Next comes a *double whip*. One end of the rope is made fast to a spar or the rigging, the other passes through a block fitted with a hook on which the weight is to be lifted. The rope then runs up and through a second block fastened to the spar or rigging beside the end of the rope, and thence to the winch or to the men who are to haul. A *gun tackle* is similar, save that the end of the rope is fastened to the second pulley, and there is, therefore, only one point of attachment to the spar. A *luff tackle* has a double-wheeled pulley at the top, and a single pulley with a hook at the bottom to attach to the cargo or sheet. The rope is fixed to the single pulley, runs up through one wheel of the double block, then down and round the wheel of the single pulley; up again, then round the second wheel of the double block and thence to the men or the winch. A *runner and tackle* is simply a luff tackle, the top block of which is suspended from a single whip. A *fourfold purchase* has a double block at the bottom as well as at the top. The rope is attached to the top block and passes twice through the pulley holes of each before being led to the winch. It is a very powerful purchase indeed. A *long tackle* differs from the previous purchase only in being made of two single blocks strapped end to end at each end in place of a double block. The rope is attached to the lower of the upper two blocks, passes through the upper of the two under blocks, through the lower of the two upper, then to the lower of the lower pair, and finally over the upper of the upper pair. A Spanish Burton is a useful tackle for lowering weights (cargo) into a vessel's hold and is almost solely used for that purpose. It consists of two blocks, one cargo-hook and a long rope (fall), and can best be explained by the annexed sketch [25].



25. SPANISH BURTON

In reeving this purchase it is necessary to know the distance from position of block A (which is generally secured to a span stretched between vessel's masts in such a manner as to be vertical over a hatchway) to the bottom of vessel's hold, in

order that the block B may not touch the upper block A before the weight attached to cargo-hook C has reached the bottom of hold. The two parts of the tackle-fall are strongly seized together at point D after its being rove through the eye of said cargo-hook and holding same in desired position.

A few days at sea will suffice to teach the would-be sailor the names and uses of the various parts of the ship, of the standing and running rigging, and we will at once give a few rigging details which the sailor may well have to perform at sea.

To Send a Topmast Down. The same instructions apply to a topgallant mast. Reeve the mast rope through a block at the lowermost head, through the sheave hole in the heel of the mast, and make it fast at the other side of the mast-head. Come up all the gear, back stays, rigging and stays, sway a little and then get the fid out. Then lower away and surge quickly just before the crosstrees come on the lowermost head. Send down all the gear with gantlines, or auxiliary ropes rove through blocks. Single the mast rope and lower the mast on deck.

To Send a Topmast Up. The same instructions apply to a topgallant mast. Lay mast on deck, after side up, and heel aft. Hook a block to eyebolt at one side of the cap, and reeve the mast rope from aft, down through the square hole in the trestle trees, along the mast, and through the sheave hole at the heel of the mast.

Bring it back along the mast, and hitch it round the masthead and the standing part of itself, leaving enough end for doubling. Rack the two parts together below the hitch. Now hoist away and point the head of the mast through the hole in the trestle trees. As soon as it is through, cast the hitch adrift and double the mast rope by taking end up through trestle trees, making it fast at the other side of the cap. Come up (slacken and let go) the racking and hoist away again, until the masthead is a few feet above the cap, and then lash gantline blocks to the topmast head, reeving the gantlines from forward and overhauling them down to the deck; bend them to the after crosstree legs and stop them to the fore; hoist away till you can rest them with the after part resting on the lower masthead, fore part against the topmast, and underside forward. Cut the stops, and the crosstrees will fall over the masthead, then heave away till the crosstrees are in their proper place. Next put on the gear of the mast; for a topmast, first the bolsters, then starboard rigging, next port rigging, starboard backstays, port backstays, and topmast stay last of all; for a topgallant mast, first the funnel or grummet, then the topgallant stay, next rigging (starboard side first), and last the backstays. A royal mast is rigged the same as a topgallant mast. In topgallant and royal mast riggings, the gear is put over the masthead as soon as the mast is pointed through the topmast cap. This done, the mast rope is hauled upon and the mast placed in position and fastened by a fid, or otherwise, according to the mast. All rigging is then tightened up and made fast.

Sending Down Yards in a Gale. These directions are for topsail yards, and for all above them; those for main or fore yards will follow. In smooth weather, such great precautions need not be taken, but it is well always to remember the sailor's proverb: "Better be sure than sorry." First unreeve the tie and reeve the yard rove through sheave hole at the masthead. Take a hitch round the lee quarter, and make the end fast to the weather quarter of the yard. Clear the yard of buntlines, clewlines, and leechlines, and of foot-ropes from the after side of the mast. Lash a preventer parral round yard and mast to keep the former close to the latter, till all is ready for lowering. Now sway away a little, and so take away the strain off the lifts. Unparral the yard, leaving the preventer parral. Take the lifts off; top the yard and stop the yard rope to the lee yardarm. Cast off preventer parral, and lower away abaft all and to windward, sliding down the other part of the yard rope, or steadying the yard as she comes down with a tripping rope. The braces are taken off as the yard comes down. When a yard is very heavy, a double purchase must be used.

Sending Down Main and Fore Yards. These, being very heavy and very long, have to be lowered athwart ship. A powerful purchase is made fast to the centre of the yard, suspended from the lowermast head, or the topmast head. At each arm a guy rope is fixed to keep the yard level as it comes down, and from the centre a whip is rove through a block on the fore side and led well forward. The purchase is hauled upon, and then the sling is unshackled and the truss unfastened. Then lower away, steadying the yard with the guys and keeping it close to the mast by the forward whip. To send up a fore or main yard, reverse the above proceedings exactly.

To Send Up a Topgallant or Top-Gallant Yard. Reeve the yard rope, abaft everything and to windward, through the sheave hole at the masthead; overhaul down to the deck and make fast about the middle of the yard, and stop it to what will become the lee yardarm. Put all gear on the yard, except the braces. Heave away, and when high enough, shackle on the braces. Cast off the lee yardarm stop when the centre is high enough. Put on the lifts and parral the yard. Let the yard take the lifts and haul on the braces. Then reeve the halyards and any other gear. For heavy yards, a purchase must be used instead of the simple yard rope rove through the masthead sheave hole.

Remember that all yards that hoist are supported by parral, lifts, and halyards, the lifts and halyards taking the weight when the yard is down, and the halyards when the yard is up. Fixed yards, such as fore, main, crossjack, lower topsail, and lower topgallant yards, are trussed.

To Send a Jibboom Out. Reeve a haul rope through a block at the cap of the bowsprit, through the heel of the boom, and make fast to the bowsprit cap on the other side. Overhaul fore and aft stays, back ropes, and guys; make flying jib halyards fast to end of boom, to keep it from tripping. Heave away till boom is far enough out, then down with the heel. Clamp it and lash preventer round boom and bowsprit.

To Send Jibboom In. Reeve heel rope as before, and slacken all gear. Make flying jib halyards fast to end of boom, and heave a little to get the heel clear. Get tackle on to heel and haul into place.

Reducing and Setting Sail. The order in which the square sails of a ship are usually set is as follows: Lower main topsail, lower fore topsail, lower mizzen topsail, foresail, crossjack, main upper topsail, mainsail, fore upper topsail, mizzen upper topsail, main, fore, and mizzen topgallant sails, main fore and mizzen royals. In some ships the crossjack is not set till after the mainsail. When reducing sails, the general practice is to take them in in the reverse order to setting them. The staysails are set

and taken in in no regular order. They are very useful in keeping steerage way on a ship, and in keeping her on her course; and the officer of the watch generally tries to keep at least one set. Here is practical example of taking in a setting sail, taken from "Reed's Seamanship."

"In a full-rigged ship, the wind begins to get up. The officer first takes in royals, flying jib, small staysails. The wind increases and all topgallant sails are stowed. As it gets worse, each topsail is reefed. If the wind gets worse, the fore and mizzen topsails are close reefed, or where a ship carries double topsails, the upper ones are stowed, the courses are reefed, and the mizzen taken in. As the gale gains power and the sea gets up, everything is stowed but the three lower topsails, the reefed foresail, and the fore topmast staysail. These would be kept set as long as the ship could stand it; then the sails would be reduced to two lower topsails, and if these could not stand, they would be taken in, the fore one first, and a storm sail set. If possible, the royal and topgallant yards would be sent down before the gale reached its height. Should the storm staysail blow away, a tarpaulin would be lashed in the rigging to take its place.

"The weather moderates, and the three lower topsails are set, with the reefed foresail and the fore topmast staysail. As it improves, the three upper topsails would follow, and then the jib and lower staysails. Next, the mainsail and mizzen or crossjack. After that, all reefs would be shaken out, and lastly the topgallant sails and royals would be added, with any staysails that had not been set."

Tacking, or Putting Ship About. First give the order "About Ship." See that all is clear, and the hands at their proper stations. Ease the helm down and haul the mizzen boom amidships. Order "Helm-a-lee." Watch, and as she comes to, and shakes, give order "Tacks and Sheets." When she comes within one point of the wind, give order, "Mainsail Haul." Down main tack and aft sheet. Trim the head sheets and shift helm, if necessary, to bring her round. When round enough for the head yards to fill—that is, when the mainsail is full, and it seems likely that the foresail will fill—give order "Let go and Haul"; down tack and aft sheet of foresail, brace yards, and haul out bowlines, and the ship is on her new course. If she will not come round, and gathers much sternway, then she has "missed stays," and you must bring her round on her heel. Shift the helm a-lee again, square after yards, haul head sheets aft, and brail in the mizzen. When she gathers headway, shift helm a-weather and keep her so till the after yards shiver. When before the wind, square the fore yards, and as soon as the wind comes to the other quarter, haul out the mizzen and brace the yards up as the ship comes on her new course.

To wear an ordinary ship, brail in the mizzen, hard up the helm, and as she goes off, square the after yards, keeping them just shaking. When before the wind, square fore yards and brace up for the other tack. As soon as the ship begins to come to, brace up after yards and set mizzen.

Setting and Taking in Sails. Instructions for setting and taking in sails are as follow:

TO SET A COURSE. Courses are the lower sails. Loose the sail, overhaul all gear, let go lifts, haul aft the slack of the sheet, down with the tack, and haul the sheet flat aft.

TO TAKE IN A COURSE. Keep ship well full, steady the lifts, ease off the lee sheet a little; man weather clew garnet, buntlines and leechlines; ease away tack and haul on clew garnet, and buntlines. The tack being close up, man lee clew garnet, buntlines and leechlines, ease away the sheet, and haul upon clew garnet, buntlines and leechlines. Then stow the sail.

TO SET A TOPGALLANT SAIL, ROYAL OR SINGLE TOPSAIL. Loose the sail, overhaul the gear, haul home the lee sheet, then the weather sheet. Hoist the yard tending the weather brace, and haul tight the lee brace.

TO TAKE IN THE SAME. Clew down the yard, check the weather brace, haul up the lee clew line, bunt line and leech line. Then the same on the weather side and stow the sail.

TO SET UPPER TOPSAIL OR UPPER TOPGALLANT SAIL. Loose the sail; let go the downhauls and sheets of the sail above. Overhaul the gear, and hoist away on the halyards, tending the weather brace.

TO TAKE IN THE SAME. Lower away, haul on the downhauls, take in slack of weather brace, haul on the buntlines; steady tight the halyards, and braces, placing the yard parallel with the lower yard, and then stow the sail.

TO SET THE MIZZEN. Ease off the weather vang and boom sheet; let go the brails, haul on the foot outhaul, and then on head outhaul, and when the head is full out tauten up everything, and trim sail.

TO TAKE IN THE SAME. Ease off weather vang and boom sheet, haul down the head, slack away the foot outhaul, and haul on the lee brails, taking in the slack of the weather brails.

TO SET A JIB. Loose the sail, haul sheet aft, let go downhaul, and hoist away on halyards, tending the sheet, and when set trim.

TO REEF AN UPPER SAIL. Lower the yard, haul in the weather brace, and check the lower yard; haul out the reef tackles, if any, steady tight the halyards and lay aloft. Haul out the earings and tie the points, slack away the reef tackles, let go lee brace, and hoist yard, tending the weather brace as yard goes up.

TO REEF A COURSE. Hook a reef pennant on to the weather clew and haul tight the lifts. Haul sail up the same as for stowing, but not quite so high, then haul out reef tackles. Lay aloft. Haul out earings and tie the points. Slack away reef tackles and set sail again.

TO SHAKE OUT A REEF. Haul reef tackles well tight. For a course ease tack and sheet, for an upper sail settle the halyards and haul tight the downhauls. Lay aloft. Each man begins untying points at the middle of the yard and works outwards. The earings are eased off together, reef tackles let go and sail set.

The Rule of the Road. This is one of the most trying branches of seamanship, and one which can be learnt from books. Vessels at night carry a red light on the port side, and a green light on the starboard side. Steamers also have a white light some distance up the foremast. Now, the primary rule is that *all* vessels overtaking another have to keep clear of the one they are overtaking. With this sole exception, all steamers under way have to keep clear of every sailing vessel.

The most common case is that of two steamships meeting. If they are end on—that is, when each can see all three lights of the other—then each has to alter her course to starboard.

> When all three lights you see ahead,
> Port your helm, and show your red.

If two steamships are meeting, but are passing clear of each other on the starboard side, the green light of the other vessel's starboard light will be seen, or on the port side, the red light. By day, it is easy enough to see whether the vessels are in the proper position for safety. The rule can be remembered by:

> Green to green, or red to red, perfect safety—go ahead.

When two steam vessels are crossing, the vessel which has the other on her starboard side shall keep out of the way of the other. That is to say, that if a steamer is crossing you coming towards your starboard side, or at night you see her red light, then you have to keep clear; if she is coming the other way, she has to keep clear of you. The fixed rule is thus memorised:

> If to my starboard, red appear,
> It is my duty to keep clear;
> To act as judgment says is proper:
> To port, or starboard, back or stop her.
> But when upon my port is seen
> A steamer's starboard light of green,
> There's naught for me to do but see
> That green to port keeps clear of me.

In the event of the light appearing very close up, both vessels must do what judgment suggests.

Sailing Ships Meeting. When two sailing ships are meeting, or liable to cross, the following rules have to be observed:

1. A vessel which is running free—that is, with the wind on the beam, or abaft it—must keep out of the way of a vessel which is close-hauled.
2. A vessel which is close-hauled on the port tack must keep out of the way of a vessel which is close-hauled on the starboard tack.
3. When both are running free, with the wind on different sides, the vessel which has the wind on the port side shall keep out of the way of the other.
4. When both are running free, with the wind on the same side, the vessel which is to windward shall keep out of the way of the vessel to leeward.
5. A vessel which has the wind aft shall keep out of the way of the other vessel.

Every vessel which is directed to keep out of the way shall avoid crossing ahead of the oncoming vessel if such is possible.

Vessels which are being overtaken at night shall show a white flare over their stern, as a warning to the oncoming vessel.

Direction at Night. To tell at night the direction a vessel is steering, the rule is as follows:

FOR STEAMSHIPS APPROACHING. If a green light is seen, take the bearing and the vessel will be steering between six points to the right of that bearing and the opposite point of the bearing nearly. If she was steering exactly to the opposite point of the bearing, all her lights would be seen. If a red light is seen, the direction will be between six points to the left of its bearing, and the opposite point of the bearing nearly.

FOR SAILING VESSELS. The same rules apply, but you must also take the direction of the wind, and remember that very few sailing ships can sail within six points of the wind, so all directions which lie within six points of the wind have to be eliminated. For instance, with the wind north, a sailing ship's red light is seen bearing due south. She must be steering between E.S.E. and E.N.E., because, though the rule gives you between E.S.E. and north as her direction, she could not sail between E.N.E. and north, because E.N.E. is six points from the wind.

Lights and Signals

Steamships under way carry	White masthead light, green and red side lights. Some have second masthead light.
Vessels under oars or sails, less than 20 tons burden.	Have ready red and green hand lamp, or a lantern showing white light.
Steamships towing.	Two white masthead lights vertical, 6 ft. apart. Red and green side lights. If towing more than one vessel, or if tow be more than 600 ft. long, then an extra light must be shown.
All vessels not under command.	Night. Two red lights, vertical, 6 ft. apart. Day: Two black balls or shapes in same position. If making way at night, side lights as usual.
Telegraph ships.	Night: Three lights, red, white, red, vertical, 6 ft. apart. If making way, side lights as usual. Day: Red ball, white diamond, red ball in same positions.
Sailing vessels under way, or any vessel being towed.	Red and green side lights.
Open fishing boats under way.	Lantern with red and green sides.
Vessels at anchor.	White light visible all round horizon. If over 150 ft. long, two white lights, forward one at least 20 ft. above hull, and after one 15 ft. below forward light.
Vessel aground.	Lights for anchored vessel and for a vessel not under command.
Sailing pilot vessels.	White masthead light, and flare up at intervals of not more than 15 minutes. Also side lights at short intervals.
Steam pilot vessels.	White masthead light, and red below it. Side lights, and flare when anchored, masthead lights and white flare as above, but no side lights.
Vessels drift net and line fishing.	Two bright lights, visible all round horizon, where best seen. Flare at approach of other vessels.
Steam vessels trawling.	Same as other steamers under way, or red and green lights to show four points abaft the beam.
Sailing vessels trawling.	Masthead lantern with red and green lights showing over 12 points each, and between 6 ft. and 12 ft. below them a white light. Or same as ships under way.
Light vessels out of place, and so useless for navigating by.	Night: Red light forward, and similar light aft. Day: All distinguishing marks struck, and red flags fore and aft.

In thick weather vessels are required to keep a foghorn or syren sounding at regular intervals when under way, and to ring the ship's bell every minute when not moving.

Warning Signals. The Morse code can be utilised for warning signals, either by giving blasts on the foghorn or by flashes of a lamp. Short blasts and flashes are of one second's duration; long blasts or flashes are three seconds in length. Between each flash or sound, a second should be allowed to elapse. Morse alphabet, as used in telegraphy, has been given on page 4382. When used in ship signalling, dashes are long flashes or blasts, and dots are short ones.

Special signals are as follow:

Preparatory signal to attract attention . . . . etc.
Answering signal. I understand — . — . — . — . etc.
You are standing into danger . . —
I want assistance. Stand by me . . . —
Have met ice . — —
Your lights are out or bad . — — .
Way off my ship. Come past carefully . — .
Stop; I have something to communicate . — . .
Am disabled; communicate with me . . — .

BETWEEN VESSELS TOWING: Steer more to starboard . Steer more to port . . Cast off hawsers . . . .

Pilot Signals. By Day: (1) Union Jack, with a white border, at the foremast; (2) International Code Pilot Signal PT; (3) International Code S, with or without pennant over it; (4) Distant signal, consisting of cone, point upwards, having above it two balls or shapes like balls.

By Night: (1) Blue light firework every 15 minutes; (2) bright, white light just above bulwarks shown for a minute at a time, constantly repeated.

Signals of Distress. Distant signal of cone, point upwards, and above or below it a ball or a bundle resembling a ball.

Morse Code V.

A flare-up or any detonating signal, or a burning tar barrel on deck, or rockets.

International Code Signals. These are made with coloured flags, as given below. The ordinary signals will be found in the "International Code of Signals," a book which every ship carries. The names of vessels will be found in the British "Code List," which is also found on most ships, and is supposed to be carried by all. The flags are as follow:

A = A burgee, half white, half blue. White next the mast.
B = A red burgee. Also signifies carrying powder.
C = A white pennant with a red spot in centre. Alone means "Yes."

D = A blue pennant with white spot in centre. Alone means "No."
E = A red, white, and blue vertically striped pennant. Red next mast.
F = A red pennant with white St. George's cross on it.
G = A yellow and blue pennant, divided vertically in half. Yellow next mast.
H = A square flag, half red, half white, vertically. Red next mast.
I = A yellow flag with blue spot in centre.
J = A flag striped horizontally blue, white, blue. Three stripes only.
K = A yellow and blue flag, halved vertically. Yellow next mast.
L = A flag quartered yellow and black. Alone means cholera on board.
M = A blue flag with white St. Andrew's cross.
N = A blue and white chessboard pattern flag. Sixteen squares.
O = A red and yellow flag divided diagonally in half. Yellow next mast.
P = A blue flag with white square in centre. Means "Am putting to sea."
Q = A yellow flag. Means "Am in quarantine."
R = A red flag with yellow St. George's cross.
S = A white flag with a blue square in centre. Means "Pilot wanted."
T = A red, white, and blue flag. Red next mast.
U = A flag quartered red and white. Quarterings vertical.
V = A white flag with red St. Andrew's cross.
W = A red, white, and blue flag; red in centre, white round and blue round that again.
X = A white flag with blue St. George's cross.
Y = A flag striped yellow and red diagonally. Ten stripes.
Z = A flag quartered diagonally. Top quarter yellow. Bottom quarter red; quarter next mast black, outside quarter blue.

CODE PENNANT. A pennant striped red and white, five stripes. Red next the mast.

Urgent and important signals are either one or two-flag signals, and will be found on pages 10 to 19 of the "International Code of Signals," which we shall call the "Signal Book." Three-flag signals are either compass signals in degrees and points, on pages 20 and 21; money, on pages 22 to 25; measures and weights, pages 26 to 31; fractions and decimals on page 32; metrical weights and measures, pages 32 and 33: auxiliary short phrases, on pages 34 to 63, or are general vocabulary on pages 64 to 414. Four-flag signals are geographical signals, on pages 422 to 515; alphabetical spelling, pages 516 to 534, or are names of vessels. These last will be found in the "British Code List." The names of men-of-war have the G pennant uppermost; merchant ships have a square flag uppermost. When a ship is signalling, you must keep the code pennant, or *answering pennant*, as it is called, hoisted as long as you understand. If you do not understand the signal, then dip the pennant, and it will be repeated. While waiting between signals, keep the pennant at the dip.

Distant Signalling. When you wish to make a signal, and the ship or point you wish to communicate with is too far away for the colours of the flags to be distinguished, you must use the distant signals, which run as follow:

Four signs are used, namely, a cone, point upwards, which we will call 1; a ball, which we will call 2; a cone, point downwards, called 3; and a square, which we call 4. The following alphabet must be read as follows: The first number given as at the top of the mast; the second just below it, and so on. Distant signals are only three-sign signals.

A = 1.1.2.	J = 2.1.3.	S = 2.4.1.
B = 1.2.1.	K = 2.1.4.	T = 2.4.2.
C = 1.2.2.	L = 2.2.1.	U = 2.4.3.
D = 1.2.3.	M = 2.2.3.	V = 3.1.2.
E = 1.2.4.	N = 2.2.4.	W = 3.2.1.
F = 1.3.2.	O = 2.3.1.	X = 3.2.2.
G = 1.4.2.	P = 2.3.2.	Y = 3.2.3.
H = 2.1.1.	Q = 2.3.3.	Z = 3.2.4.
I = 2.1.2.	R = 2.3.4.	

Code flag sign, 4.2.1. Alphabetical sign, 4.2.2. Numerals, 4.2.3. End of word or number, 4.3.2.

With these signals, any of the methods given in Signal Book can be used, the distant signs being hoisted instead of the flags, only, of course, the equivalent of each flag must be hoisted separately, and when the end of each hoist of flags is reached, 4.3.2. is sent up.

Law of Storms. The ordinary casual storm which we know in this country is also found at sea. It is not a storm following any specific course, and so is not liable to be reduced to rule. The revolving storms, or cyclones, which are really dangerous, follow definite rules. The first point of importance when a cyclone is met is to be able to determine the probable bearing of its centre. This is done by the following rule:

Take the direction of the wind, and in the northern hemisphere, from 12 to 8 points to the right of the direction of the wind for the probable bearing of the centre. In the southern hemisphere, allow from 12 to 8 points to the left of the direction of the wind for the probable centre. These points are allowed as follows: At the beginning of the storm allow 12 points; when the barometer has fallen three-tenths of an inch allow only 10 points; and when the fall is six-tenths, or more, allow about 8 points for the centre.

If during the cyclone the wind changes towards the right, then the ship is on the right hand of the line of progression: if to the left, it is on the left of the line. In the northern hemisphere, in the first case, it is advisable to heave to on the starboard tack; in the second case, run with the wind on starboard quarter, or, if compelled, heave to on the port tack. In the southern hemisphere this would be reversed; with the ship to the right of the line of progression, run with the wind on the port quarter, or, if compelled, heave to on the starboard tack; with the ship to the left of the track, heave to on the port tack. If the wind does not change, run with the wind on the starboard quarter in the northern hemisphere, and run with it on the port quarter in the southern hemisphere, till the barometer has ceased falling.

When the ship is in the line of progression of the centre of a cyclone, the wind does not shift, but the barometer falls rapidly and the sea increases. When the barometer falls rapidly and steadily, the wind and sea increase, and the wind shifts about fitfully, then the ship is approaching the centre of the cyclone; the opposite conditions mark departure from the centre of the storm.

Storm Tracks. The following are the principal tracks taken by cyclones:

IN THE NORTH ATLANTIC. Storms begin generally in lat. 8 to lat. 20 N., travelling to the W.N.W. and N.W., and when in about lat. 30, to the N., N.E., and E.N.E., gradually increasing in diameter, but getting less violent as they expand. They occur most frequently from July to October.

BAY OF BENGAL. The track runs westerly to north-westerly during May, June, October, November, and December.

THE CHINA SEAS. Cyclones run westerly to north-westerly in July and August, and south westerly to north-westerly from Sept. to Nov.

INDIAN OCEAN. Cyclones begin generally in lat. 8 to 20 S., travelling to W.S.W. and S.W., and when in 30 S. change to S., S.E., and E.S.E. in direction. They expand after that rapidly, and blow themselves out. They are most frequent from January to April.

Continued

A SHORT DICTIONARY OF NAUTICAL TERMS

A.B.—Able (bodied) seaman.
Aback—Wind striking forward side of sails.
Abaft—Nearer the stern.
Abeam—Abreast ship; in the distance at right angles to the keel.
Aboard—Upon or in a vessel.
Aboutship—Tack, or turn head of ship to wind, so that the lee side becomes the weather or windward side.
Ahead—Object in advance of a vessel.
Aloft—Above deck, in rigging.
Astern—Behind.
Athwart—Across.
Avast—Stop.

BACK A SAIL—Let wind press on fore side of sails to stop ship's way.
Backstay—Rope supporting upper mast, secured to gunwale abaft same.
Batten down—Fasten down all hatchways by means of covers or tarpaulins.
Beam—Extreme width.
Beam ends—When a ship lies on her side so far as to be unmanageable.
Bear up or away—Steer for desired point or destination.
Bearing—Direction.
Beating — Zigzag progressing of a sailing vessel against head wind.
Belay—To secure a rope.
Bells—Half hours of a watch struck on ship's bell.
Bend—To fasten; sails are bent to yards or to stays.
Bight—A loop in a rope; the middle of a slack rope suspended horizontally.
Bilge—A channel at bottom of ship each side; the union of the flat of a vessel's bottom with its sides.
Bitts—Appliance constructed of wood or hollow cast iron fastened to upper deck or rails, for the belaying of hawsers, warps, etc.
Block—A pulley.
"Blue pigeon"—Seaman's term for hand and deep sea lead.
Bollards—see *bitts*.
Bolt rope—A rope of superior quality to which the canvas for sails is attached.
Booms—Spars of light character.
Bow—The fore end of a vessel.
Bowers—The principal anchors.
Bowline—A rope to bow leech of sail forwards; a knot; "to sail on a bowline"; to sail close to the wind.
Box—To "back" all foresails; to name the 32 points of the compass.
Braces—Ropes from yardarms by which sails are trimed.
Brace up—Haul yards further forward.
Brail up—Take in sails attached to masts by the brails.
Break bulk—Commence discharging cargo.
Bring to—To stop a ship by anchor or sail.
Broach to—To come to the wind against the helm.
Bulkhead—Partitions of wood or iron by which compartments are formed; or transverse water-tight divisions in vessel's hold, usually constructed of steel or iron plating.
Bunk—Seaman's bed on board ship.
Bunt—Middle of furled sail; buntline ropes from foot of sail to haul it up.
Bunting—Light fabric of which flags are made.

CABLE-LAID—A rope of nine strands.
Cant—To turn over.
Cap—Fitting joining upper and lower masts.
Capstan—A vertical winch worked by steam or by capstan bars.
Careen—To heel over till part of bottom is out of water.
Cast off—To let go.
Cat block and fall—Large block and rope for hoisting anchor.
Cathead—Projecting piece of timber on each bow. It is fitted with sheave holes, through which a purchase, called a cat-fall, is rove for hoisting anchor from hawse pipe to cathead.
Chain-hooks—Iron rods about three feet in length, hook-shaped at one end, for handling cables or other chains.
Chain-locker—A trunk made of wood or iron, usually situated underneath the windlass, and extending from deck to keelson, used for stowing chain cables.
Chain plate—Iron plate fastening deadeyes of rigging to gunwales.
Cleat—Appliance used in belaying; piece of wood to reeve anything through.
Clew of sail—Corner to which sheet is attached.
Clew line—Ropes for hauling up clews of square sails.
Clew garnet—Ropes for hauling up clews of square sails and courses.
Clew-up—To haul up square sails to yards by attached gear (ropes).
Club haul—To tack by letting go and then slipping the hawser attached to an anchor.
Coamings—Frame of hatchways extending above level of deck.
Courses—Foresail and mainsail and crossjack of square-rigged vessels.
Crank—Top heavy, easily heeled over on to side.
Crosstress—Spreaders on masts to support topgallant rigging.

DAVIT — A crane to lift boats or anchors.
Deadeye—A block of wood with three plain holes; a rigging frame.
Deadlight—Cover or shutter, fitted to protect the glass of a skylight or sidelight during stormy weather.
Derrick—A spar of wood or iron held by guys and topping lifts for lifting weights.
Dog Watches—From 4 to 6 and 6 to 8 p.m.
Downhaul—Rope attached to headcringle of fore-and-aft sails for furling same.
Drag—An anchor not holding drags.
Draught — Depth of ship's immersed surface below waterline.
Draw—When sail takes the wind properly.
Draw-bucket — Appliance made of canvas in the shape of a bag, with a strong hoop fitted to keep the mouth of same open, to which a rope lanyard is attached, used for drawing water from over side.
Driving—Dragging anchor in gale or tideway.
Drop of sail—Distance from foot to yard.
Dunnage — Odd wood placed in stowage of cargo as required.

EARINGS—Upper corners of square sails and ropes fastening them.
Ease helm—Move it more amidships.
Ease her—Go slow.
Ease off—Slacken rope.
Even keel—Drawing same water fore and aft.

FAIRWAY—Free passage to or from harbour; deepest channel.
Fall—Part of a tackle hauled upon.
Fill—To make sail take wind.
Fish—Strengthening piece of wood or iron.
Fish davits, blocks, fall, etc.—Crane and tackle for hoisting flukes of anchor.
Flatten sail—To make it taut.
Flowing sheet—Sheet eased off to fair wind.
Foot-ropes—Ropes below yards on which sailors stand; rope attached to lower side of sails.
Fore and aft—Lengthways of keel.
Forecastle—Forward part of upper deck. Sailors' quarters (generally).
Foul—Entangled, contrary, dirty.
Freeboard—Distance between deck and waterline.
Furl—To roll up square sails and secure to yards. Others are stowed or made fast.

GAFF—Small spar abaft a mast to which the head of a fore-and-aft sail is bent.
Galley—Cooking place on board ship.
Gangway—Entrance to ship. Narrow passages fore and aft. If under bridge or upper deck, called "alleyways."
Gantline—Small rope rove through single block, used for lifting or lowering purposes.
Garboard—Lowermost strake of outside plating, and connected to the keel.
Gaskets—Plaited bands, generally small manilla rope, to secure furled sails.
Ground-tackle—Term applied to a vessel's anchors and cables.
Guys—Ropes to keep small spars in position.
Gybe—To let fore-and-aft sail shift from side to side by action of wind changing from quarter (of ship) to quarter.

HALYARDS—Ropes for hoisting sails.
Hard down or hard a lee—Position of helm the reverse of hard up; command given in tacking ship.
Harness casks — Teak wood barrels of peculiar shape for holding salt beef and pork for immediate use.
Haul up—Alter course to windward; to furl a sail.
Hawse holes, pipes, etc.—Part of ship through which anchor cables run.
Headsails—Jibs and fore topmast staysail.
Heave in stays—To come up into the wind while tacking ship.
"Heave or cast the lead"—Command given when depth of water in which vessel is sailing is desired to be known.
"Helm's a lee"—Helm is down. Answer of helmsman to order given in tacking ship.
Home—When sheets are close to yard, or when anchor is at hawse pipe.
Hove to—To lay aback main or fore yards in order to stop ship's progress; in heavy weather to keep ship's head (or bow) as close to the wind as possible.

IN IRONS—When ship will not obey helm in tacking.
In stays — Term used when the manœuvre of tacking ship is being performed, and vessel has lost headway.

JACKSTAY—Tight rope to which others are fastened; the iron rods secured to yards by eye bolts to which sails are attached.
Jacob's ladder—Rope sides and wooden treads.
Jettison—To sacrifice, by throwing overboard, part of a vessel's cargo in order to lighten her, with a view to saving the vessel from some imminent danger.
Junk—Old, condemned rope.
Jury mast, etc.—Temporary substitutes.

KEDGING—To move by means of small or kedge anchors.
Keelson—Timber or iron vertical plate on top of keel.
Keep away—Steer farther from wind.
"Keep her Full"—Command given when ship's sails are not filling properly.

Keep to the wind } Steer nearer to
Keep your luff } wind.
Kentledge — Pigs of iron or lead when used for permanent ballast.
Knot—A nautical mile.
LABOURING (of a vessel)—Rolling and pitching in a heavy sea.
Lanyard — A rope for tightening larger ropes.
Lash—To secure by ropes.
Lay to—To stop; to heave to.
Lazaret—A compartment above the after peak in a vessel for the stowage of provisions, etc.
Lead—Weight, usually made of lead, to ascertain depth of water. It is often "armed"—a cavity in bottom of lead filled with tallow, to find nature of bottom.
Lee—The side to which wind is blowing, opposite to weather.
Leech—Either side of square sail. The sides of triangular sails are named leech, luff, and foot.
Leech Lines—Small ropes attached to leeches of square sails and used in "clewing up" same.
Leeway—Drift to leeward; out of course indicated by compass.
Lifelines—Protection lines on yard, spars, or on deck to hold on by.
Lift—Rope near end of each yard to lift it or top it up.
List — Heeled over from upright position.
Load line — Water line along ship's side when fully laden. The statutory mark painted on outside plating or planking amidships of British vessels beyond which they may not be loaded; thus -⊖- (upper edge of bar passing through disc must not be submerged in salt water).
Luff—An order to steer nearer the wind; the fore part of a stay-sail, trysail, or jib.
Lying to—Keeping ship's head close to the wind, under storm sails, during stormy weather attended with a heavy sea.
MAKE SAIL—To set sail.
Marl—To secure things by a row of half hitches.
Marline spike—Steel spike used for splicing and rigging.
Martingale—A tackle and spur to prevent jib-boom from topping up.
Midships—The centre line or middle section of ship's deck.
Misstays—To try to tack and fail.
Moorings — Chains, hawsers, and warps used for securing a vessel to a quay or wharf.
NEAPED—To be in dock or on shore when neap tides do not provide enough water to float ship.
Near—Helmsman is too near the wind when steering by same.
Nip—Part of rope subjected to greatest strain.
"No higher"— Command given to helmsman when ship's course is directed too close to the wind.
Nun buoy—Double cone buoy.
OFFING—Distance from shore.
Off the wind—Not so close as she might be if sailing on a wind.
Orlop deck—Lowest in large ships.
O.S.—Ordinary seaman.
Overhaul—Slacken tackle; to examine; overtake.
PAINTER—Rope by which boats are made fast.
Palm—Implement made of stout leather, into which a steel indented disc is fitted, used by sailmakers to protect the palm of the hand when forcing a sail-needle through canvas.
Parbuckle—Hoist by rolling a thing in the bight of two ropes.
Parcel—To cover a rope with strips of canvas.
Parrel—Circular hinged band of iron round mast and secured to yard.

Pay a seam—To fill it with melted pitch.
Pay away or out—To slacken; to run out; generally applied to cables or warps.
Pay off—To sail off the wind; to pay and dismiss crew.
Peak—Outer part of gaff and of gaff sail; compartments at extreme ends of hold.
Pendant—Large rope with tackle attached.
Plain sail—All except studding sails.
Pooped—When wave comes over stern.
Preventer brace or stays—Additional supports to spars during a gale.
Purchase—A tackle or lever.
QUARTER—Part of sides near stern; middle halves of yards.
RAKE—Inclination of masts aft or forward from the perpendicular.
Ratlines—Ladders made of rope secured to the shrouds of masts; also the rope from which same are made.
Ready about, ready o' ready—Warning for tacking.
Reef points—Small ropes fixed to sails for reefing them by.
Reef tackles and pendants—Lines for hauling up leeches of sails before reefing.
Reeving line—Small line passed through block to drag larger one after it.
Rendering—Slipping, not holding.
Right the helm—Bring it amidships.
Rolling tackle—Ropes to relieve strain on yards in bad sea.
Round down—To overhaul.
Round to—Heave to.
Rudder — An appliance fastened to stern-post by means of gudeons and pintles, which controls the direction of vessels' movements when under way.
Running rigging—All ropes used in handling sails or yards.
SAG TO LEEWARD—Difference between ship's course as shown by compass and that actually made.
Sail close to wind—Sails of ship barely full.
Sail free—To keep sails clean full; off the wind.
Scarph — The connection of two pieces of timber or iron by shaping and overlapping their ends.
Scudding—Running before gale.
Scupper—Channel at side of decks, for water to run off by, through holes pierced in vessels' sides for that purpose.
Scuttle—Hole in side for light and air; to sink ship purposely.
Seizing—Small cordage, or flexible wire, by which two pieces of rope are firmly bound together.
Serving or service—Covering of rope with spun yarn or other protection.
Shackle—A U-shaped joining for chains.
Shears—Two large spars like an inverted V for lifting heavy weights.
Sheer—To swerve from course; the curve of the deck line between stem and stern.
Sheet—Rope holding lower lee corner of sail.
Sheet home—To haul sheets attached to clews of sails to position when setting same.
Shift helm—To put it over the other way.
Shorten sail—To take in some sails.
Slew—To turn or cant.
Splice—To join two ropes by intertwining strands.
Spunyarn—A thin line of two or three yarns of loosely twisted tarred hemp.
Square-rigged—Having yards on the masts.
Stand by—Be in readiness.
Standing part—Fixed ends of running gear.

Standing rigging—All fixed ropes and wires of ship's equipment.
Staysails—Small sails set on stays between masts.
Stevedore—Man who loads or discharges ships' cargoes.
Stiffness—Stability under sail pressure.
Studding sails—Small auxiliary square sails now rarely found.
Surge—To slack back quickly.
TACK—The lower weather corner of every sail; to change course by bringing wind ahead and round to other side; opposite to *wearing*, when wind is brought astern.
Taken aback—When wind suddenly shifts and all sails are thrown back.
Taut—Tight.
Thimble—An iron ring in a rope.
Throat—Upper corner of gaff sail near mast.
Throat halyards—For hoisting end of gaff next mast.
Thwart—Across. Cross seat in a boat.
Tiller—Lever to shift helm.
Top—Platform on crosstrees of lower masts. To top a yard is to lift up one yardarm higher than the other.
Traverse—To make several tacks.
Trestletrees—Wood or iron supports for crosstrees and standing rigging.
Trice—To haul up.
Trim a ship—To load her properly and ensure balance.
Trim sails—To brace yards and adjust sheets.
Trip anchor—To break it out of the ground.
Truck—Disc or ball at top of mast with sheaves for signal halyards.
Trusses—Fittings to keep centre of lower yards to mast.
Trysail—Triangular sail attached to lower masts, sometimes termed storm sail.
Tye—Large rope on which halyards act when hoisting a yard.
UNBEND—To untie and take off anything made fast, as casting adrift a sail from a yard or stay.
Under way — Moving under control of helm.
Underwriter — One who insures a vessel or her cargo.
Unmoor—To release a vessel from ropes or chains by which she has been held stationary.
VANGS—Ropes to steady gaff.
Veer—To slack out hawser or cable. Once was term for "wear."
Veer and haul—To pay out and haul in. The fluctuation in the direction of wind.
WAIST—Middle part of ship's fore-and-aft line on deck.
Wake—Track left in water; in way of.
Warp—Small hawser.
Warping — Transporting a vessel by means of warps or hauling lines.
Watches—Periods of four hours each, commencing at 4 a.m., with the exception of the dog watches, which are two hours.
Wear ship —see *tack*.
Weather gage—Bearing to windward of.
Weigh—To raise the anchor.
Whip—Single rope passing through block to increase purchase.
Whipping—Binding at end of rope to prevent fraying.
Windsail—Ventilator made of canvas.
"Work to windward"—Term used when a vessel is beating against adverse winds.
Worm—To fill grooves in a rope with twine or spunyarn.
YARD—Spar with spread sails.
Yaw—An accidental swerve from course.
Yoke — Small piece of hard wood fitted at right angles to the head of a boat's rudder, to which lines are attached for steering the boat.

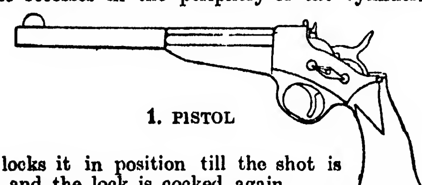
THE MANUFACTURE OF GUNS

Various Types of Pistols, Revolvers, Rifles. Sporting Guns and Machine Guns. Their Mechanism and Manufacture

By JOHN W. WAINWRIGHT

Pistols. The present type of pistol has a steel rifle barrel [1] fixed or with a drop-down joint, with fixed breech parts containing the striker and mechanism. The barrel is forged steel and rifled, the lock plates are of iron and steel, stamped and milled, and the action part springs. The butt is of walnut. The barrels are blued or browned. But the pistol has been almost superseded by the revolver and automatic pistol. Many revolvers and guns were made during the last two centuries having the cylinder revolved by hand, but the metallic centre-fire cartridge has enabled a great advance to be made.

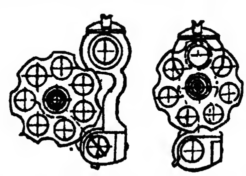
Modern Revolvers. The simplest modern type is the single-acting "Colt revolver" [2]. In this the cylinder, which contains six cartridge chambers, is made to rotate by the action of cocking the hammer. This causes pawls to engage in ratchet teeth cut in the rear face of the cylinder, and moves it one-sixth part of a revolution, and at the same time a small catch or latch engages in the recesses in the periphery of the cylinder.



1. PISTOL

and locks it in position till the shot is fired and the lock is cocked again.

In a later type the cylinder was swung out sideways to give self extraction [3]. This revolver had a solid bridge frame [FR in 2]. The frame or body is stamped hot—that is, forged by drop hammer between top and bottom dies. The fins of extended metal are dressed off by finning dies, and the stamping is then placed in a clamp jig or fixture for machining and the base pin hole is drilled through; the pin, previously prepared, is then inserted in order that each subsequent operation may conform with this centre. The frame still in the fixture is faced, the recess for the cylinder is machined out, and the barrel hole is drilled and tapped. The stock is shaped and spring beds recessed; all holes are then drilled and tapped, through the hardened bushes of the fixture. The frame is recessed for the hard steel shield which takes the thrust of the cartridge base.

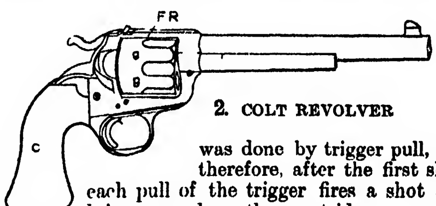


3. SWING-OUT CYLINDER OF COLT SERVICE REVOLVER

The Cylinder. This is either forged or of special rolled steel. The centre axis pin-hole is first drilled through and the cylinder is faced. The chambers are drilled and bored six at one time, in a multiple drilling machine; afterwards they are accurately chambered out to suit the cartridge. The front face of the cylinder is well fitted to prevent, as far as possible, the escape of gas. In the periphery of the cylinder the channels are now cut; also the slots for the latches are accurately milled out to an index plate to ensure true pitch, in relation to each other and the corresponding chambers; also, at the rear end, the ratchet teeth are cut. The limbs, or parts of the action, are of high grade steel stamped hot approximately to their finished form, and also machined in jigs or fixtures by automatic tools.

The Barrel. The barrel is bored, rifled and screwed; the outside is turned, the component parts are finished off by filing, and after hardening and tempering, they are sent forward in the bulk for section viewing—that is, for detail examination by gauges and to be assembled from promiscuous heaps, each part being thoroughly interchangeable. The sear and spring are then adjusted, to give a slight pull off, and the sighting corrected. Given these conditions, a champion revolver shot can fire as rapidly and accurately with a single-action revolver as with a double-action automatic [described later], the latter having a somewhat dragging pull.

Webley's Revolver. The next advance was a double-action revolver, Webley [4], in which the revolving of the cylinder and cocking the lock



2. COLT REVOLVER

was done by trigger pull, and therefore, after the first shot, each pull of the trigger fires a shot and brings round another cartridge.

The frame is made of a solid steel stamping, forged under a drop-hammer in recessed dies, and milled out to receive the cylinder and drilled, all the work being done by the clamp jigs and fixtures to gauges with a maximum and minimum allowance, usually about ·002 in. to ·004 in., depending on the requirements. All the operations start from one face or point to ensure accuracy. The limbs are crucible steel stampings, machined all over in special jigs, by plain or finger mills or former mills. Each is tempered or case hardened where required, and inspected and tested, and the holes lapped out and the sears adjusted, the holes being tested by plug gauges through plates to see that they are at right angles to the part.

The cylinder must be truly concentric with the axis pin and the chambers co-axial with the barrel and in line with the striker, when the cartridge to be fired arrives at the upper position. This must also be assured by the latch engaging the corresponding recesses in the cylinder; moreover, the ratchet teeth on the back face must engage and disengage at the right moment, as must also the sears and bents, so that the motions synchronise. In others the barrel is swung down on a pivot below the axis joint pin, and the extractor is made to push out the cartridges. An extension of the

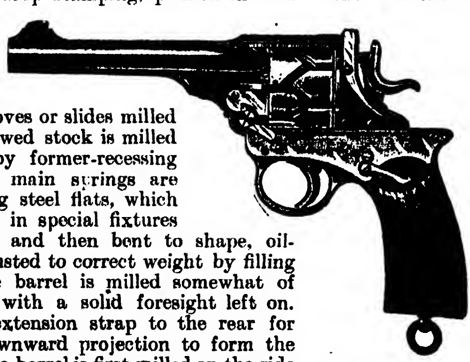
barrel has a recess which is locked securely by a latch on the top of the frame. This locking gear must be well fitted.

Automatic Revolver. A further development is the automatic revolver—such as the Webley-Fosbery, shown in **5**. It consists of a frame and handle that does not recoil, and a recoiling part composed of the barrel body with mechanism and cylinder attached. The body recoils on explosion, sliding in a groove in the frame, and is returned by springs actuating a lever; at the same time a fixed stud works in the zig-zag grooves that are cut in the outer surface of the cylinder. The cylinder is rotated by the fixed stud for half the movement, then the stud passes down the return groove, thus completing the movement.

The frame is a drop stamping, pickled in acid to clean off the scale; the flat side surface is then milled or shaped straight across the top horizontal grooves or slides milled out, and the hollowed stock is milled or wibbled out by former-recessing finger-mills. The main springs are forged from spring steel flats, which are put in groups in special fixtures and milled across and then bent to shape, oil-tempered and adjusted to correct weight by filling or grinding. The barrel is milled somewhat of hexagonal shape, with a solid foresight left on. There is a solid extension strap to the rear for locking, and a downward projection to form the axis pin joint. The barrel is first milled on the side flats, and faced and drilled and bored. The axis pin joint is faced, and milled out by section mills, and the holes are drilled through. The hole for the cylinder axis tube is drilled and bored. The barrel and its extension is milled to section, and the latter radiused out to suit the cylinder, and the barrel is rifled and lapped out. The body stamping has a long rectangular portion to form the sides, an axis pin joint projection at the fore end, and a triangular block at the rear with its apex upwards. This last when machined contains the action. The bottom slides are faced and grooved out by section mills. The thrust face is squared across and recessed for the hard steel shield, and for the rear of the cylinder extractor and the various recesses milled out for the trigger and hammer, etc., to operate in, and the cross pin holes are then drilled through a jig. The hard steel shield, after being faced and machined outside and recessed, is hardened and ground true. The barrel catch is adjusted and fitted.



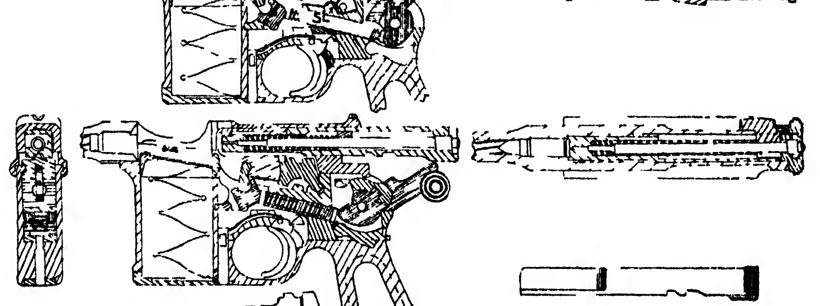
5. WEBLEY-FOSBERY AUTOMATIC SERVICE REVOLVER

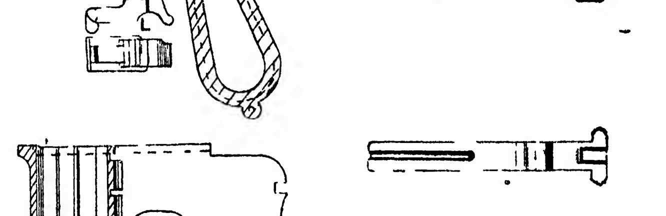
The handle and the trigger-guard form the non-recoiling portion of the revolver. The handle has long slides grooved out by section mills in its top table for the body to slide on, and a recess cut out in front; also a fixed pin to rotate the cylinder. The stock projecting downwards is faced on both sides, and recessed out right through by former mills to contain the recoil-lever, which is fulcrumed at its lower end on a cross-pin. The stock also envelops the main spring and sear that hang downwards from the sliding body. The trigger-guard forging is shaped out and fitted into the handle together with the trigger. The stock is recessed by former mills for the two vulcanite side-plates. The rear plate of the stock is machined to form a hinge at its lower ends to give accessibility to the recoil-lever. The vulcanite plates are pressed to shape in hydraulic presses, and screwed into the recesses provided in the stock. The cylinder is manufactured as previously described, with the exception that in the place of the rear ratchet-teeth the exterior is grooved; this being done by placing the bored cylinder on a mandrel, which is revolved,

and special revolving finger mills form the grooves from a copy.

These grooves give the rotation to the cylinder when it recoils and returns with the body after each explosion. The action-limbs are machined in the same manner as described for revolvers. In assembling, it must be arranged that the slides and grooves work freely, but without jerk; the sears and bents are adjusted to engage and disengage correctly, so that as far as possible an even pull only is required on the trigger. The barrel and body, with the cylinder with the action attached complete, form a recoiling part, when the axis-pin is inserted.

When assembled complete and ready for firing, the revolver becomes automatic, in that the trigger on being pressed trips a sear and releases a hammer. After the explosion the barrel and body recoil, locking the hammer, and the cylinder is rotated by the fixed stud passing down one groove, and completing its revolution, by passing down the other groove by the reaction of the recoil-lever moving the body forward again, thus bringing a fresh cartridge into the firing position, and leaving the body and trigger and hammer, after again pressing the trigger, ready for firing. The parts are case-hardened and tempered where required.





6. MAUSER AUTOMATIC PISTOL

Mauser Automatic Pistol. This is illustrated in 6. The barrel is a solid steel stamped forging, with a round barrel and solid foresight, and a hollow, square extension forming the body, with two lower projecting lumps. The barrel is faced, and then drilled from end to end in a multiple drilling machine; it is then milled across to square the body, is slotted or milled across, and is then recessed through vertically between the breech and the body. The barrel is then draw-bored, and the interior of the body opened out to square section by shaper tools—like keyway slotters—and then to finished size by drawn drift-cutters. The barrel is finished, turned, and the foresight formed. The exterior is milled square, with projecting ribs left on the lower edges to slide in the frames. The bottom lumps [BL 1 and BL 2] are machined on the sides by gang-mills, and radiused for the bolt-lock L at the front end and also between the lumps, forming an oblong recess, which is carried up right through the bottom of the body. This latter recess is for the bolt-lock to pass through. A slot to take the stop-block is slotted through the side walls near the rear end of the body.

Bolt-lock. This has a tooth-shaped crossbar at the front end to fulcrum around the front of B L 1. Two webs extend to the rear end, joining a rectangular block with two locking teeth on its upper edge, and two legs projecting downwards. The rear legs rest on a supporting lug [S L] on the top of the lock-frame; and this leg, on recoil, slips down over the lug, the two legs straddling the lug and disengaging the locking teeth from the body. It is first milled on the outsides, and the recess wibbled out. The tooth is milled outside, and carefully inside, to form a fulcrum. The corners left by cutters are cleaned out so that it has a bearing right across.

Lock Frame. This is slid in from the rear into the main frame. It is of somewhat rectangular shape, with two webs projecting to the front to embrace the knife-edge fulcrum upon which the rocker works; also above this is a front-stop cross-member, which projects over the rear wall of the magazine. The main rectangular portion has a lug on the top face, and a bulb projection standing up at the rear, the latter to form a stop for the bolt-lock and a flat top over which the body slides. The rear of the block is recessed out to form the cheek-joints for the hammer to work between. The whole is secured in position by a rear stop-block pressing into a groove in the frame and recess into the main frame, and held down by a vee-spring.

The stamping is first faced parallel on the sides, and on top and bottom. The cheeks are milled out, leaving a rear crossbar. The hammer axis pin-hole is drilled through a jig. Then the front face of the fulcrum-bar and the knife-edge of the same are shaped, and the hole for the mainspring is drilled out relatively to the axis-pin. The top lug, the recess for stop-block, and the recesses for lever and sear on one side are all machined to gauges, using the axis-pin and bottom and side faces as "spotting" points.

Main Frame. The main frame is a steel stamping. It has two projecting outside top slides and one inside, hollow, deep, oblong sides to contain the magazine in front, and also the lock-frame in rear, and it is continued down to form the

stock and trigger-guard. The stamping is first faced on the top table, then milled to section outside, to form the guides and faces, also the stock. The interior is drilled out with relief holes, and opened out by former mills. The stock is recessed right through, except where rebated for the vulcanite side-plates, and is machined out to form the trigger-guard.

Action. The hammer is a stamping. After facing, the axis pin-hole is drilled, and the faces and edges are milled to template. The front projection forms the sear-bent, and the lower projection is left to press against the mainspring plunger. The circular finger-grips are knurled. The action is then adjusted, hardened, and fitted.

The rocker is of hook shape, to engage the tooth projection of the bolt-lock. It has a round face,

on which the mainspring plunger acts. An axis-pin is driven in to form gudgeons. It rests on the knife-edge of the fulcrum when the barrel is home, but is turned over and forced back against the mainspring on recoil, by the bolt-lock tooth. In manufacture it is made, in some cases, from a rolled section sawn across to length, and is then faced and the pin-hole drilled. It is hardened on the hook-point and fulcrum face.

The Bolt. The bolt is milled square in section outside, bored from end to end in a multiple-drill press to contain the striker and its spring. It has a long slot in the right-hand side, through which the buffer-stop to the spring is inserted. The fore end has a plug inserted with a taper-hole to contain the striker and its rebound spring. The rear end is also bushed, and the striker pinned in. The rear end has knurled horns for grasping when required to pull back by hand, to cock the lock at the start, or to fill the magazine. The notches are milled across the underside. In these the bolt-block teeth engage and disengage. A long V-shaped groove is milled on the underside for some distance from the front end. The top front has a recess and holes to bed in the extractor; the latter is a spring-tempered hook. The striker is of high grade, round-section steel, and is turned down in rod-feed hollow-spindle lathe, and the point tempered.

Another very good type is the Colt automatic pistol [7]. Its manufacture need not be described in detail. Complete sectional views are shown in the figure and a list of the component parts is gi en. It is adopted in the United States service.

Another automatic pistol of this type is Browning's Patent, which is used by the Belgian police and for householders' protection. Though small, it is very effective.

Military Rifles. Most of the modern military rifles have the door bolt type of breech and steel barrels, fitted with walnut stock, the cartridges being fed up from a magazine carried below the butt and front of the trigger guard. Typical of this class is the Lee-Enfield [8] and the Mauser [9], the former being used by Great Britain, and the latter by Germany, Belgium, Spain, Turkey, and other countries.

The chief difference in the breech-locking is that the lugs in the Mauser are at the front of the bolt and close up to the barrel, whereas in the Lee-Enfield they are at the rear, and this is considered bad practice by many experts, as the pressure tends to spring the bolt on an excessive pressure obtaining; moreover, as a long pillar practically unsupported, it is mechanically weaker.

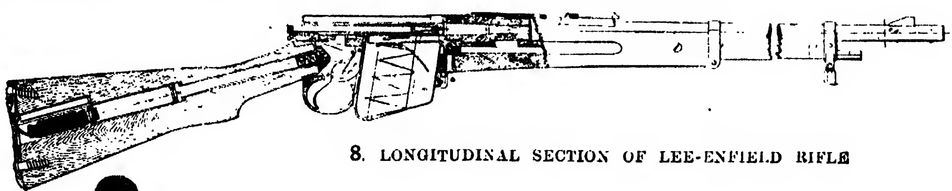
The Lee-Enfield Rifle. The number of component parts of the Lee Enfield is much in excess of the Mauser, but it has come out fairly satisfactorily through severe campaigns. The barrel is made from ·31 to ·41 carbon Siemens steel. It may be rolled, as at Enfield, from a round bar of suitable dimensions through a series of ten pairs of horizontal rolls, which elongate the barrel and taper it in transit, all in one heat. The work put on the barrel materially improves its capacity for standing the strain of the explosion. It is also claimed that this method enables the barrels better to retain their straightness during the drilling and following operation. But satisfactory barrels are also obtained by the use of the tilt or Bradley rapid blow-hammer, which is generally used on the Continent.

After this process the enlarged breech is stamped by steam or power hammers between top and bottom dies. The barrels are then cold straightened either in rolls, or in the machine shown in 10. They are then spun on centres, and finished, straightened by hand hammers very rapidly by experts, turned and clamp milled, that is, by

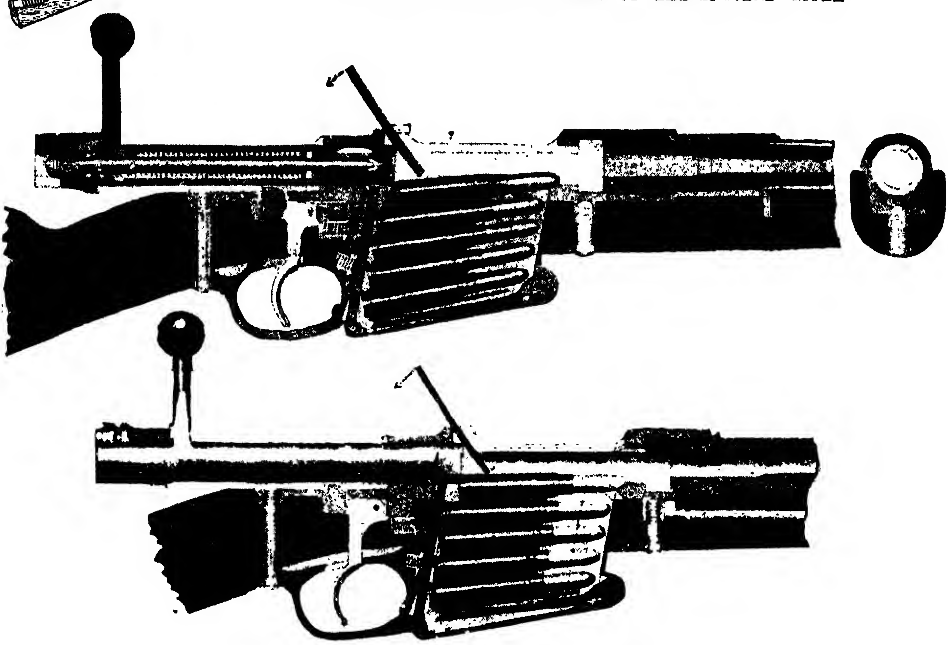
revolving cutters to gauge sizes in three places. These turned portions are called *spotting points*, the subsequent taper-turning work having reference to them, the ends are faced and centred, and afterwards drilled in a special drilling machine.

In the older practice, which is still followed, the barrel is drilled from both ends at the same time, the barrel being revolved at about 1,000 revolutions per minute, half round bits being used, at the same time a copious supply of soapy water being pumped at high pressure on to the cutting face through small brass tubes, carried along with the bits, thus washing the turnings out backwards, and also keeping the bits cool. The bits are made to vibrate to clear out the swarf more effectually. On arriving near the centre the operation is com-

They then place the tube or barrel across a hollow anvil, and give blows with a curiously shaped hammer. In the sighting and setting the men acquire marvellous dexterity, and are able to make the barrels absolutely straight in bore. The barrel is fine bored with a square bit, one or two corners of which are kept from touching the bore by wooden spills. Packings are inserted between the spills and the bar, to compensate for the wear of the cutting edge of the bit. The barrels are now second turned and polished, and are then ready for rifling, and again set. Furthermore, they are now tested in a machine for truth of bore, and any want of truth is indicated by the long arm of a lever of bell-crank shape; the short arm rests in the bore of barrel, which is spun on a tension mandrel.



8. LONGITUDINAL SECTION OF LEE-ENFIELD RIFLE



9. MAUSER RIFLE, SHOWING MAGAZINE

pleted by one set of drills. In later practice the barrel is drilled from end to end in one operation.

Draw boring follows this operation with a three-cornered bit of short length. the barrel revolving at low speed. It is again set as required. The barrel is then further turned, using the two spots at the ends and others in the centre, by several cutters or tools, the barrel being spring-supported by back rests; these latter, and the cutters, traversing the bed automatically, copy the taper or shape required from a fixed tangent bar.

After rough turning, the barrels are corrected by the barrel setters, who place the barrel at an angle with the muzzle towards a window with a horizontal board in its top pane, and looking through the bore observe any irregularity of the "shade" or shadow that is cast on the bottom of the bore.

Rifling. The usual method of rifling adopted in England is the old single hook cutter method. In the machine [11] the tool, when passing up the bore, is drawn in like a cat's claw, and then, being drawn out towards the muzzle, the hook tool cutter is pushed out. Each separate groove is thus cut or planed out to the required depth in the bore, while at the same time the required twist is given, in some cases by a fixed tangent bar, which causes a rack to traverse across the slide rest, and in doing so its teeth engage those of a pinion attached to the rifling bar, thus causing it to revolve, and in this manner to produce the required twist.

Other methods adopt a tail rod—that is, a continuation of the rifling bar, having grooves with a twist identical to that required to be produced in the barrel. Each groove engages a white metal

stud, which causes the tail rod to revolve, and thus directly imparts motion to the rifling bar. With its cutter box each groove is planed out separately, and its relative position to the next groove is guaranteed by advancing one notch of the division plate at the end. The rifling tool, or cutter box, is shown in detail [15], and will be described. Oil under high pressure is continuously pumped through a small tube on to the cutter; the shavings as they are drawn back, are examined by the rifler, and form a good criterion as to the state of the cutter and the inside work. Great care must be taken not to tear the grooves, but to get a clearly planed out cut from end to end.

Rifling Head Cutter Box. In this machine [15] the hooked cutter C at the end is solidly backed up by stop plunger P when cutting. The depth of the cut is regulated by screw adjustment, A, and an incline plane, I, up which the cutter is pressed by the spring S acting on its tail end. It will be seen that when making idle strokes up the bore the cutter is pushed down against the spring, but when returning on the cutting stroke it is pressed out again to the stop P. Other countries use drift cutters following each other through the bore with quick light feed, each drift following closely to the other. After rifling, the barrels are lapped out with lead laps in a lapping machine, and then pass to a polishing machine, which takes the grooves. Finally, a high revolving cylindrical lap finishes the *lands*—that is, the projections between the grooves. The thread of the breech end is then cut and rectified, and the barrel finished outside, cut to length, and the muzzle end rounded. The barrels are then sent to proof with a screwed plug on the breech end with a touch-hole through it, and returned duly stamped if correct. The barrel is then chambered to suit the cartridge. A good type of gauge has a taper plug used in conjunction with a cylinder, with a sector cut out.

10. BARREL-STRAIGHTENING MACHINE

The barrels are then browned. To do this they are first plugged at both ends, boiled in soda water, and covered with lime, then dried, and then immersed in a heated acid mixture and rusted, then scratch brushed. This treatment is repeated till an even surface is obtained. The barrel is then dipped into a bath of soft water with alkali to kill the acid, then cleaned off, and polished. The resulting surface is now practically rust-proof. The bolt and other components are also browned. After tapping for the sight-bed screws, and various inspections, the barrel is ready for sighting. The barrel is adjusted, and the sights fitted on and tested, then breeched up, and it must be correctly in line; also, when it is screwed up dead home the sights must be vertical.

Body. The body is made from a special mild steel, which is first broken down roughly to shape from the bar, and then stamped, and then the fins or extruded metal are cut off. The forging is then box-annealed in charcoal for half a day, after which it is pickled and placed in a dilute acid bath, which cleans off the scale. It is now ready for the various machining operations.

The body is first faced at both ends, then centred, and the breech face and the body drilled for the bolt hole in a multiple drilling machine; this hole is then drawn and fine bored. The hole in the socket end is drilled and tapped, in a jig or fixture. The recess for the breech screw is now opened out to the tapping diameter. It is then tapped in an automatic thread-milling machine. The work is held in a special chuck, and a milling bob is rapidly revolved, cutting into the bore to the full depth of the thread. The chuck portion with the work makes one revolution, but during this revolution it also has a longitudinal travel imparted to it by cams, equal to the pitch of the thread. By this means the whole of the thread is obtained. The machine has all its motions instantaneously arrested on the completion of the revolution by automatic gear. The face is then milled off accurately. The thread and face, together with the bolt hole, and with the tapped hole in the socket end and a flat face that is milled on for the tongue, form the spotting points or working faces, which enable the subsequent operations to be carried out relatively to them in the numerous jigs and fixtures.

The body in suitable fixtures is now passed to the various milling machines, the slides and various recesses accurately milled out to the correct contour and depth by former or profiling mills. Generally the latter consist of two overhung spindles on a vertical slide parallel and connected to each other, one having at its lower end a pin or stylus, and the other having cutters. With this arrangement and that of the freely-moving longitudinal transverse slides on the machine, any template or former fixed alongside the work will be copied, by the cutters or mills grooving out the solid metal as required. In addition to this some of the jigs allow the work to swing to cut out radial recesses or slides, and in others an end-on movement is given to form the helical recess for the locking lug. It is hardened at the recoil shoulders. The body stamping in its finished state weighs only about one-fourth that of the original, showing the large amount of machining done to this part alone. The action limbs are stamped out of high-grade steel and machined.

Bolt. This is of crucible steel and is stamped hot, and the handle set, finned, and then pickled to clean any scale off. It is then faced on both ends and turned where possible, and the knob milled. The ribs, etc., are milled, and it is then drilled through to contain the striker, then finished milled. After one hundred detail operations, the bolt is hardened and tempered and straightened.

Bolt Head. The bolt head is made of special gun-iron; it is a forging in most cases. After the facing and milling of the faces, the striker hole is gradually opened out and coned, the stem turned and screw milled, and the various recesses milled and slotted out. There are sixty operations. The head is then hardened, the screwed part being protected by fireclay.

Stocks. The stocks are of European walnut well seasoned, and without defects. The blocks are rough sawn to shape and turned in a copying lathe

by revolving cutters, as shown in **12**, and grooved out for the barrel and magazine, etc. In the case of the Mauser, it is in one piece, but the English rifle is divided into two parts, the butt and fore end.

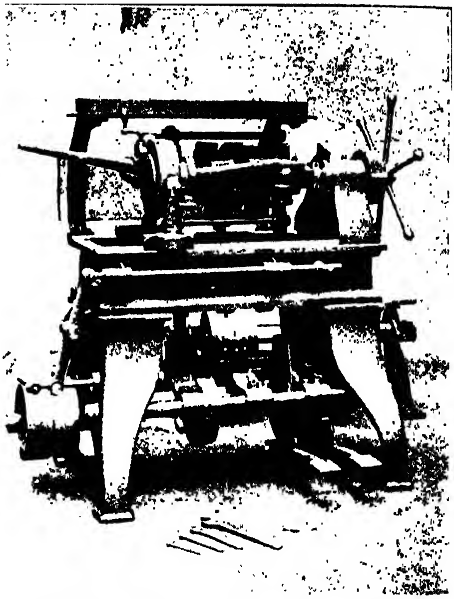
The barrel and body with bolt head and action are now placed in a carriage for final proof, and the compression of a copper crusher-gauge in rear of the cartridge head referred to, a known deflection of a similar copper cylinder, enables the maximum pressure on the base to be obtained. If correct, the parts are then proof stamped. The whole is now assembled on the stock, examined, adjusted and tested on the range.

The Mannlicher and Mauser bolt and action are much simpler, and can be stripped by hand in a few seconds. They are also much simpler for manufacture than the Enfield, and the bolt stands up to the work better.

The table below gives a list and full particulars of the magazine rifles used by various Governments. The tendency now is to make a lighter bullet, by decreasing the weight of the lead interior towards the nose, or by decreasing the calibre of the rifle, but should an absolutely reliable automatic rifle be produced, it would no doubt be adopted.

Sporting Guns. Sporting guns are made in great variety, and include single and double barrel shot guns, smooth bore, also rifled express guns. Nowadays, they are chiefly hammerless breech loaders.

The smooth-bore barrels are made from either (1) twisted and welded Damascus type, or (2) high-grade steel of special quality. The Damascus barrels, which have a beautiful pattern upon them, due to an arrangement of iron and steel twisted bars, which when acted upon by the acid, the steel remains light colour and the iron brownish.



12. LOEWE'S STOCK-TURNING MACHINE

This effect is produced by first piling the iron and steel alternatively with a larger proportion of steel for strength, then by rolling the same into rods, preferably of square section. In the English Damascus type three rods are taken; each is twisted on its own axis and then rolled together in a mill to the form of a ribbon. The ribbons are then coiled by gearing over a loose corebar. The coils are then brought to welding heat and welded around a mandrel by hammering. The thicker coils are then interlaced or scarped on the muzzle portion of the barrel, and the whole is drawn out to the required thickness and the protruding metal is cleaned off. It is to be noticed that the metal must be kept free from scale.

The resulting pattern in this type is that of a chain of interlocked circles, but

Mauser also used by Belgium, Spain, and Turkey.

Mannlicher also used by Roumania and Holland.

11. RIFLING MACHINE FOR B.C. GUNS

many other patterns may be obtained; one type is shown in **16** But this type of barrel is now being rapidly superseded by the weldless steel tube, which is more suitable for the modern nitro powder and the gun of the hammerless drop down type [**17**] with double extraction.

In shot guns the tubes may be drilled, drawn down or of drawn tubes, or forged out of the solid and drilled, as in express rifles. The usual methods of boring are somewhat similar to those described under rifle manufacture.

The latest practice is to drill through the bar of steel from end to end (instead of from each end and meeting at the centre) with a Loewe drilling machine, and finish the boring in one process, and any straightening is done mechanically or by hand setting. These tubes are then finished by the gunmaker and finished bored or choked to his special requirements.

The outsides are not turned, but ground true by hand. Also, in addition to this, many barrels are choke bored. In one type, for instance, the muzzle is contracted to concentrate the shot, and this improves the target pattern. This is done by finishing the bore at the muzzle end with special tools of smaller diameter than the main bore, but some makers contract the muzzle by dies in the hydraulic press. The effect of this choking is shown in the diagram [**13**]. The bores are lead lapped out to get a fine polished surface. The tubes are subjected to a provisional proof to test the barrel, and afterwards to a definite proof.

One noted gunmaker uses the steel marked A for shot guns, and that marked B for rifles. Others use an excellent steel made by Messrs. Wm. Jessop & Sons, marked C in the table in next column.

In double-barrel guns the tubes after proof are assembled and fitted together by the barrel filer with their ribs, lumps, etc. The top and bottom

ribs are fitted and jointed up, the inner edges of the barrels being filed so that they converge. The top ribs may be fluted or shaped as desired. The breech lumps and wedge pieces are brazed on. The breech body, already machined, is now fitted on. The jointing up of the breech is an important item in drop-down guns, and these parts are filed and scraped to fit together in the most careful manner. The holes and ends must also be dead square, so that all parts transmit the shock to the fixed breech, but at the same time the gun must open freely and with regularity. The locking bites must be tight with no slogger. The extractors, which have usually two legs, are fitted in to work freely, and the end faces when home must not project beyond the breech end of the barrel.

The breech body is usually made from a solid forging with front or fore-end projection, a flat squarish part for the mechanism (action). This block is machine recessed for the mechanism, but in many cases two side lock plates are fitted to carry the lock mechanism, as shown in **18**.

There are a great variety of extractors; many of these are actuated by the fore end, which eases the cartridge case and flips it out completely when clear of the standing breech. At the same time the mechanism cocks the hammer. In all cases the

striker must be clear of the barrel face before the gun is opened out.

The body fore end and action and lock plates are hardened in animal charcoal, or the steel action components are hardened and tempered by gas-muffle furnace with oil and water hardening.

The walnut stocks are sometimes shaped (as described in rifle manufacture), but in sporting guns most of the stocks are varied in length, set, and shape to suit the balance of the gun and the purchaser. They are highly finished and polished; also the gun may be finally decorated by engraved lines. A list of the approved minimum dimensions for various gun chambers is shown in the table at the bottom of preceding page, which refers to the dimensions of **14**. The taper in all cases is ·005″ per inch in length.

Maxim Automatic Machine Gun. It is necessary to explain that this gun is fully automatic—that is to say, after firing the first shot the explosion causes the barrel and lock to recoil together and the following cycle obtains. The empty case is withdrawn from the barrel at the same time that a loaded one is pulled out from the belt. The barrel returns home again, causing another loaded cartridge to be brought forward in the belt, into the feed box, by moving the belt. But the lock continues its rearward course, cocking the lock; and, coming forward again, raises up and inserts the loaded cartridge into the barrel, seizes another full one in the belt, having ejected the empty case; and, lastly, when the breech is quite securely home, the trigger is tripped, releasing the firing pin, and again firing the gun. The recoiling parts of the gun are brought back by a strong fusee spring situated at the left-hand side of the gun. That the reader may follow out the action of the gun, and so become acquainted with the various parts, we reproduce drawings [**19** to **23**] furnished by Messrs. Vickers, Sons, & Maxim. Each part is numbered on the drawings, and the names of the parts to which the numbers relate are as follow.

1. Lock casing 2. Safety sear 3. Sear spring 4. Sear axis pin 5. Firing pin 6. Tumbler 7. Tumbler axis pin 8. Trigger 9. Trigger axis pin 10. Lock spring 11. Extractor levers 12. It is to be noted that when firing automatically a complete cycle occurs in the space of $\frac{1}{16}$th of one second.

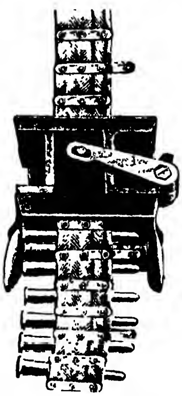
Barrel. This is of very high grade "Vickers" steel drawn down under a Ryder hammer from a round bar. While at the muzzle end it is about the same thickness as a rifle barrel, it is much larger at the breech end. At this end it has a reduced part reinforced by a block with barrel trunnions on each

end. This is screwed on to the barrel, and has in it a stud on each side called the *trunnion bearing* to attach it to the recoil plates, and is recessed for a cartridge head and extractor. The barrel is bored and finished, rifled and chambered in a similar manner to the ordinary rifle barrel; but it is also hardened internally for some distance from the breech to withstand the high temperature of continuous firing. This is done by heating this portion of the barrel, after it is rifled, in a muffle, and then by attaching an oil and water injection pipe, through which first oil is forced and then water. This gives it a harder surface well in front of the shot that prevents the lands and grooves of the rifling being washed away or eroded by the flame of the nitro-cellulose powder. It is then finished, chambered, and touched up, bobbed out to correct any little irregularities due to the hardening process, and finished turned, and also has a deposited copper coating on its outer surface; the breech block is then screwed on dead home in such a way that the axes of the trunnions are at right angles to the axis of the barrel.

Casing. This consists of two plates with two hardened cam plates riveted on, a bottom plate, a rear crosspiece, and a hinged top cover. The side plates are of saw plate quality, and are first flattened out, and then edge planed, drilled to template, and two hardened cam plates are riveted on inside. These control the path of the carrier. In each side plate is a gap extending to the rear edge, for the crank bearing of the recoil plates to slide in. The rear portion is milled to a V shape, and filling-in pieces are fitted in, to close this portion. They can be removed when the rear block is taken off, so that the barrel and all the action can be withdrawn. The bottom plate is of bronze. It is drilled, and the side plates are riveted to its angle fillets. There are also gaps machined through for the feed box, and pin holes for the spring box on the left-hand plate.



23. FEED BOX AND BELT, MAXIM R.C. GUN

Cover. The steel cover has a gunmetal casting with cam projections downward on it to ensure the extractor dropping on recoil of the lock. They also keep the lock down when back. This casting (which also contains a recess for the backsight spring) is machined first and riveted in the correct position; a spring catch is fitted on the rear end of the cover. Holes are drilled for the tangent sight in the upper face, and a milled-out hinge piece is riveted on the front end. The rear crosspiece is a gunmetal casting with a bottom hinge to the side plates; also a pin to secure these passes through them. This pin has a turned T-head split pin to make it readily removable. The rear crosspiece is milled out to take the firing lever, and drilled for its pivot pin. A gunmetal safety catch with its springs is attached. The gunmetal castings on arrival from the foundry are well cleaned and pickled in acid solution and then machined in fixtures to templates and gauges.

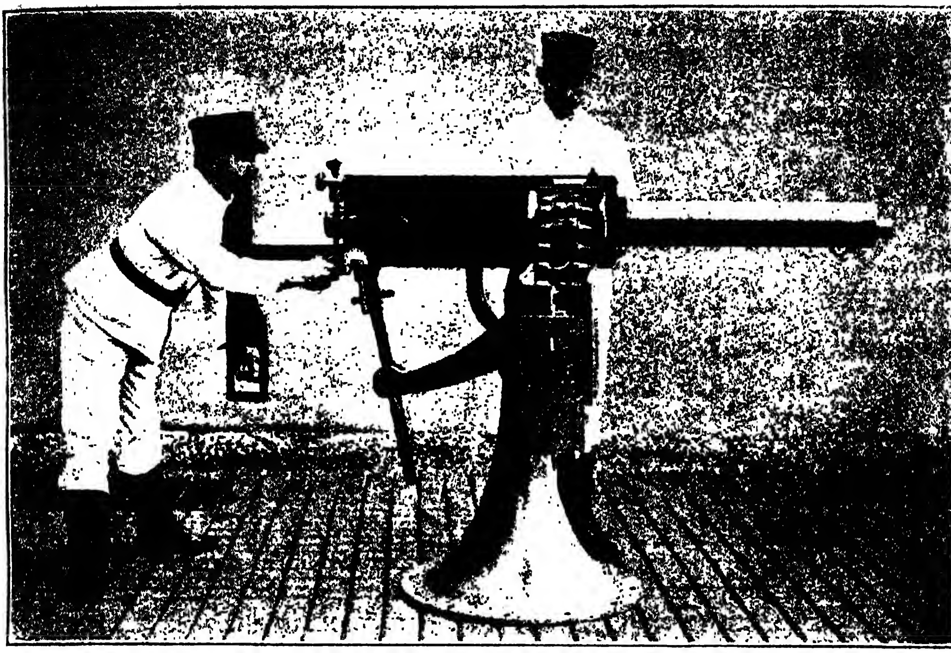
The Water Jacket. The water jacket is made up of a rear block and tube and front cap. The tube is either a bronze casting, or, as in the latest type of steel, with corrugated gills.

The rear block for the water jacket is a bronze casting joining by screw threads to the water jacket in front, and extending rearwards to form a sleeve for the barrel with an ejector tube below it; its top portion has hinged cheeks for the lid. At the side are two dovetails to form a rigid connection with the casing. This casting requires very careful coring and moulding to prevent contraction flaws. After casting it is pickled and sent to the machine shop. The sides are planed or milled parallel, and the fore end turned and screwed. The front and rear faces are milled to length, and the male screw thread is cut on its fore end. The holes for the asbestos-packed barrel breech are bored out and carefully finished to give a good sliding fit to the barrel. The top face is milled across, the hinge cheeks milled through, and the pin holes drilled. The dovetails must be very carefully machined and fitted on to the casing, being driven home with a raw hide or lead hammer. It is drilled for the axis pin and recessed for the extractor spring.

The Tube. When this is of bronze it is a cylinder cored hollow; it must not be porous. It is turned up and polished outside, screwed at both ends, and the sight bed is machined. A water plug and drain plug are screwed in. When in position it must be adjusted so that the sight is vertical.

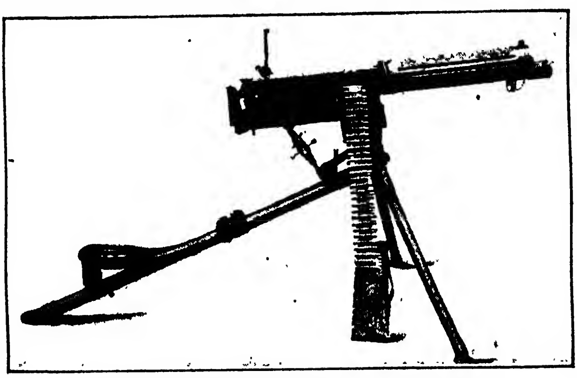
Front Cap. This is a bronze casting with front gland, with asbestos packing to make hydraulic slide joint. There are screwed plugs to receive the steam tube end. When assembled, a boring bar is passed through this gland and the bearing in the rear block to ensure correct alignment, or this would grip the barrel and prevent it sliding properly.

Lock Frame. This [20] is of steel, broken down from the bar, and is a beautiful stamping with the vertical horn web and slides, also side trunnion projections raised up. It is first faced on the front face and slides and wibbled out on the sides, and the two solid side trunnions are formed by hollow mills through a fixing. Then the interior is milled out between the side cheeks in a jig, using the two first machined surfaces as spotting points; then a guide race for the firing pin is slotted out longitudinally, the striker hole is coned out, and the top stop machined. After the outside of the side walls are machined, the pin holes are drilled and reamered out through a jig, so that they are true to pitch and square with the rest of the lock frame when the lock frame is completed outside. The side levers are previously machined, are slipped over the side bearings, and joined together at the rear by riveting them on a square block. The block has a projection rearward forming the male portion of the bayonet joint, and the extractor lever stampings are machined and mounted. The various components, firing pin, and tumbler are machined and hardened. The front face of the thrust block, on which the base of the cartridge rests, is tempered very hard. In front of the lock frames, and gripping it with flanges, is the extractor. The extractor contains a gib with its spring and back plate, and the tail spring. The centre portion is a solid block, through which the point of the striker passes. The front face also has small flanges vertically, but these are discontinued below to liberate the empty cartridge case when in the up position. This component is carefully recessed out by former mills for the gib; also the cone for the firing pin is bored out, and the grooves to form the guides milled. The tail spring is riveted at its lower end to the extractor.



24. 37-mm. MAXIM AUTOMATIC SHELL GUN (POM-POM)

Recoil Plates. These are flat steel plate stampings with square crank bearings stamped up; the left-hand plate has a forward prolongation with an open slot, which engages the bell crank lever, and gives transverse motion to the cross slide of the feed box. It is squared first on the top and bottom edges, and then the outside faces are milled across, leaving the crank bearings projecting up. The insides have projections inwards left on them to form stops to the upward movement of the crank cheeks; also grooved guides are milled in them to contain the extractor slides on the front end. The crank axis holes are drilled and bored out dead square with the plates in jigs, and the front fork or slot of the left-hand plate is machined out with a slight radius The slides and fore end and axis holes are all oil hardened, after heating in a muffle furnace.



25. LIGHT AUTOMATIC GUN ON TRIPOD

Crank and Connecting Rod. The crank is a solid stamping with two web cheeks and axles projecting on each side of them, hexagonal at one end for the hand lever, and at the other for the fusee. They are first turned on the axle parts. The cranks are milled out between the webs, leaving a wedge-shaped portion there; also, outside, they are machined by gang mills. The crank pin hole is bored through the cheeks in a jig and slightly countersunk, and then the finished pin is riveted in place.

Feed Block. The feed blocks [21 and 22] are bronze castings, and contain the steel pawls, slide, and lever. The casting is machined longitudinally outside to fit the casing plates, and transversely inside to suit the various shaped cartridges, also for the cross slides, and bored for the lever. The bottom steel pawl has a fixed fulcrum in the casting; the top pawl is on the slide. The longitudinal movement of the recoil plates imparts a transverse movement to the slide through the bell crank lever, and the top pawl slides back over the cartridge and feeds it forward on the return stroke, the bottom pawl retaining the cartridge belt [23] in position.

Hotchkiss Machine Gun. The only other type of automatic machine gun that has been adopted is the Hotchkiss, which is used by the French and other Governments. It is simple and effective. It has no water jacket, but a very thick radiator barrel, and the number of working parts is small. It can be stripped and reassembled by hand if necessary without the use of tools. It was in use in the Boer War. Another type of Maxim gun, or Pom-pom, is shown by the 37-mm. shell gun [24] somewhat on the same principle as the R.C. type described. This gun fires small shell of about $1\frac{1}{2}$ in. diameter. The latest type of light R.C. Maxim gun is shown in **25.**

Continued

FURS AND FURRIERS

The Quality and Colour of Furs. The Various Processes Involved in their Preparation. Making the Skins into Articles

By J. P. MILLINGTON

THE covering of certain animals is known generally as fur. In speaking of a "fur," the term is usually applied to the pelt or skin proper, and the wool or hair attached to it. On examination of most furs, two kinds of fibres will be noticed—those making up the under-wool, which are soft and flowing, and stiffer, straighter ones, more closely resembling those of human hair. The latter are of service in keeping the woolly fibres from becoming matted or felted, and also assist in keeping the wool from being saturated with water, as they allow the water to shoot away "as from a duck's back."

The value of a fur-skin depends upon the colour, texture, and durability of these fibres, and also upon the nature of the pelt; and it is because they possess one or all of these characters to a high degree that certain skins are held in such high estimation.

Colour and Quality. The colour of wild animals is generally well adapted to the surroundings amongst which they severally live and have their being. Generally speaking, the farther north we go the lighter do we find the prevailing colours, and it is only in the extreme north that white animals are found in any appreciable quantity. Cold has a marked influence on colour, and many animals whose summer coat is grey or even drab assume during the winter a more or less pure white colouring, though, as a rule, certain portions retain their original share of pigment, as, for example, the Arctic hare, which has some pigment remaining in the tips of the ears, and the ermine, in which the tail is yellowish white at the root and black at the tip.

Like colour, quality is influenced by climatic conditions. As a rule, the colder the winter the better is the fur, and those skins taken about mid-winter are usually better both in quality and colour. When the new coat begins to appear, certain of the half-grown fibres are to be seen. A skin in this condition is said to be "stagey," and is generally much poorer in quality. Summer skins are those obtained from animals wearing their summer clothing. These also are of considerably lower quality than those taken in winter.

The Application of Furs. In the first place it should be pointed out that the skins of fur-bearing animals are used for two main purposes. Their chief application is to the manufacture of articles for domestic use—wearing apparel, rugs, etc. In the second place, the fur, after being separated from the pelt, is converted by pressure into felt used in the making of hats, cloth, and so on. In addition to these uses, there are certain other industries on a smaller scale which deal in fur products, as, for example, the manufacture of badger-hair brushes, and of artists' brushes from sable and kolinski tails. Our chief concern will be with the fur trade proper in connection with the collecting, trading, preparing of furs, and their manufacture into saleable articles of clothing.

Before proceeding to an account of the treatment of furs, it will be as well to give a short account of the fur-bearing animals. For details concerning their nature, habits, and relationships, see the course on NATURAL HISTORY. We shall consider them here only so far as they are important from the furrier's point of view.

FUR-BEARING ANIMALS

Angora. [See GOAT.]

Badger (*Meles taxus*). Found across temperate parts from Britain to Japan. Rather stiff greyish upper hair, and whitish under-wool. The hair is used for making brushes.

Bear (*Ursus*). Various species are used by the furrier. The brown bear (*Ursus arctos*) is found all over the Old World north of the Atlas and Himalaya ranges. Fur varies much in colour and quality, that of the cubs being woolly while that of more adult members of the species is stiffer.

The *Grizzly Bear* (*Ursus ferox*) is found distributed over a large area in North America. The under-wool is brown or dark brown, and the hair almost black. Certain skins yield hair suitable for brushmaking, but the majority is used for ordinary furrier's work, and large numbers are employed in the manufacture of caps and robes for military purposes.

The *Polar Bear* (*Ursus maritimus*) is found only in Arctic regions. The fur of the young is quite white, but becomes yellower with age, though some adult specimens are of an almost pure white. A certain number of skins are used for rugs.

Beaver (*Castor*). Two species only are known—the European beaver (*Castor fiber*) and the American beaver (*Castor canadensis*). The former is widely distributed over Europe and Asia; the latter is practically confined to Canada. The fur is a very beautiful one of a grey-brown or reddish colour, with rather long, somewhat stiff hairs. Usually, beaver skins are "pulled"—that is to say, the upper hair is removed and the colour of the fur altered by a chemical process known as "silvering." Beaver is used largely for trimmings, coat linings, and sundry other purposes, the old application to the making of hats being practically a dead industry. The numbers annually taken have of recent years shown a marked decrease, owing to persistent hunting.

Blue-backs. [See HAIR SEAL.]

Buffalo (*Bos americanus*). Found in western and northern American prairies. Hair rather coarse and dun in colour. Used chiefly for making leather, though the finest skins are made into robes.

Cat (*Felis*). Various species used in fur work. The domestic cat, of which large numbers are obtained from the Continent (more particularly from Holland), is used in large quantity for fur work of an inferior kind. The skins are made into linings for coats, etc., and these are known as "genet." Fur poor in quality; colours various.

Wild Cat (*Felis catus*). Poor in quality and in limited demand.

Civet Cat (*Viverra zibetha*). Sometimes used on account of singular markings.

Chinchilla (*Chinchilla lanigera*). Found in various parts of South America—the finest qualities in Peru. The hair is very soft and of almost the same length as the fur. The fur is long and silky, in the ground parts of a dark slate colour, while the upper portions are silvery grey. Used very largely for muffs, boas, and trimmings.

Another variety, known as *Bastard Chinchilla*, comes from Chili. The skins are smaller and the fur poorer than the real chinchilla.

Caragan. A variety of fox found on the steppes.

Deer (*Cervus*). Many species are found in various parts of the world. There is little fur, and the hair is rather short and stiff. Chiefly used for making mats, rugs, etc.

Ermine (*Mustela erminea*). Found in Russia, Siberia, and North America. Hair and fur both soft. The best almost pure white. Inferior qualities have a more yellowish tinge, and are frequently bleached before use. Tail yellowish, with a black tip. Used for muffs, boas, trimmings, etc.

Fisher (*Mustela pennanti*). Found in northern parts of America. Fur rich and close, hair long, dark and glossy. Pelt strong, and the whole skin of a durable nature.

Fitch (*Mustela eversmanni*; also *M. putorius*—the pole-cat). Found in various parts of the Continent and in Siberia. Hair long, with dark tips. Fur light grey to yellow. Used very largely for cheaper varieties of fur work.

Fox (*Canis*). Many species and varieties used for all kinds of fur work [8].

Black Fox (*Canis vulpes argentatus*). Found in North America and in Russia. Best from Labrador district. Fur fine, and dark in colour. Hair long and glossy. Value varies according to colour, the darkest being the most valuable.

Blue Fox (*Canis lagopus*). Found in Arctic regions. Best from Archangel district and others from Greenland. Fur soft and woolly, of a blue colour, hair of a grey-blue colour.

Continental Fox. European red fox.

Cross Fox (*Canis vulpes pennsylvanicus*). Found in North America—best come from the Hudson's Bay district. Fur pale in colour; hair darker at the tips, the darkest parts being along the spine and across the shoulders, making a distinct cross [c d].

Grey Fox (*Canis cinereo-argentatus*). Found in America. Fur greyish or yellowish; hair silver-grey on the back, more yellow on the sides.

Japan Fox (*Canis procyonoides*). Poorer in quality than above. Hair greyish and somewhat stiff and short [8b].

Kitt Fox (*Canis velox*). Found in some parts of Russia and in North-West America. Skins small; fur and hair rather soft.

. and Fox. Name usually given to red fox from Germany and Switzerland. Smaller and poorer than Asiatic and American kinds.

Red Fox (*Canis vulpes*). Found all over the northern hemisphere. Some of the best come from America, of which there are two varieties—western and eastern—the former being the finer. Very fine skins are also obtained from North Europe—those from Finland are, perhaps, the best. Very fine skins come from Asia, the Kamchatkan kind being particularly good. Colour of fur various, yellowish to blue-grey. Hair yellow to a rich dark red [8c and e].

Silver Fox (*Lanis vulpes argentatus*). A variety of the black fox obtained in Russia and North America. Fur dark in colour, hair silvery white.

White Fox (*Canis lagopus*). Found in North America and in North Asia. Fur and hair pure white, though the former often has a tinge of blue. Sometimes darker hairs are present. These lower the value of the skin. Enormous numbers are dyed various shades [8a].

Genet. [See CAT.]

Goat (*Capra hircus*). Found in many parts of the world. The Angora possesses fine silky fur, and is largely employed in the making of rugs. Certain kinds of goat obtained from Thibet and China come into the London market in enormous quantities, and are classified according to colour into "whites," "greys," and "natural blacks." The best skins of the last-named class are dyed to imitate bear, and are much used in the manufacture of rugs. Some of the finest come from China and Manchuria.

Guanaco (*Lama acus*). Found in South America from Ecuador to Tierra del Fuego. Colour reddish to yellow. Chiefly employed for making carriage rugs, etc.

Hamster (*Cricetus frumentarius*). Found in large numbers in Germany and on the Continent. Fur and hair short, yellow to grey, with curiously shaped black markings down the back. Made into linings for coats, cloaks, etc.

Hare (*Lepus europæus*). Found in northern hemisphere. Fur soft and fine, hair long and fine, pelt weak. Pure white found in Russia and Siberia in enormous numbers. Thousands used in this country in the natural state, and dyed to imitate the more costly varieties of furs. Sold by the *poud* (a Russian measure). Value according to the weight in *pouds* of 100 skins.

Kaluga (*Spermophilus citileus*). Found in Central Europe and Siberia. Practically no fur, but very short hair. Poor skins in every way, both as regards fur and pelt. Colour grey, yellow, or reddish. Made into coat linings, etc., and often dyed some darker colour.

Kangaroo. Various species used to a slight extent.

Kolinski (*Mustela sibirica*). Found in Northern Asia. Fur soft and short, of a blue-grey colour in the ground, lighter on the top; hair yellow to orange-red; skins generally dyed to look like sable, and used for muffs, stoles, etc. The hairs from kolinski tails are used in making artists' brushes and pencils.

Lamb (*Ovis aries*). Many varieties are known in the fur trade, and have received names according to the districts from which they are obtained—*e.g.*, Persian, Krimmer, Ukraine, Astrachan, etc. The fur is curly, the value depending on the size and tightness of the curl. The better the curl, the more valuable the skin.

Persian lamb is the most valuable, as, when dyed, it takes a most beautiful gloss. Ukraine, Astrachan, etc., are less valuable, but are largely used. Colours are various. A certain number of pure white skins are used in the natural state ... turely. Lamb from Western Europe has a longer wool, and is used for lining gloves, etc.

Leopard (*Felis pardus*). Used for rugs, etc.

Lion (*Felis leo*). Used for rugs, etc.

Lynx (*Felis lynx*). Obtained in Europe. An American species (*F. rufa*) is also used in fur work. Fur grey, yellowish or bluish. Hair fine and soft, of a greyish colour, flecked with black. Many used natural for ties, etc., some dyed, chiefly blue and black colours.

Marmot (*Arctomys*). Various species obtained in Europe and Asia are employed. Different kinds are known by special names—*e.g.*, Orenberg marmot, Tarrabagan, etc.—and the values differ according to the kind. Fur is rather harsh, generally of a greyish black colour in the ground, becoming lighter and more yellowish red at the top. The hair is reddish, often speckled with black, and rather stiff and harsh. The skins are generally dyed to imitate the more costly sable.

Marten. Various species belonging to the genus *Mustela* are used. The whole genus is characterised by a certain softness and richness of the fur, which makes them amongst the most highly esteemed furs.

American Marten (*Mustela americana*). Found principally in the Hudson's Bay district, Labrador, Alaska, and certain other parts of North America. The fur is bluish grey, except under the throat, where it is a yellowish white. The top of the fur is lighter in colour, and the hair varies from a light yellow to a rich dark brown. Next to the Russian sable, it is the most valuable skin of the marten tribe. The darker the skin the more valuable it becomes.

Baum Marten (*Mustela martes*). Found in Central and Northern Europe and in Asia. Fur rather like that of American marten, but somewhat lighter. The hair is fine and soft, and varies in colour from light yellow to dark brown. The fur on the throat is of a yellow to deep orange colour.

Fisher Marten. [See FISHER.]

Japanese Marten. This is a much less valuable fur than the preceding, both on account of its harsher nature and of its brilliant colouring value, which ranges from yellow to orange.

Japanese Sable. In character this skin rather resembles that of the Chinese sable, which seems to be a variety of the Russian sable.

Russian Sable (*Mustela zibellina*). One of the most highly-prized furs. The fur of the best skins is of a rich, greyish blue in the ground, becoming somewhat lighter towards the top. In character it is exceedingly soft and "full." The hair is dark brown and glossy, and here and there greyish hairs are to be seen. The lighter-coloured skins are much less valuable and are frequently dyed to look more like the darker natural skins.

Stone Marten (*Mustela foina*). Found distributed over Southern Europe, some of the finest skins being obtained from Turkey, and in certain parts of Asia. The fur is of a lighter colour than that of the other martens, and is generally of a pale greyish blue colour, though in many skins it is almost white. The hair is very long and less soft than in the other species. In the best skins it is of a dark brown colour.

Mink (*Mustela*). Various species are used.

European Mink (*Mustela lutreola*). Found in Poland, Russia, and Eastern Europe generally. It is known as "nörtz" or "sumpf-otter," and is not used in large quantities.

American Mink (*Mustela vison*). Occurs in America. The fur and hair are short, and vary from a pale yellow to a rich brown. The upper lip is generally white, and there are also white patches on the breast.

Japanese Mink (*Mustela sibirica*). Closely allied to the Siberian mink, and resembles the polecat tribe. Its fur is short, rather harsh, and of a yellowish colour.

Mole (*Talpa Europœa*). Found distributed all over Europe. Very fine, soft fur, short and close, of a bluish-grey colour. Has been used in exceedingly large numbers during recent years for jackets, etc.

Mongolian. Under this name are included the skins of various animals from Thibet and China. The skins of certain kids from these districts are sewn together in the form of a Maltese cross, and are known as China kid crosses. The small pieces of fur which cover the legs are also made up in a similar fashion, and are sold under the name of "kidleg crosses." They are generally classified according to colours, four principal varieties being recognised—viz., grey, white, black, and mixed, or spotted. The value depends on the quality and length of the fur, the longer and coarser varieties being the least valuable. The name "Mongolian" is often used as synonymous with Thibet lamb, a species of sheep having long, soft, curly wool.

Monkey. Certain species from West Africa, with fur of a bluish-grey colour, have a limited use.

Moufflon (*Hircus laniger*). Found in various districts in Europe and Asia. The hair is "pulled," leaving a soft wool. Skins are dyed various colours—blue, grey, etc., and are used for making necklets, etc. The true moufflon (*Ovis musimon*) is found only in Corsica and Sardinia. The skins of certain Mongolian goats are also known as moufflon.

Musquash (*Fiber zibethicus*). Found in North America. The hair is coarse and generally dark, the fur soft, close,

and of a rich, grey-blue to slate colour. When "pulled," the fur shorn so as to be of about 14 millimetres in length, and dyed, these skins are used very largely for making ladies' jackets, as the finished article is a very passable imitation of sealskin. One variety, known as "natural black musquash," which is obtained from Maryland and Delaware, is of much greater value than the ordinary kind.

Nutria (*Myopotamus coypu*). Found in the River Plate, South America. The hair is coarse and stiff, and is usually removed by "pulling." The fur is short and close, and of a rich brown colour. For use as trimmings for ladies' garments it is often "silvered." [See BEAVER.] The fur of skins of which the pelt is damaged is much used for felt manufacture.

Opossum. Two varieties are used by the furrier—the American and the Australian. The characters of the furs of these two animals are quite different. In the American opossum (*Didelphys virginiana*) the hair is long and coarse, often split at the ends. The fur is generally white or ashy grey. In the Australian opossum (*Phalangista vulpina*) the hair is shorter, less stiff, and the whole effect is more woolly than in the American form. The colour is usually blue-grey on the back, while the belly fur is white or yellowish.

Otter (*Lutra*). The otter is found distributed over a large portion of the earth. The European species is *Lutra vulgaris*, and some of the best skins come from Norway, though occasionally good ones are obtained in the Shetland Islands. The Canadian otter (*Lutra canadensis*) is also largely used. A very large otter is obtained in South America (*Lutra braziliensis*), and a certain number of these skins are used by the furrier. The African species (*Lutra capensis*) is large in size, but the quality of the fur is rather poor.

Sea Otter. [See SEA OTTER.]

Platypus (*Ornithorhyncus paradoxus*). Found in Australia and Tasmania. The fur is not of first-rate quality, and has but a very limited use.

Rabbit (*Lepus cuniculus*). Found all over Europe, and its fur is perhaps one of the most largely used. Many thousands of tame rabbit skins are used on the Continent. When shorn and dyed they are used as an imitation of sealskin under the name of "electric seal." Several varieties are known to furriers and fur merchants, and amongst them may be mentioned Blue Rabbit. The last-named is used as imitation ermine, and for millinery purposes. The fur is also largely employed in the manufacture of felt for hats, etc. The American rabbit has fur more resembling that of a hare.

Raccoon (*Procyon lotor*). Found in North America. Fur long and well developed, greyish or yellowish grey in colour; hair often flecked. Pelt strong and durable. Largely used for linings and rugs. The tail is ringed with black.

Sea Otter (*Latax lutris*). One of the most valuable furs at present in use. Found in the North Pacific. Formerly it was comparatively common, but persistent hunting has greatly reduced the numbers. The fur is very full, rich, and soft, and its colour varies from a greyish brown to an exceedingly dark brown. The pelt is extraordinarily strong and thick.

Seal. Under this name are included many species which may be conveniently divided into two main groups—the fur seals and the hair seals. In the former class the fur is very thick and soft, while in the latter it is reduced to a minimum.

The Fur Seals. There are four species used in the fur trade which are classified according to the districts from which they are taken.

Alaska Fur Seal (*Otaria ursina*). Found in the Behring Seas, and the greatest numbers are taken on the seal beaches of the Pribylov Islands, and those belonging to the Aleutian group. The hair is stiff and strong, the colour varying according to age. The fur or wool is very thick, and after removal of the hair is seen to be of a greyish yellow or brown colour, and tightly curled. (This description applies in the main to the other three varieties of fur seal.) The seals taken in the open sea and known to commerce as "North-West Coast seals," as well as those taken off the coasts of the Copper Islands, also belong to this species.

Cape Horn Seal (*Otaria australis*). Found in the South Pacific. "Lobos" skins, caught near the Lobos Islands, belong to this species. The fur, as a rule, is not so thick as in the Alaska seal.

Cape of Good Hope Seal (*Otaria pusilla*). Found in the neighbourhood of the Cape of Good Hope. Somewhat similar in general characters to the Cape Horn seal.

New Zealand Seal (*Otaria forsteri*). Found near New Zealand and in the South Sea Islands. The fur in favourable specimen of "South Sea skins" is very long and full.

The quality of the fur depends to a great extent upon the age of the animal. Three or four year old seals generally possess the richest and thickest fur. According to the size they are sorted and named as follows, beginning with the largest: Wigs, middlings, middlings and smalls, large pups, middling pups, small pups, extra small pups, grey pups, and black pups. Further details concerning fur seals is given later.

The Hair Seals [9]. Various species from the Pacific are known to commerce—*e.g.*, the Cape sea lion (*Otaria jubata*), the Northern sea lion (*Otaria stelleri*), the Californian hair seal (*Otaria Gillespii*), and the Australian seal (*Otaria lobata*). Those most frequently met with are the Atlantic varieties, of which the following are the most commonly used.

Grey Seal (*Halichœrus grypus*). Found in North Atlantic. Certain numbers breed in the Shetland Islands. Not very plentiful.

Common Seal (*Phoca vitulina*). Found all round the British coasts. The hair is yellowish with black spots on the back and flanks, yellowish white on the belly [9c].

Ringed Seal (*Phoca hispida*). Found in the North Atlantic. The hair is stiff and of a yellowish colour, marked down the back and flanks in the form of rings of blue or black hair.

Blue-back (*Phoca grœnlandica*). Found in the Northern seas. The hair of the back is a bluish grey—sometimes quite a dark blue, while on the flanks and belly it is white or yellowish white [9b].

Whitecoat. The young of various species of hair seals having their first coat are known as whitecoats. The fur is soft, the hair softer than in the adult, and varying in colour from silvery white to light yellow. Some are even of a pale orange colour. The hair seals are used chiefly for the making of coats for motoring, though whitecoats, when dyed, are used for making military caps, etc [9a].

Sheep (*Ovis*). Three kinds of wild sheep are used in the fur trade—viz., the argali (*Ovis argali*), from Siberia; the moufflon (*Ovis musimon*), from Sardinia; and the American sheep (*Ovis montana*). There is generally a stiff hair and a soft under-wool. The former is usually removed by the process known as "pulling."

The lambs are very largely used under names denoting their place of origin—*e.g.*, Astrachan, Persian, Ukraine, etc. Caracule, from the south of Russia, is largely employed.

Skunk (*Mephitis mephitica*). Found in North and Central America. Of a dark brown, almost black colour, with dark under-wool. Generally, there is a more or less well-defined white stripe of a V-shape. Dark skunk are valuable skins, both on account of their colour and durability. The white stripes are often cut out, sewn together, and then dyed to imitate the darker portions. Largely used for muffs, ties, collars, etc.

Squirrel (*Sciurus vulgaris*). Found in the northern parts of Europe, Asia, and America. The common red squirrel is not much employed, the kind chiefly valued being the Russian and Siberian. The fur is soft, full, and of a rich dark slate colour, and the hair is grey, slightly flecked with a darker blue. The belly is white, while the flanks are often slightly red. Squirrel is largely used for coat linings. The skins are divided into back and belly, and the backs made into what are known as sacs. These, when dyed of a sable colour, form a very tolerable sable imitation. The bellies are also sewn together to make "squirrel lock sacs." The best varieties of Russian squirrel are known as Obsky, Tobolsky, and Lensky.

Susliki. [See KALUGA.]

Thibet Lamb. [See MONGOLIAN.]

Tiger (*Felis tigris*). Found in Asia. Chiefly used for making rugs, etc.

Vicunia (*Lama vicunia*). Has practically the same distribution and characteristics—as regards fur—as the Guanaco, and the skins are employed for similar purposes.

Wallaby (*Petrogale xanthopus*). Found in Australia. Fur soft; hair rather long, and of a greyish colour. Largely used when dyed as an imitation of skunk.

Whitecoat. [See SEAL.]

Wolf (*Canis lupus*). Found in the northern parts of Europe, Asia, and America. Hair fine, wool soft, and very liable to "felt." Best come from Siberia and the Hudson's Bay district. Colour varies from yellowish grey to blue, some skins having hair that is almost black.

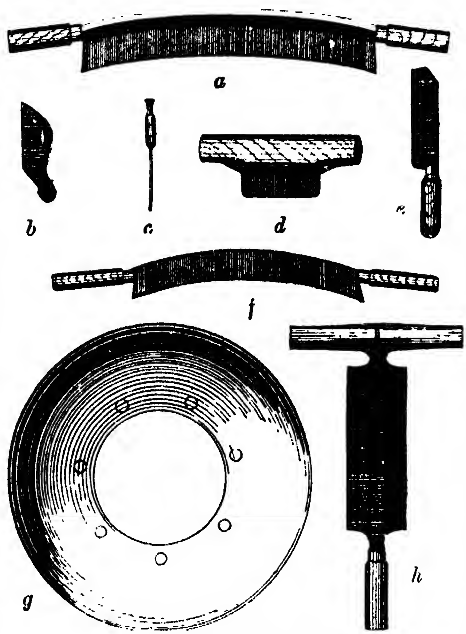
Wolverine (*Gulo borealis*). Found in Arctic regions. Known also as the Glutton. Fur soft and thick. Colour somewhat similar to that of the wolf.

The Trade in Furs. At the present day there are certain recognised centres of the fur trade, and to these almost all the skins are brought and sold either by private treaty or by public auction. Amongst these centres are London, Leipzig, Nijni-Novgorod, and Irbit. To the London market come all the goods belonging to the Hudson's Bay Company. These are sold by public auction twice a year, in January and March, the chief skins being beaver, musquash, red fox, white fox, cross fox, kitt fox, silver fox, mink, otter, American

marten (known as Hudson's Bay sable), fisher, lynx, wolverine and wolf.

Furs collected in America other than those of the Hudson's Bay Company are sent direct to London—and a small number to Leipzig—where they are received by commission agents and subsequently sold. To London also come most of the South American (chinchilla, guanaco, nutria, etc.) and Australian furs (opossum, wallaby, kangaroo, etc.), as well as large numbers of what are known as "China goods," including goats, Thibet lambs, China kid, and kid crosses, Jap fox, Chinese sable, weasel, kolinksi.

The fur sales in London take place in January, March, June, October, and December. At the December sales practically the whole of the world's seal catch is disposed of to merchants, who distribute them between London and Paris for dressing, dyeing, and those subsequent operations which are necessary before they are ready to be made into jackets and other articles. At the March sales, which are the largest, almost every conceivable variety of skin is to be seen, and at this time of year certain parts of the City seem to be more than usually cosmopolitan, for merchants come from the ends of the earth to prepare for the following winter. The China goods are sold mostly in January, and, as in every other branch of trade to-day, there is a tendency to specialisation to be seen, for certain business houses devote almost the whole of their attention to this China trade. About Easter time, Leipzig presents a similar cosmopolitan aspect, for then the great fur fair is held. At this fair the majority of the goods sold are those obtained from the Continent of Europe—including part of the Russian produce, and, in addition to the various kinds of sable and marten, such as stone and baum marten, fitch, kolinski, etc., large numbers of American skins—skunk, beaver, musquash, etc.—are sold.



1. THE FURRIER'S TOOLS
a. Beaming knife b. Furrier's knife c. Shaver's ste d. Sleeker e. Unhairer's pulling knife f. Blubberin knife g. Moon knife h. Cross-handled shaver's knife

To Irbit, one of the centres of the Russian trade in furs, are brought Russian furs, such as marmot, hare, and fitch, white fox, ermine and squirrel, as well as lambs of many kinds—Persian, Ukraine, Krimmer, Astrachan, and others. The skins are sorted, half-prepared, and sold, to come eventually to Western Europe, often *via* Leipzig and London.

The fair at Nijni-Novgorod was formerly the greatest in the world. Here, East and West met to haggle and barter, buy and sell. To-day, however, it is of considerably less importance, though still the centre for Siberian goods such as ermine, hare, sable, squirrel, and other furs.

At the London sales all goods are sold by public auction to the highest bidder. Goods must be cleared from the warehouses by a certain fixed date, so that many merchants and furriers who do not wish to have their goods worked immediately have them warehoused. Some skins are best kept in cold stores; for others it is sufficient to put them away at the ordinary temperature with some substance which will prevent them from being attacked by moth. Camphor is excellent for this purpose, but on account of its lower price naphthalene is much more largely used.

Tariffs and Duty on Furs. The Customs duty on furs was abolished in 1845 after having been reduced three years earlier, so that all skins, whether raw, dressed, or dyed, come into this country free of charge. The same applies to Germany, but in France, dressed and dyed skins are charged duty according to tariff, with the exception of certain China goods, and some kinds of hair seals.

All raw goods are admitted duty free into the United States, but charges are made upon dressed skins amounting to about 20 per cent. of the value, while for manufactured articles an even higher rate is charged.

There are also certain tariff charges in Canada and some of the Australian Colonies.

So much then for the trade in raw products on the large scale. The courses usually adopted in retailing are two in number. The merchant, having obtained his goods, sorts them according to colour and quality, and either sells them in the raw state to the furrier, or to another merchant, or hands them over to the fur-skin dresser and dyer. By the latter they are dressed—that is to say, the hard, horny skin is converted into a soft, pliable pelt of the nature of chamois leather, and, if necessary, shaved down to a suitable thickness. Certain goods require dyeing in order to improve their lustre and colour generally, or so to change them in appearance that they resemble a more costly and pleasing fur. From the dresser and dyer they pass once more into the hands of the merchant; from him to the furrier, and so to the retailer of the finished articles. Certain furriers, however, prefer to buy the raw goods from the merchant, and have them prepared according as they are needed, this applying particularly to the more valuable varieties.

Prices of Skins. In the following list, the prices and numbers given are only to be read as approximate. It is impossible to obtain accurate figures as regards numbers on account of the enormous amount of business that is done by private treaty at the various Continental fairs, and, in addition to this private sale there is still, at Leipzig, at any rate, a certain amount of barter. Russian merchants, for example, exchange Persian lamb for the red fox of their German brethren. Amongst the skins which are sold by auction to only a small extent are squirrel, marmot, fitch, nutria, baum and stone marten, kolinski, and Persian lamb,

and of these any figures that may be given represent but a small fraction of the total number.

With regard to prices, we are again forced to approximate figures. As a rule, two prices are given, the one representing the lowest grades and the other the highest. Between the two are innumerable values.

There are various causes which determine the prices, the principal being demand, which is ruled by the dictates of fashion, and supply, which is practically beyond control. A few seasons ago, there was a large demand for moleskins, and whilst the fashion lasted millions of skins were made up into jackets, muffs, and other articles of wearing apparel. At the present time the demand is considerably lessened, and, in consequence, far fewer skins come to the market. Persistent hunting frequently causes a shortage in numbers, and disease and increase in the number of the natural enemies of fur-bearing animals are also contributing factors.

2. FLESHER AT WORK

APPROXIMATE PRICES AND NUMBERS OF FURS ON THE MARKET

Kind of fur.	Number.	Value per skin.

Wolverine	1,063	1s. ,, £2 10s.

There are few who would recognise as things of value the rather unpleasant skin of the fur seal as it comes to the fur-dresser, covered with salt on the fur side, and its natural coat of thick blubber on the pelt side, or the shapeless-looking object with a hard, horny skin which later forms part of my lady's sable set. Yet it is to this recognition of value and quality in the raw state that most capable fur merchants owe their success; and it is due to the skill and energy of the dresser that the pelt is made into leather as soft as chamois, and the fur and hair cleaned and laid as Nature intended, so that the unsightly and often evil-smelling raw skin becomes a thing of beauty and a joy to its owner. Frequently, furs which are inferior in natural colour are dyed to resemble the more pleasing skins, and of this process more is said later.

Curing the Skins. The first process, the curing of the skins, is usually performed by those engaged in the work of capturing fur-bearing animals. It consists essentially in removing the skin with its attached fur from the body, removing excess of fat, and drying in the air. Certain skins, however, such as fur seals, bluebacks, calves, etc., are dressed with salt before packing. Mention is made of this later when considering the dressing of seals.

As stated, in the case of most animals the skin is stripped from the body and dried. This removal of the skin is usually effected in one of the three following ways: (1) An incision is made in the middle line of the ventral surface from mouth to rump, and the skin carefully cut away. This method is almost universally employed in the case of marmot, chinchilla, and Australian furs, such as wallaby and opposum. Large skins—e.g., bear, goat, sheep, etc., are also treated in this manner. (2) The animal is opened at the mouth and rump and the body of the animal drawn through. This is by far the most usual practice, and most of the smaller skins with which the fur dresser has to deal are thus obtained. (3) The body is drawn through the mouth, leaving the rump or "breech" end closed. Usually the legs and tail are opened and the bones removed, though so cleverly is this method employed by certain hunters that although the breech is not opened the tail and leg bones are taken out, in all probability with some sharp rod-like instrument. Many Russian sable and stone marten come to the dresser in this fashion.

One animal—the nutria, from the River Plate—is remarkable in that the belly fur is better than that of the back, and in consequence the removal of the skin is always effected by making a longitudinal incision down the centre of the back instead of the belly. As a rule, the head, legs, and tail are left attached, though this is by no means a universal custom. In seals, the fore flippers are cut off, and in the skin as received from the curing house are to be seen two round or elliptical holes marking the places which the flippers occupied [5]. Many skins, such as goat, Thibet, marmot, wallaby, nutria, come to the market minus heads and tails and legs.

The Drying Process. Where the method of salting is not employed, the next process is that of drying. Where the skins are "cased" or "round"—*i.e.*, obtained by method 2 and 3 above—they are dried with the fur inside. If "open"—method 1, above—the skins are merely spread open, pelt uppermost. It is during this drying that a certain number of skins become "burnt," owing to great heat, or sometimes on account of "taint" present in the skin. When a skin is "burnt," the pelt is converted into a very hard, horny substance which resists all subsequent attempts to convert it into leather. Some skins seem much more liable to this burning than others; for example, one frequently finds burnt patches in bear, wallaby, and marmot; more rarely in fox, sable, squirrel, and such-like small skins. Seals are cured with salt, laid in piles, and after remaining in the salt for about fourteen to twenty-one days, are corded up in rolls and shipped. Ordinary dried skins are packed in bales, fur to fur if "open," pelt outwards if "cased," though naturally the exact modes of packing differ according to the kind of skins and the customs of the district from which they come.

The first operation necessary for the conversion of the skin into leather is the one known as *fleshing*. The skins are first treated with water—sometimes with a weak brine—allowed to remain a certain length of time in order to become soft, and then the surplus fat and connective tissue removed by pulling them over a knife of the type shown in 2.

Grease Dressing. The skins are then ready for the next operation, which is that of *greasing*. For this purpose, grease of special nature (English dressers generally use animal oils, while in France colza and other vegetable oils are employed) is smeared over the pelt, allowed to soak in, and then the skins are subjected to a process by which the fats are driven into the substance of the pelt, rendering it soft and pliable. This is accomplished in one of two ways, according to the nature of the pelt. For small skins and such as possess a tender pelt the process of *foot tubbing* is employed. The skins, thoroughly greased, are placed in tubs inclined at a slight angle to the vertical, in which men with bare feet stand. By a continuous up and down motion of the feet the skins are constantly turned over and over, the grease is worked into the substance of the skin, and the result is a soft, supple pelt. During this process, a certain amount of heat is developed by the constant friction, and this in no small measure helps towards the accomplishment of the object in question.

3. DRUM FOR CLEANING SKINS

4. SHEEP SKIN DRYING IN FRAME

5. SEAL SKIN DRYING IN HOOP

In the case of skins having a stronger and heavier pelt a different method is employed. After greasing, they are placed in a mill which consists essentially of a box into which a wooden block descends. This block is attached to the end of a lever, and the whole is so constructed that the skins receive a hard blow at the moment of the fall of the lever, and at the same time are pushed slightly away from their former position. Here, again, a turning is effected, and the amount of heat developed is quite considerable. This method is the one always followed for heavy skins, such as seals, bluebacks, wallaby, etc., and is, of course, more economical than the slower process of tubbing. As might be expected, the length of time taken in each of these operations varies enormously. In some cases the skins are greased again, and the leathering process repeated. No definite rules can be given; the judgment of the dresser alone can decide when the skins are sufficiently leathered.

Removal of Excess of Grease. The skins at this stage are very greasy, and require careful cleaning before they appear in any way presentable. The chief substance used as an absorbent for this excess of grease is sawdust, though other materials are used, such as plaster of Paris and French chalk. Some French dressers sometimes mix a small amount of fine sand with their dust in order to secure more perfect cleaning. The greasy skins are worked about in the dust either in the foot-tub or in a mill like the one described above, except that it is boxed in, and so has received the name of a *box-mill*. Finally, the skins are turned fur outwards, if cased, and the fur cleaned in a similar fashion in what is known as a *drum* [3]. A drum consists of a hollow cylinder of iron or wood mounted on an axle and capable of rotation about this as an axis. Into the drum are placed the skins and sawdust, or whatever the cleaning material used may be, and the drum caused to revolve for a varying length of time. To free them from dust, the operation of *caging* is necessary. The process is a simple one. They are placed in a wire cage, mounted like the drum just mentioned, and as the cage revolves the particles of dust are beaten out, and fall through the meshes of the cage.

Finally, the skins are *shaped*—that is, stretched so as to look somewhat natural in appearance, and, if necessary, the pelt *knifed*—that is, pulled over a knife similar to the one used by the flesher [2], in order to further soften it and to remove inequalities; beaten with canes in order to free the wool from felt and to make it free and

flowing, and any parts of the pelt which may be torn carefully repaired.

This, in short outline, is the process of grease dressing, but there are so many details to be carefully observed, and so many pitfalls for the unwary, that it is only after much experience that really good work can be obtained.

Other Methods of Dressing Furs. Many other methods of dressing are in vogue. For example, the white Russian and Siberian hares come to this country in the dressed state; the leather, which is not by any means good, is made by soaking the skins in a solution of alum to which barleymeal is added. On drying, the pelt is left white, and is covered with very fine dust—a mixture of alum and meal.

China goods, such as goats, Thibet lamb, and kid-crosses are native-dressed with Glauber's - salt and rice flour. This, like the Russian method, does not give a leather which is at all to be compared with that obtained by grease dressing.

Much of the German dressing is done by a quick process involving the use of sulphuric acid. For certain skins this method seems peculiarly well adapted, though for others the results are interior to those obtained by the grease method.

The dressing of long-haired sheepskins is usually done with alum and salt. The skins are first scoured with soap and soda to remove grease, the pelt is scraped with various kinds of knives—*e.g.*, beaming knife [**1***a*], and then a solution of alum and common salt is rubbed into the pelt, this last-named operation being repeated several times. The skin is then stretched out in a *frame* as shown in **4** and allowed to dry slowly.

Fur Seal Dressing. In the case of fur seals of all kinds the procedure is somewhat different, and is as follows: First of all, the thick coating of fat is removed by what is known as *blubbering*. The skin is laid, pelt uppermost, on a *beam* similar to the one used by the unhairer [**6**], and the fat scraped off with a special kind of knife—a blubbering knife [**1***f*]. After this the skins are washed in a warm solution of soap and soda to get rid of grease from the fur, and they then undergo the process of *hooping*. This consists in stretching out the skin in an oval iron hoop by means of string passed alternately through the edge of the skin and round the hoop. Figure **5** shows a seal in the hoop. Next follows the process of *unhairing*. As previously explained, the fur seal possesses a beautiful soft under-wool and stiff upper hairs. By wetting the fur and then drying quickly these latter are so much loosened as to be easily removed by means of an unhairer's knife. The skin is placed over a beam, and the hair removed by a pushing motion of the knife. An unhairer is seen at work in **6**. Even after this some hairs are left, and to get rid of these a pulling knife [**1***e*] is used. The hair is caught between the blade and thumb and pulled out. This process of pulling is usually employed in dealing with otter, beaver, and nutria.

6. UNHAIRER AT WORK

7. SHAVERS AT WORK

There are probably no trade secrets so jealously guarded as those of the fur dyer. The particulars of the composition of various colours and dye-baths are known only to a very limited number, and these particulars are handed down from generation to generation with such modifications as are of necessity introduced.

The principal centres of this industry are London, Leipzig, and Paris, though the work is also carried on to some extent in various towns in France — *e.g.*, Lyons—in Belgium, and in America.

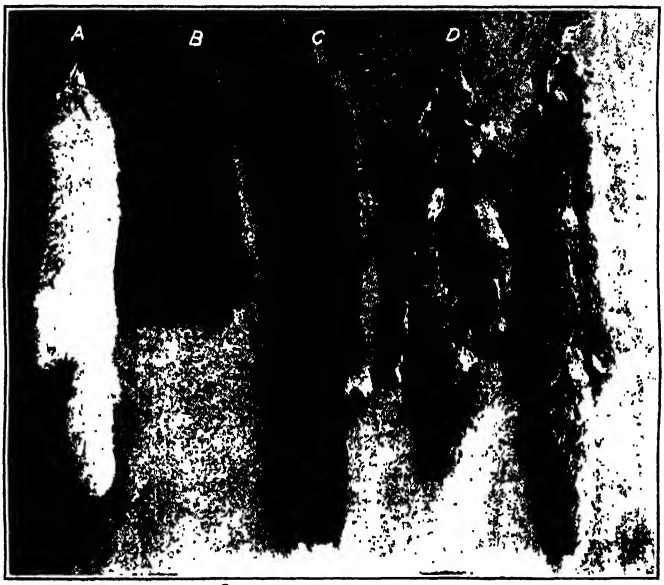
Materials Employed for Dyeing Furs. When it is remembered that the majority of the furs used in every-day life are of very sober appearance — black, sable, brown, etc.—it is easy to see that the wide range of colours obtainable by the use of dyestuffs derived from coal-tar products is useless to the fur dyer. He may require blues and reds and yellows for shading purposes, but to all intents and purposes, it will be seen that the so-called aniline dye industry derives but little support from him.

Nor is the limited choice of colours the only explanation of this fact. Most artificially prepared dyestuffs are only taken up from solution by the animal fibre at a temperature approaching the boiling point of water. Such substances are useless for dyeing furs, because, not only would the fibres themselves be injured at such a temperature, but the pelt would lose its supple nature and become hard and horny, and so worthless from the furrier's point of view; and, further, the hair and wool would become loosened, and readily detachable from the leather. In consequence, the dyer of furs must choose such substances as will be absorbed by the fibre at a low temperature—that is to say, not higher than about 50° C. Amongst such dyestuffs, those of natural origin occupy the first place, and they are therefore largely used. Blacks are obtained by means of

logwood and various metallic mordants, such as chromium, iron and copper; blues with various materials containing tannin substances, such as galls and sumach; yellows and browns with cutch, gambier, and turmeric. In addition to these other dyes are used for special purposes and for obtaining shades of colours.

Preparations for Dyeing. The covering described generally as fur consists, as previously stated, of two parts—the wool lying at the bottom next the pelt, and the stiffer upper hair. The outer covering of a hair is composed of a substance known as keratin, which is of a similar nature to the materials which go to make up the outer layers of the skin, nails, and hoofs. This possesses to a high degree the property of resisting the action of dyestuffs, and as it forms a layer which is very impenetrable, the colouring matter reaches the medulla of the hair only with difficulty. Consequently, before the hairs can be made to take up colour, this layer must be softened, so as to become more absorbent and to allow of the passage of the dyestuff into the medulla.

This object is achieved by a process known as *killing*. The killing is applied to the tips—in some cases to the wool as well—by means of a feather or a brush, and is usually of an alkaline nature, such as lime, soda, etc. As a result of this application the fibres are softened, and so more readily take up dyestuffs. Then follows a process known as *mordanting*. The skins are either brushed with or dipped in a solution of the mordant, the composition of which varies with the shade of colour required and the dyestuff subsequently used. Logwood, for example, is a polygenetic dyestuff—that is, with different mordants, different colours are obtained. Thus, with alum mordants, greyish violet shades are obtained: with chromium, iron and copper mordants, grey to black is the resulting colour; while tin mordants yield reddish violets. The principle underlying this process of mordanting is this: Certain metallic salts are absorbed by the fibre, and as a result of decomposition in and on the fibre—*e.g.*, aluminium acetate—or of oxidation—*e.g.*, ferrous salts, a *mordant*, usually a hydrated oxide or a basic salt, is formed. This mordant possesses the property of combining with dyestuffs to form *colour lakes*, to the presence of which in the fibre the final colour is due. It is usual to allow goods that have been mordanted to remain exposed to the air for some time before they are put into the dye, to allow the above-mentioned decomposition to take place.



8. SPECIMENS OF FOX
White fox *b.* Jap fox *c.* Kamchatka red fox *d.* Cross fox American red fox

The Dyeing Process. After mordanting the goods are ready for the dye. This is either applied with a brush, or the skins are immersed in the dye-vat and allowed to remain for such time as previous experience has shown to be necessary. In some cases the skins may be dipped twice or even four times, a definite period being allowed between each dip, during which time the skins are allowed to air. By this means oxidation takes place and the colour becomes fixed.

In using some materials—*e.g.* logwood—a different method is occasionally adopted. Instead of mordanting and dyeing in separate baths, one bath is made containing the mordant and dyestuff together. This, however, is not a common practice, as there is a considerable loss of colouring matter on account of combination between mordant and dyestuff, whereby the insoluble lake is precipitated, and has no opportunity of being fixed upon the fibre.

Of recent years a new class of dyestuff suitable for fur dyeing has been placed upon the market. These substances are chemical compounds prepared from coal-tar products, which on oxidation yield insoluble matters varying in colour from light brown to black. Some of them are exceedingly useful to the dyer, though for some purposes they are much inferior to the natural products.

How to Apply the Dye. In the dyeing of certain classes of skins it is advisable to apply the colour with a brush rather than by dipping them into a dye-bath. This is well illustrated in the case of the fur seal. On examination of the fur of a sealskin jacket, it will be seen that the colour of the lower part of the fur, or the *ground*, as it is called, is of a deep brown colour, while the top is much darker—almost black, in fact. This result is attained by brushing the fur with mordants and colours to different depths. That is to say, several brushings are made to a fixed level—care being taken that the same level is reached at each operation—with one mixture, and later another mixture is applied to the ground. The latter application produces a different colour where the fur has been previously treated, and so a distinction between *top* and *ground* is produced.

In the case of sable, marten, fitch, and such like skins, a large number is found in which the upper hairs or *tips* are too light to be quite pleasing. To correct this defect, and to accentuate the natural dark stripe which runs down the centre of the back, colour is carefully applied by means of a feather or a

light pad, this process being known as *tipping and striping*.

Beaver and nutria are skins which, after *pulling*, or removal of the top hair, are frequently *silvered*. This operation of silvering consists in the light application of various substances, which produce a lustrous appearance and considerably enhance the beauty of the skins.

Imitation Furs. Apart from the improvement in colour of natural skins, there is another branch of the fur-dyeing industry which is of great importance. This is the dyeing of cheap kinds so that they resemble to a certain extent the more costly furs. Enormous numbers of white Russian hares are dyed to imitate sable, Russian sable, stone marten, etc.; marmot are dyed sable colour; white fox and red fox are made to look like blue fox and silver fox respectively. Of course, it is only in the colour that there is any resemblance between the real and the imitation fur. One can no more make a Russian sable out of a white hare than the proverbial silk purse from a sow's ear, but to the uninitiated there is no very obvious difference in appearance between a jacket made of electric seal, which is only the common rabbit worth, say, five guineas, and a seal-skin jacket worth, perhaps, ten times the amount.

9. SPECIMENS OF HAIR SEALS
a. Whitecoat *b.* Blue-back *c.* Common Seal

After dyeing, all skins must be carefully dried and cleaned to get rid of any mechanically adhering dyes. When taken from the dye-bath, they are allowed to drain, washed in clean water, again allowed to drain, and the excess of moisture got rid of by means of a hydro-extractor, which is merely a cylinder with perforated sides revolving at a high rate of speed about a vertical axis. The centrifugal force causes the water to be driven outwards, and the skins are then partially dry. The drying is completed in drying-rooms or stoves heated by steam-pipes, and here great discretion is required, as, if the heat is too great or the process too hurried, both pelt and fur may be injured in quality, and the latter in colour. In order that they may dry flat, some goods are *nailed*—that is, placed on flat boards and nailed round the edges after a moderate amount of stretching. Others are merely stretched and allowed to dry slowly. To some, it is advisable at this stage to apply substances which keep the pelt soft and supple on drying, but this is not necessary in all cases, as much depends on the manner in which the skins are first dressed.

When dry, the skins are cleaned. This is accomplished by placing them in sawdust in a revolving drum of the type previously described. The length of time during which they must be *drummed* varies enormously, and depends largely upon the nature of the materials employed in dyeing. For some skins one hour is sufficient, others require twenty-four hours or even longer. When judged to be clean they are *caged* to remove the dust, and then passed to the finishing department. Here they are beaten with canes to free the under-wool from felt, the pelts damped, and the skins stretched and *knifed*—that is, pulled backwards and forwards over a blunt flesher's knife. This softens them, and makes them pliable, so that the fur lies evenly and "flows" under the hand.

Finally, the fur is *set*, or brushed with a damp brush in the proper direction, so as to straighten any hairs that may have got twisted and laid out of position.

Here the dyer's work comes to an end. From him the skins pass to the merchant, who disposes of them to the furrier, or direct to the furrier, who makes them into the thousand and one articles for which there is a demand

There are several processes used by the fur dresser and dyer which have not hitherto been mentioned. Some of the more important ones will be here described.

Shaving and Sleeking. The pelts of some skins intended for use as garments are so thick that unless a portion of the leather is removed the finished article would be uncomfortably heavy to wear. To remedy this defect the pelt is *shaved*. To perform this operation the skin is laid over a shaver's beam, which is similar to that employed by the unhairer, except that it is flat instead of being convex outwards, and by a series of downward pushing strokes layers of leather are stripped off, and the whole brought to a level surface of even thickness. To do this the skins must be sufficiently moistened, and the knife used of a special kind. Figure 1*h* shows one of these cross-handled knives. The edge is turned backwards and kept very sharp.

In 7 two *shavers* are seen at work on dyed whitecoats. The pelt, before shaving, is discoloured by the dyes used, and where the knife has passed over the pelt the white unstained leather is to be seen. Each shaver holds between the first and second finger of his right hand a small steel [1*c*], with which he sharpens the turned-back edge of the knife.

Various mechanical contrivances have been devised with a view of replacing this manual work, but so far no process causes so little damage to the skin or gives such a good result as this one just described. All seals, including fur seals, bluebacks, hair seals, and whitecoats, are shaved, and sometimes heavy-pelted skins like wallaby undergo the same treatment.

Sleeking is a process adopted in order to soften and make smoother the skins which are dressed with a heavy pelt such as goats. The skin is laid out, pelt uppermost, upon a flat table, and the *sleeking knife* [1*d*] pushed over it. Inequalities are removed, and the friction also causes a certain amount of softening.

In fur seals, after dyeing, there are to be seen short, stiff hairs which escaped the unhairing and pulling knives. These, if allowed to remain give to the skins an unpleasant *handle*—that is to say, they feel harsh when the hand is passed over the fur. In order to remove these, various types of machines have been devised. One of the earlier instruments was so constructed that the skin was stretched over a bar, the fur blown back and held down while the stiff, upstanding hairs were burnt out at the roots by means of an electrically-heated wire. In a later and improved pattern the hairs, instead of being burnt out, are cut off by the scissor-like action of two blades which are moved after the fur is blown downwards and held in position by two combs. By a system of gearing the skin is caused to move forward a fraction of an inch immediately after the release of the blades from the cutting position, so that every part of the skin is in turn subjected to this process.

Even then, certain hairs, known as *stage hairs*, are left, and these are removed by a pulling instead of a cutting action in a machine of somewhat similar construction, known as a *stageing machine*. The process of machining is essential for many skins, though there is an unavoidable removal of some of the fur which tends to make the skin poorer in quality.

Shearing. For some purposes, such as the manufacture of glove tops, fur for covering ladies' hats, etc., it is usual to take certain kinds of skins and by shearing off the top hair secure a shorter fur with an even surface. This is largely done in the case of white Polish rabbit, Russian hares, and some skins which, when dyed and shorn, resemble furs of a shorter staple.

The skin is fastened to an endless band in the shearing machine which passes over rollers. The tips of the hair come against a knife over which passes a set of blades set round a cylinder. This cylinder revolves at a high rate of speed and cuts off the tips exactly as grass is cut by a lawn-mower. Attached to the machine is a pipe connected with some arrangement for creating suction, by which the loose fur is carried away.

In addition to these processes there are others which are of use in various departments. For example, some skins can be mechanically brushed and beaten, and in such cases manual labour is dispensed with.

In connection with the subject of the dressing and dyeing of furs, it must be remarked that there are probably few branches of industry where experience counts for so much as in this one. To become a successful dresser, and perhaps still more so in the case of the dyer, great patience must be exercised in the acquiring of details concerning the methods to be employed for each particular class of goods. No two parcels of goods can be treated in the same manner; each requires careful consideration and must be treated according to its merits. Unceasing watch must be kept lest at any one of the many stages mistakes should be made, lest skins should be kept too long in a moist state, or the drying should be hurried.

Formerly, as in the drying of textiles, rule of thumb methods were the fashion; but the old order has changed and is yielding place to new. Science, the handmaiden of all arts and industries, is beginning to take her rightful place, and in consequence new methods are being introduced, and better and more constant results are to-day attainable.

The Manufacture of Fur Articles.

From the fur dresser and dyer the finished skins pass to the furrier, whose work consists in making them into articles for personal and domestic use. This work may be divided into several divisions, and though an experienced furrier is capable of executing the whole of the work, most firms employ men for each department.

Let us suppose that a lady's sable set is required. The skins to be used are carefully sorted and matched according to colour. A pattern in paper is usually made and the skins laid over this in order to see how many are required. The furrier then cuts off legs, tails and heads, as well as any bad patches on flank or belly. Should there be small bare patches in the skin they are cut out, a V-shaped cut being made from the pelt side, and the edges again sewn together. In this process of cutting, a knife of peculiar pattern is used. One is shown in **1b**, and will be seen to consist solely of a blade. It is held with the blunt end in the hollow between thumb and first finger, by the thumb and second finger, while the first finger is curved over the blunted circular back of the knife.

It is necessary sometimes to match different parts of the skin. For example, in sewing together two sable skins, head of one to rump of the other, there would be considerable inequalities in the surface, so that it may be advisable to remove a portion of the rump in order to get a more even surface. Again, two skins, A and B, stitched side by side, may be of slightly different colour or fulness. Accordingly, they are cut down the centre of the back, the left-hand half of A is stitched to the right-hand half of B, then the remaining halves are sewn together and the two composite skins sewn as required. By this means a more even article, both in surface and colour, is obtained than would be possible if the skins were merely sewn together.

After cutting away all undesirable parts of the skin, and the process just described, the skins are sewn together. For this purpose a special machine is used. It consists essentially of a needle travelling horizontally, which just clears the surface of two circular discs or shallow cylinders placed in the horizontal plane and touching tangentially. These discs are kept together by a spring which can be released at the will of the operator. In using the machine, the two edges which are to be sewn are brought together between the discs above-mentioned and held there after any upstanding fur has been placed in position by means of a blunt needle or other object. When ready, the machine is set in motion—they are usually driven by a foot-treadle—and as the discs revolve, the skins travel on and the needle passes through both skins forming the stitch, and at the same time locking it.

"Nailing." When the various pieces are sewn together, the whole must be stretched so as to make the seams lie flat and to bring the piece to the shape required. To effect this, the process of *nailing* is necessary. For a flat article such as a tie or coat-lining, the skins are moistened on the pelt side, stretched out on a flat board, fur side downwards, and small nails driven in at the edges. For muffs a block is used, generally made in three pieces, which fit into one another by means of a tongue and groove. The skins are stretched round the block and nailed securely round the edges: sometimes several parallel rows of nails are also driven in in order to keep the skins straight.

The articles are allowed to dry on the nailing board or block and are then removed. Where a block has been used, the nails are drawn and the centre piece of the block taken out. This allows the muff to be easily taken off without altering the shape. Next comes the process of lining. Silk, satin or other material is employed, and between it and the fur a layer of cotton-wool or wadding is placed. This serves a double purpose, that of increasing the thickness and so making it more serviceable as a defence against cold, and also that of making the muff or other article feel *fuller* and softer than it would otherwise do.

Linings and Rugs. A large part of the furrier's work consists in the manufacture of fur linings for coats. The skins are matched as far as practicable for colour and quality and the processes of cutting and nailing carried out. Sometimes this work is done in the countries from which the skins are obtained—as, for example, the dog robes from China, or the kidcrosses and kidleg crosses from the same country. Marmot skins are occasionally made up into linings, which are sold under the name of marmot robes.

The chief furs which are made into linings are musquash, opossum, hamster, kaluga (or susliki), squirrel back and squirrel belly (or squirrel lock, as it is generally called), mole and mink.

Rugs are made from skins which are best adapted for the purpose for which required. Vicuna, guanaco, and raccoon are largely used for carriage rugs, while for hearthrugs, bear, wolf, goat, dyed either black or bear colour, and sheep skin, are most frequently used.

Seal Skins. In order to summarise the various processes which are necessary to convert a raw skin into a finished article, it will be convenient to take the sealskin as an example and to describe in their proper sequence the different operations which are performed.

The seals are killed either on the beaches or in the open sea. In the latter case they are sometimes speared, but it far more frequently happens that they are shot. When taken on land, care is required in the stages prior to the killing. On the Alaskan Islands the bachelor seals, or *holluschickie*, as the natives call them, of ages varying from two to seven years, are driven from the seal beaches to the killing grounds. This must be accomplished slowly, or the animals become heated, and the fur rubs away at the least touch. They are driven in herds, and on arrival at the place of slaughter are stunned by means of blows on the head delivered with heavy wooden clubs. A sharp knife is plunged between the fore flippers right into the heart, to kill the seal and to prevent further *blood heating*, as it is called. As soon as possible the animals are skinned, and every available piece of skin is removed and only little patches on the upper and lower lip and tail are left. The skins, with their thick coat of blubber attached, are taken to the curing house, laid in piles, fur to pelt, and salt plentifully applied to the flesh side. After remaining for about three weeks, they are rolled and corded, and sent for shipment, and it is in this state that they arrive in London. They are then sorted according to size and quality and put up for sale by public auction.

From the sale-room they pass to the dresser and dyer, whose work it is to change the unsightly objects into a presentable skin. The first work to be done is the removal of the fat or blubber, after which process the skins must be washed with various cleansing materials, then dried as already explained.

The "Unhairing" Process. The next process is that of *unhairing*. By damping the skins and quickly drying at a comparatively high temperature the hair is loosened while the fur remains unaffected. The unhairer then proceeds to remove all hair, as far as is possible, first with the unhairing knife, and then with his pulling knife.

At this stage the fur presents a curly appearance, and is yellow to grey-brown in colour. From the unhairer they pass to the dresser, who greases, mills and cleans them, and prepares them for the dyer. It is important that all grease should be removed from the fur, as if this is not done the dye is not properly absorbed and an uneven and patchy colour is the result.

On receiving the dressed skins, the dyer combs out the fur, and proceeds to apply the various mordants and colours. This is always done by brushing, because by this means the curl is taken out of the skin and also the pelt is less injured than if the skins were dipped in the dye liquor. Between each operation of brushing—and there are many of them—the skins are allowed to dry, and are then beaten to get rid of dust from the materials employed.

When the dyeing operation is completed, the skins undergo a thorough cleaning in sawdust to make the fur bright and soft, and to remove all traces of the dyestuffs from the bottom of the wool, where it is apt to lodge. This is necessary in order that the skins may feel soft and full to the touch. If dirty they feel somewhat harsh, and the fur does not flow easily when the hand is passed over it.

Preparing the Pelt. Attention to the pelt is now required, as it is thick, heavy, and almost black from long contact with colouring matters. To alter this state of things the skins are handed over to the shaver, who moistens them and then shaves down the pelt to an even thickness. In doing so, he takes off the outer discoloured layer and leaves the pelt almost white—generally tinged with yellow.

After drying, the skins are carefully examined in order to pick out any that require *machining* and *stayeing*. During these various processes, the fur may become slightly disarranged. Certain portions may be twisted, and, by the weight of skins above—they are always folded down the middle, pelt outwards, and laid in piles—*print marks* are produced. These spoil the appearance of the skin, and are got rid of by the process of *setting*. The fur is brushed with a soft brush, moistened with either plain water or a weak solution of various substances, and then allowed to dry.

The skins are now finished, and are sent back to their proper owners. The merchant disposes of them to the furrier, who proceeds to manufacture from them jackets, capes, or other treasures so dear to the feminine mind. The furrier, instead of employing his own permanent staff, may hand the skins to a *chamber-master*, who is required to make so many articles from the skins provided. This practice is less common than formerly, as most furriers prefer to have the work done under their personal supervision. The processes already described are employed, the skins are cut, nailed to shape, and the pieces sewn together. Then the lining and padding are added and the garments pass to the retailer, who supplies the public needs.

FURS AND FURRIERS *concluded; followed by* FEATHERS

BACTERIOLOGY

Varieties and Structure of Microbes. Their Life and Growth. How a Bacteriological Investigation is Made. Bacteria the Scavengers of Nature

Following TAXIDERMY from page 6329

By Dr. GERALD LEIGHTON

ONE of the principal factors in the causation of disease is the action of bacteria. In considering their office in disease we may learn something of the function of these minute organisms in various natural processes, and so gain at one and the same time a comprehensive, if brief, view of the whole science of bacteriology. It is one of the most modern of studies, dating from the invention of microscopes of immense magnifying powers, and the discovery of many methods of staining by means of aniline dyes. Without these means little could have been discovered about bacteria.

Terminology. First let us understand the terms used in describing the group of minute organisms under consideration, which take such a prominent place in modern scientific work and thought. Some of the terms used are popular but somewhat vague; others have a definite meaning in bacteriological science. Thus the terms "germs," "microbes," "micro-organisms," "bacteria," are used synonymously and rather loosely to refer to the whole group of these minute cells. The word *bacterium* really means a rod, but it is used in reference to all shapes of organisms, the term *bacillus* [3] being the one chiefly used to designate those of a rod-like shape. Other shapes of organisms have each their appropriate designation: thus the round cells are termed *cocci* [4] or micrococci, the curved ones are termed *spirilla* [7], these, with the rods or bacilli, being the most important shapes. When the small round micrococci are arranged in groups somewhat resembling a bunch of grapes, the whole cluster is called a *staphylococcus* [2]; when the micrococci are arranged in a chain they receive the name of *streptococci* [1]. A glance at the illustrations of these various shapes will make these terms perfectly clear.

The globular cells, straight rods, and curved rods constitute the lower micro-organisms, and are by far the most numerous kinds.

Size and Movement of Microbes. The lower microbes are minute masses of protoplasm, containing no chlorophyll, and are not more than $\frac{1}{25000}$ in. in diameter. Their outline is sharply defined as they are seen under the microscope when stained.

Germs are, of course, dependent upon their environment for being scattered about—winds, water, food, the circulation of the blood in the body, all acting as means of dissemination. But, apart from this general movement, they have special means of locomotion by means of which each individual changes its attitude and position—at least, some species have them. This movement is effected by means of fine, hair-like protoplasmic processes called *cilia* [6], which are attached to one or other end of a bacillus or spirillum, or to both ends, or to the sides, and by the lashing of these cilia the cell is moved in a liquid medium just as a boat is moved by oars. The position and direction of the movement of the cilia will determine whether the microbe darts, rolls, or simply vibrates. Organisms which possess the power of locomotion by these flagellæ or cilia are termed "motile," the rest being called "non-motile."

Reproduction. The great majority of the lower organisms reproduce themselves by the simple process of fission [see BIOLOGY, page 381, 6 and 7]. A simple constriction appears in the middle of the organism which eventually divides into two individuals [5]. In some species this process takes place rapidly, in others more slowly. Some will divide in twenty minutes. A simple calculation will show that even if the division occurs only once every hour, as many as 17,000,000 organisms will arise from a single pair in the twenty-four hours. For this to occur, the environment must, of course, be a favourable one as regards temperature, moisture, and nourishment. Such an environment for some disease-producing germs is found in the human body, and we can thus realise the rapidity with which an organismal disease may become serious and even fatal.

Effect of Environment. Thus, at the outset we see that, in order to check the ravages of pathogenic—that is, disease-producing—germs the physician must direct his attention to making the surroundings of the germ as unfavourable to reproduction as possible. Once in the body the only way to do this is by assisting the natural resistance of the person by suitable drugs, and especially by the special antibacterial or antitoxic substances which are rapidly becoming the most reliable means of treatment. Outside the body, in Nature, or in the artificial growths of germs in the bacteriological laboratory, the effect of environment is seen to be dependent upon the presence or absence of fresh air, moisture, certain gases, the degree of heat or cold, and the supply of nutrition.

The Food of Microbes. In Nature, germs live chiefly upon complicated organic substances, and upon the dead or living bodies of plants or animals, or in excretions. As a rule, a number of different species are found living together, and no doubt they are affected to some extent by this presence of neighbours. When one germ is grown by itself by a bacteriologist, it is probably in better surroundings than in actual natural life; it is better looked after. As a matter of fact, it is found that the fluids and nutritive media made from animal tissues suit their growth best. All germs need nitrogen in some form, as well as salts, such as chloride of sodium, sulphates, and phosphates. Some few require special elements, such as sulphur, in order to flourish. Most require to be in an alkaline medium; some, indeed, being unable to stand even a trace of acidity.

The Effect of Moisture and Gases. In order that continued growth may take place, moisture is absolutely essential. The resisting power of germs to dryness varies greatly, however, in different species. Thus, two to three hours of dryness kills the cholera germ, while that of diphtheria will stand much longer. Those which form spores can remain alive in the spore condition for a very long time, even years, although dry, but they do not actively reproduce in this resting state. They are in a condition

of suspended animation, ready to resume active life when a favourable opportunity occurs, but for the time being quiescent.

The influence of the presence or absence of oxygen is very marked; indeed, it supplies one means of classifying germs into two groups, according to their manner of reaction. Most can live in oxygen: indeed, require it. They are termed *ærobes*, or *ærobic* organisms. Some cannot live in the presence of oxygen, or can do without it; they are termed *anærobes*, or *anærobic* organisms. Many germs do not flourish well in the presence of carbonic acid gas.

The Effect of Temperature. Every organism has a special temperature at which it grows best (the optimum temperature), a temperature above which it will not live (the maximum temperature), and a temperature below which it cannot survive (the minimum temperature). The best, or optimum, temperature is that of its natural habitat. Thus, for the germs which induce putrefaction, the best, or optimum, temperature is that of warm summer weather (20° C. to 24° C.). For those which flourish in the tissues of animals it is from 35° C. to 39° C. For most germs the highest or maximum temperature is from 42° C. to 44° C., and the lowest or minimum temperature from 12° C. to 14° C. Some exceptional germs will live up to 70° C., and others as low as 5° C. The optimum temperature for most of the microbes which are active agents in the production of disease is, as would be expected, about the same as the temperature within the human body.

The Study of Microbes. In order to study the life-history of any given microbe a good deal of training in laboratory methods is required, together with much practice in the use of high-power microscopes. It is not our purpose here to enter into minute details of bacteriological work, but it is of interest to learn a little concerning the methods of investigation which have yielded such immensely important results in the science of health and disease. Some of these methods are highly technical, but certain general principles underlie them all, and it is to these we may direct our attention.

Suppose, in imagination, that we are fortunate enough to be allowed to watch all the proceedings of an expert bacteriologist in his laboratory. He is about to make an investigation of the microbes contained in a specimen which has been sent to him, concerning which a report is wanted by the public health authorities or some other body. He is about to ascertain what germs are present, if any, in the specimen of water, food, discharge, or organs (whatever the specimen may be), and we are at his elbow watching all his doings. How does he set about such a task?

In the first place the investigator, being absolutely ignorant of what he may find, keeps constantly in mind the fact that every precaution must be taken to prevent accident to himself or to others in the laboratory. Many microbes are extremely dangerous to work with, and a good many scientific bacteriologists have lost their lives in this kind of experimental work. The microbic enemy is invisible, but of deadly potency, and so minute is its size that the slightest scratch upon the skin of the investigator will suffice for the germ to make an entrance into the tissues under the skin, which may be followed with fatal results. The bacteriologist, therefore, first of all, protects his hands by soaking them in some strong antiseptic solution which will kill any germ which may happen to lodge thereon. If the specimen to be examined be a carcase or a body he will put on special indiarubber gloves for the first part of his task, gloves which, while they are impervious to the passage of germs, do not interfere with the movements of the fingers. But his precautions do not end with his own hands. The greatest care is taken to see that every instrument and all kinds of apparatus which come in contact with the suspected material is likewise sterilised by boiling or heat both before and after use. Thus, if it be necessary to cut the specimen with a knife, the blade is first passed through the flame of a Bunsen burner and again passed through the flame before the knife is laid upon the table. In this way no germs from the specimen are allowed to contaminate the laboratory.

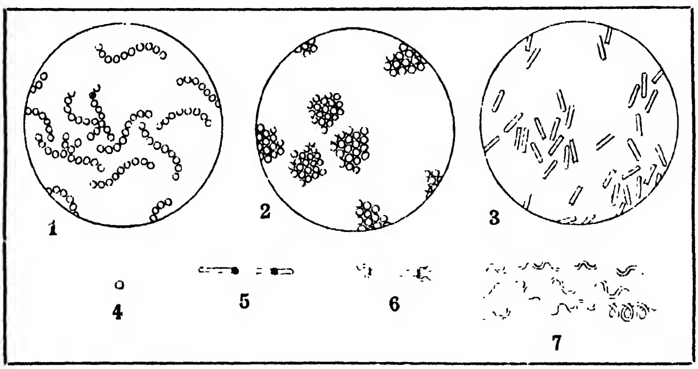
The Examination of Microbes. The bacteriologist, having taken all these and other similar precautions against possible mishap, now proceeds to find and examine the microbes present in the specimen. Two methods of examination are open to him, and he generally avails himself of both. In the first place, he may prepare a "slide" for examination under the microscope, which will reveal the presence or absence of microbes, and, if treated by special staining methods, may enable him immediately to say whether certain species of microbes are present or not. The microscope will show the relative abundance or otherwise of the germs, their shapes, their sizes, and their relation to the tissues in which they are lying. In certain diseases, such as anthrax, an examination of suspected blood by means of the microscope and a stained slide, may be completed under half an hour and a definite diagnosis given. In other cases, however, the microscope may reveal the fact that large numbers of germs are present, all mixed together, and it may be impossible to say what these are, or to which the condition is due, until they have been separated from each other and examined one by one. The investigator then proceeds to the second method—namely, that of separation of organisms and their artificial growth in the laboratory. He "cultivates" the microbes, on suitable media or soils specially prepared for the purpose.

Cultivating Microbes. The nutritive media in the laboratory are some solid and some liquid preparations. Without entering into the details of their preparation it may be noted that they are all devised to supply food for the growth of the different germs, and to provide convenient methods for the observation of the germs while they are growing. The more generally used nutritive liquids are bouillons or broths, milk, the aqueous humour from the eye of animals recently killed, and blood serum. The best broth is made from the flesh of bullocks, finely minced and freed from fat, mixed with filtered water, with a little common salt added, and the whole rendered slightly alkaline by the addition of some carbonate of soda. The resulting broth is poured off into test tubes and sterilised by heat to make sure that no living germs are left in the broth from extraneous sources, otherwise these would at once begin to grow. The tubes are sealed up with cotton wool, which prevents the entrance of organisms from the air by acting as a fine filter, and they are then ready for use by making "inoculations" into them. The test tubes or flasks are themselves sterilised first, as are all the implements and apparatus used in these investigations. All that is necessary now in order to cultivate the germs is to introduce some of them into the sterilised flask containing the nutrient medium. Their subsequent growth produces definite appearances in

the medium which can be watched and which are characteristic of the various species.

Separation of Germs. But here arises one of the many difficulties in bacteriological work. If the suspected specimen contained but one kind of microbe, all would be well. A portion of the specimen introduced into the flask would then give rise to a growth of the one organism present, which could be studied at once; but this is rare. As a rule, many microbes occur together; all sorts and sizes of germs flourish in Nature under the same conditions, some of them disease producers, others perfectly harmless. Before the appearances of any one of these can be studied in a culture, it must be separated from all the others and grown by itself in its own tube or flask. This is what is termed "making a pure culture," as opposed to a "mixed" culture, which contains two or more species of microbes.

A Pure Culture. To overcome this difficulty of the mixture of microbes resort is had to the use of solid media for cultivations instead of the liquids mentioned above. These solid media have a similar basis of meat extract as the real food on which the organism flourishes, but to this is added some substance of a stiffening nature, which, when the medium is cooled, renders the whole mass solid and firm instead of liquid. The two substances generally used for this purpose are gelatin and agar-agar, the latter being prepared from the roots of Chinese seaweeds. In other words the ordinary liquid medium is gelatinised. It is further rendered free from opacity and made quite clear and transparent by the addition of the white of an egg, the result being a beautifully clear, solid medium which can be poured into test tube when warm and left to solidify in any shape desired by merely sloping the tube in the direction required. It can also be poured into flat dishes or on to plates having a broad surface.



COMMON FORMS OF BACTERIA

1. Streptococcus 2. Staphylococcus 3. Bacilli 4. Coccus 5. Bacilli with s 6. Bacillus with cil 7. Spirilla

With these at hand the bacteriologist can proceed to isolate the different microbes in his mixture. The first point is to get the mixed germs as far as possible apart from each other so that when they are allowed to grow upon the nutrient gelatin each single germ will give rise to a small colony of its own species uncontaminated by any other species. A drop of the suspected solution or a minute portion of the suspected material is introduced into a tube of this sterilised melted nutrient gelatin and thoroughly shaken up so as to separate the contained germs. A glass plate, having been previously sterilised, is placed upon a perfectly flat surface and on to this the melted gelatin, with the organisms scattered through it, is poured. This is allowed to cool, carefully protected from contamination from the air, and as it cools the gelatin solidifies. This fixes each organism at a given point where it starts growing, either at the ordinary room temperature, or in an incubator in which the temperature can be raised as required. In the course of a day or two small points are observed to appear in the gelatin, each of which represents a colony of one species of microbe. Each one of these separate colonies can now be inoculated into nutrient gelatin in separate tubes, so that finally the investigator has got a number of germs growing in pure cultures. They are inoculated by picking off a minute portion of the colony on the plate with the point of a platinum needle which has been passed through the Bunsen burner or other flame first, and the minute portion thus taken is plunged into the solid gelatin in a tube, or simply stroked along a sloping surface of gelatin similarly in a tube. In the one case we get a "stab" culture, in the other a "stroke culture." The former grows down into the gelatin along the course of the needle track, the latter merely on the surface of the gelatin, also along the track of the needle stroke.

It need hardly be pointed out that if it be suspected that there are great numbers of organisms present in the original matter to be examined, these can be diluted to any extent before pouring the finally separated organisms on to the plate.

Characteristic Growths. Now the bacteriologist has got his germs growing in pure cultures, and their bacteriological characters and their methods of growth can be noted at leisure. Among the most important points which are ascertained by means of such pure cultures the following may be mentioned.

When grown on these solid media some organisms cause a liquefaction of the gelatin, others do not; some produce gas (ærogenic), others do not; some produce colour (chromogenic), others do not; a few are phosphorescent (photogenic); whilst those which are disease producers are termed "pathogenic."

In addition to the purely biological method above described, much information has been gained concerning germs by the experimental method of making inoculations into living animals. This applies especially to the pathogenic germs, and it is by this method that bacteriologists have been able to produce the antitoxic serum which is so successful in the diagnosis and treatment of some microbic diseases.

Proof that a Germ Causes a Disease. Before the bacteriologist is justified in asserting that the cause of any given disease is *proved* to be due to any given germ, the following results must be obtained:

1. The said microbe must be present in every case of the disease.
2. The said microbe must be isolated from the body and cultivated as a pure culture.
3. The said microbe, if inoculated into an animal, must produce a condition similar to that from which it was separated.

4. The said microbe must be again separated and cultivated from the diseased animal into which it was inoculated and in which the disease was produced.

This is what science calls proving a question, and in those diseases which are now known to be due to special forms these four tests of causal relationship have been repeatedly carried out.

So much for the general principles of bacteriological investigation and the isolation and cultivation of these germs. We may now turn for a moment to a brief consideration of the general place in Nature occupied by these minute agencies, for their functions are by no means merely those of destructive agents in the production of disease.

Bacteria in Nature and Commerce. In the early days of the science of bacteriology, only a few years ago, there was considerable uncertainty as to whether these multitudes of organisms which occurred everywhere in earth, air, and water, did so as a mere accident, or whether their presence was in any way essential. We now know that they are an absolute necessity for the carrying on of a large number of the most ordinary everyday occurrences of Nature. For example, all the processes of fermentation are microbic in origin, and so also are the processes of putrefaction. The lactic acid fermentation of milk, which is so common, is due to the action of microbes, the sugar of the milk being broken up and lactic acid produced. In the ripening of cheese, the resulting flavour is due to products of bacterial action. Another fermentation, the study of which is applied to the commercial manufacture of vinegar, is also due to microbes, and here alcohol is converted into acetic acid.

In the various brewing processes bacteria play a very important part, especially in interfering with the excellence of the products of the manufacture. The various conditions of bitterness, muddiness, abnormal colours, and so forth, are all microbic in origin, and all associated with some form of acid production. Most of these organisms are easily killed by heat.

In the everyday work of baking some of the starch is converted into sugar by the action of the yeast organism, and this sugar in its turn into alcohol and carbonic acid gas, to the latter of which the "rising" of the bread is due. The subsequent operation of baking serves the purposes of killing the ferment, fixing the starchy food in position, and driving off the alcohol and carbonic acid gas. In like manner certain faults in bread are due to the presence of unwelcome germs.

Bacteria as Scavengers. One of the useful qualities of certain microbes is that of being able to break up complex organic matter into much simpler substances, and it is now recognised that bacteria act as the scavengers of Nature by thus acting upon dead animal or vegetable matter. This takes place not only out of doors, but also in the alimentary canal in the human and other animal bodies. A special organism termed the *Bacillus subtilis* produces many of these changes. It is found in all putrefying fluids along with other organisms which also help in the process of disintegration. These putrefactive organisms, therefore, play a very important part in the economy of Nature by keeping up the circulation of matter, making the excretions of plants and animals, as well as their dead carcases, available once more for the nutrition of others. Germs thus convert organic matter into inorganic substances. In Nature this process goes on on the surface of the soil or near the surface and in the presence of the air. The organic matter lying there is oxidised and so made ready for the nutrition of plants. In fact, it would appear that this process of microbic oxidation is absolutely necessary, and that if the soil be made sterile or free from organisms it would be incapable of furnishing enough nutrition for plants to grow at all well. The organisms which do this work need the presence of oxygen for their active growth, and from this fact they are termed *ærobes,* or ærobic organisms.

Germs in the Deep Earth. But in addition to these superficially living germs there are others, which work at greater depths, out of contact with the atmosphere—that is, with oxygen—and which are termed *anærobes*, or anærobic organisms. They have the faculty of wresting oxygen from the substances containing that element which come down to them from above, using some, and freeing the rest for purposes of oxidation, thus helping on the decomposition of organic matter. This material, when freed from its oxygen, is of no further use for nutrition, and hence deeper still we find no organisms at all, this depth varying with the nature of the soil, but being commonly stated as being about 12 ft. from the surface. The bearing of these facts upon the purity or otherwise of water supplies drawn from surface sources, or deeper ones, is too obvious to need further comment.

Contamination of Water. It is thus evident that water taken from near the surface must contain a certain number of germs, and if there be organic matter on the surface putrefactive germs will be there too. Matter from under the soil surface is usually free from the putrefactive germs, but has some peculiar to itself, while deeper still, water will be obtained free from microbes altogether. It does not follow, however, that water taken from a depth must of necessity be pure and fit for hygienic purposes, because there is always the risk of such water becoming contaminated before it reaches the consumer. It is a very simple matter for a disease-producing microbe, such as that of typhoid fever, to contaminate an otherwise pure water supply.

Suppose that a case of this disease exists in a given locality, the organisms of the disease are present in numbers in the intestines of the patient, and pass out with the excreta. Now, unless these excreta are disinfected and the microbes killed, the microbes simply pass into the drains or on to the surface of the soil, according to the disposal of the sewage. The organism grows and multiplies, and sooner or later finds its way into the water supply of the district, and thus spreads the disease, perhaps, to many people, causing an epidemic. Milk pails and cans may similarly be easily contaminated from one case.

From what has been said of the action of the microbes in the earth and the part they play in breaking up organic matters and rendering them fit for the food of plants, it will readily be recognised that the processes of agriculture are dependent ultimately upon the action of bacteria. This is an actual fact.

Fertilising Bacteria. The uses of all the manures which are applied to the enriching of land depend upon these bacterial processes. The various changes undergone are collectively spoken of under the general term of *nitrification.* All the compounds in dung, manures of various sorts, dead carcases, plant tissues, and so forth, when spread over or dug into the earth, become oxidised, and ultimately a large part of the nitrogen from these becomes converted into

nitrates of calcium or potassium. This nitrification process will not take place in a soil which contains no bacteria, hence germs are essential in agriculture. The process is illustrated diagrammatically on a previous page, to which reference should be made at this point [see page 277]. It will be noticed there that the process has two stages: first the partial oxidation into nitrites, then the further oxidation of these into nitrates. No one germ is capable of doing the whole process as seen in the diagram, two sets of organisms carrying out the two stages. Both kinds of germs are to be found in manure heaps, sewage, and soils, and both require the presence of oxygen and water for the performance of nitrification. It follows that their work is interfered with in extremely dry soils, and a temperature below 5° C. or 6° C. inhibits their activity. For the further and more detailed study of the value of artificially prepared manures, that is to say manures ready nitrified, the reader should consult the course on AGRICULTURE.

Useful Work of Bacteria. The bacteria which feed upon dead organic matter are called *saprophytes*, in opposition to those which live in or upon the living organic compounds composing the tissues of animals or plants, these germs being termed *parasites*. Many of the latter are disease-producers: many of the former are very useful agents in various natural and artificial processes. The saprophytic species are of greater importance to the farmer, for, as we have explained, they are the active agents of putrefaction, and they render carcases and dead plants available for the nutrition of living plants. To these saprophytes also are due the processes in the ripening of cheese, the nitrification of manures, and many chemical changes included under the general term of fermentation. These latter changes result in the production of certain definite compounds which are essential in the special processes concerned. Thus, the "lactic bacteria" are useful in cheese ripening. In order to be sure of the presence of these germs a little sour milk is added to the sweet cream, or the cultivated bacteria themselves may be used.

If beer or wine containing less than 14 per cent. of alcohol be left exposed to air for a few days the surface becomes covered with a tough, whitish film, and the beer or wine goes sour. The film contains numbers of bacteria which produce acetic acid from the alcohol. This process is the basis of the manufacture of vinegar from fermented malt liquors or fermented grape-juice.

Bacteria and Milk Products. Two milk products in which bacteria are active agents may be mentioned here. One is known as *koumiss* or kumiss, an intoxicating beverage made from the soured and fermented milk of mares. It has an acid taste,and is much esteemed by the Kalmucks, the most numerous of the Mongol nations. A spirit is made from the koumiss by distillation, and since it is said that the tribes which are addicted to the use of koumiss are free from the ravages of consumption, the use of an artificial koumiss has become fairly general. This preparation is made from milk of asses or cows.

The second of these products is termed *kephir*, a drink used in the Caucasian districts, which is also made from milk. In the process the casein is dissolved, and the milk sugar is acted on as in a lactic acid and alcohol fermentation. The masses of bacteria which cause this process are called kephir grains.

Koumiss, or fermented mare's milk, has been used with an undoubted degree of success in the treatment of consumption in Russia. The secret of the success is that the milk is slightly fermented, highly digestible, and hence large quantities can be taken without producing dyspepsia. It is really an invalid food. In Russia the mode of treatment is for the patient to rise early and drink a glass of koumiss every half hour, excepting the two hours just before dinner and supper.

Artificial kephir, prepared from cow's milk, is made as follows. The milk is as new as possible. A bottle is nearly filled with the milk and some water, and to this are added some yeast and a lump of sugar. The bottle is tightly corked and the cork wired down, to prevent escape when fermentation occurs. It is placed in a warm spot and shaken two or three times a day for from four to six days. The bottle must be carefully opened to prevent much being lost, as it is very effervescent.

Both koumiss and kephir are more easily digested than ordinary milk. In both the casein-forming material is thrown down in a finely flocculent, easily digested form, already partially peptonised. Most of the sugar is turned into lactic acid; a little alcohol is produced, and a good deal of carbonic acid gas. These two preparations, therefore, present milk in its most easily digested shape; hence their value as invalid foods in dietetics.

These milk products are good examples of processes dependent upon bacteria, which are not merely harmless, but of the greatest service to mankind.

Bacteria and Water. The relationship of bacteria to water is a matter of profound importance, inasmuch as water is perhaps the most convenient method of carrying germs from place to place. Thus, after rain the air is wonderfully free from microbes, which have been carried down on to the ground. Stagnant pools and slow streams —in fact, surface water of all kinds—always contain large numbers of microbes, the numbers and their species differing greatly according to the nature of the soil, the depth of water, and the degree of oxidation going on. The less the water is disturbed the more numerous the germs. In spring water few or no germs occur until contamination happens at the surface. In examining water for bacteria the sample should be examined immediately it is obtained, for the simple reason that if there be any nutriment in the water the germs therein, however few to begin with, will soon multiply with great rapidity and thus give a most fallacious result if left for any length of time. "If a sample of even the purest water (containing, say, 200 germs per cubic centimetre) be left to stand in a room in which the temperature is comparatively high, and therefore suited for the rapid growth of these organisms, it may be found that in place of 200 germs per cubic centimetre, there may be present on the second day 5,000, on the third day 20,000, whilst on the fourth they are almost innumerable."

HOW TO TUNE A PIANO

Unisons, Octaves, Laying a Scale. The Piano-tuner's Apprenticeship. Piano-tuning as a Vocation

By ALGERNON ROSE

IN all keyboard instruments tuning is a far more complicated process than it is, for example, in the violin, which has but one string for many notes, and not more than four strings altogether. On the other hand, in the piano, instead of four lengths of catgut, there may be upwards of 200 steel wires strung across an iron or steel framework, the total tension, according to the size of the instrument, being approximately from 15 tons to 30 tons. A tension to so many strings, were every tuning-pin adjusted ever so slightly, would alone demand more time than any professional pianist has to spare.

Unisons. The knowledge most usually required is that for pulling-up and adjusting a new string. First, the broken string must be extracted. To do this in an upright piano (we are not speaking of grands) take off the front. First turn the buttons inside the top panel at the bass and treble ends; draw the front forward, lift it out; turn back the cover or cylinder over the keys and lift it out. If the front and cylinder are joined, both come out together. To remove the action (or hammer mechanism), turn the buttons at either end of it, or undo the thumbscrews. Grasping the hammer rail, draw forward the action. Lift it up out of the sockets and place it on a table, or in some other convenient position. Unfasten the catches under the keyboard. Draw the bottom door forward and take it out. In an upright piano, the gauge for strings varies from treble to bass, from No. 9 to No. 21, the sizes of wire being marked below the tuning-pins. In a trichord cottage, the pins are placed in threes, one over the other. If one string serves for two pins, the bottom pin of one note and the top pin of the next, or the two middle pins of neighbouring notes will need new wire. Having obtained the necessary length (by sending the old wire to a maker as a pattern), bend one end of the steel into a loop ½ in. long. Twist the end round twice, and clip it off with a pair of cutting pliers.

"Chipping Up." Place loop on hitchpin projecting from the iron frame at the opposite side to the tuning-pin. Fit the string between the two pins in the bridge, alternately inside the first and outside the second. Pass the wire up above the keyboard. Thread the string through the hole in the brass stud, if necessary. Cut off the wire with the pliers 2 in. beyond the position of the tuning-pins. Insert the string through the eyehole of the pin. Put the tuning-hammer or tuning-crank on the latter; twist the pin round twice to the right, making the coil even. If the tuning-pin has been taken out of the plank, drive it in with some smart blows from a hammer till even with the other pins. Now turn the hammer round to the right, "chipping up" the tone of the new string with a piece of bone or a mandoline plectrum, until it is in unison, as regards pitch, with the other wires belonging to the same note. After taking off the hammer, replace the action. With the right hand, re-adjust the hammer to the tuning-pin, and with the left try the note on the keyboard. Listen attentively to the throbbing of the vibrations. Gradually turn the hammer to the right until the quick and uneven beats merge into one steady and clear sound.

An identical tone is the easiest for the student to begin with. In trichord pianos, where three strings go to each note, two-thirds of the total are so tuned. When the throbbing has resolved into a steady vibration, the new string will be in unison. To ensure that the note will stand, "set" it by striking the key sharply to ascertain that the wire does not slip through the stud nor over the bridge. If it does, repeat the tuning and the proof till the note holds firm.

Octaves. If a new string put on is a single one of covered wire in the bass (the steel core being overspun with copper), it must be tuned by the octave note above. Strike these two notes together. In point of importance and facility, the tuning of the octave, so far as the student is concerned, comes next to the perfect unison. Though no longer identical, the sounds resemble each other strongly. Turn the hammer on the pin of the new string gradually to the right. Listen attentively. At first the beats will be uneven. When the lower string reaches its proper tension, the two sounds will cease to vibrate unevenly, and the compound tone then produced will blend smoothly. Take care not to raise the new string above the pitch required, or it may break; neither put any side pressure on the tuning-pin, or it may snap off. Avoid turning any pin unnecessarily, otherwise it may become loose, and a piano with loose pins cannot stand in tune.

"Laying" a Scale. In this country tuners generally lay the scale from C (third space, treble clef). On the Continent the start is made from A (second space, treble clef). It is the tuning-fork, therefore, which gives the initial tone. The correct pitch of the latter is thus of paramount importance. Pitch-pipes are not recommended, as they are frequently inaccurate. What is known as "concert pitch" is a nebulous term. In England there is the Kneller Hall sharp military pitch, the low French pitch, and the Society of Arts (or medium) pitch between the two extremes, besides other fanciful standards used by various piano-makers. Accurately measured tuning-forks are difficult to get at an ordinary music-shop. The point is to get a fork at the new pitch (stamped "C 522" double vibrations per second), not the old Philharmonic pitch (C 540), as the latter is considerably sharper, and puts a greater tension on the strings of the piano as it does on the voice of a singer. In addition to a tuning-fork, when tuning a trichord instrument three wedges are needed. These consist of narrow strips of whalebone, or pliable wood, ¼ in. wide and 9 in. long. The ends are padded with one or more layers of wash-leather, the thick tip being for unisons and the thin for octaves. From the front, insert a wedge obliquely through the action, so as not to touch the hammer striking the note to be tuned.

Having wedged out two of the three strings of pitch C, put on the hammer. Sound the tuning-fork by striking one of its blades smartly on the knee with the left hand. Place the small end of the fork on any portion of the woodwork in front of the piano. To the sound it gives C, third space, treble

clef, must now be tuned. Raise or lower the pitch of the string gradually until, when the note C is struck it agrees accurately with the tuning-fork. Stop the vibrations by a wedge inserted between two of the unisons of the C below, and get the octave perfect. Do not strike the lower note too hard at first. The sharp blow is only required for "setting." There are various ways of laying the bearings of a keyboard instrument. Different tuners naturally pin their faith to the methods which they have been taught and have found most useful. But as all these systems, properly carried out, have the same result in making the tone of the instrument agreeable musically, the student may adopt any one of them profitably.
